About the cover

Day Octopus (*Octopus cyanea*). Found throughout the tropical Indo-Pacific, this is the most commonly seen octopus in Hawai'i. Hidden in a lair on the reef floor by night, the octopus will reach out with tentacles to gather coral rubble to protect the entrance. When at rest in its lair, it is a uniformly dark reddish-brown but during the day when hunting crabs on the reef bottom, it displays a spectacular array of color patterns and textures to match the varied landscape it crosses. An ink cloud released during escape contains mucus, melanin, dopamine, and tyrosinase, and is thought to confuse a fish predator and to depress its olfactory ability.

Larry Jon Friesen, PhD, completed his graduate research at the University of California, Santa Barbara, in Animal Communication. Dr. Friesen is a Professor of Biological Sciences at Santa Barbara City College, teaching Natural History, Evolution and Animal Diversity and continuing his life-long passion for nature photography.

Invertebrates, Fourth Edition

Oxford University Press is a department of the University of Oxford. It furthers the University's objective of excellence in research, scholarship, and education by publishing worldwide. Oxford is a registered trade mark of Oxford University Press in the UK and certain other countries.

Published in the United States of America by Oxford University Press
198 Madison Avenue, New York, NY 10016, United States of America.

We dedicate this book to all our fellow teachers
and students of invertebrate zoology around the world.

Brief Contents

CHAPTER 1 Introduction 1

CHAPTER 2 Systematics, Phylogeny, and Classifications 27

CHAPTER 3 Introduction to the Animal Kingdom: Animal Architecture and Body Plans 43

CHAPTER 4 Introduction to the Animal Kingdom: Development, Life Histories, and Origin 91

CHAPTER 5 Phylum Porifera: The Sponges 119

CHAPTER 6 Two Enigmatic Phyla: Placozoa and Ctenophora (The Comb Jellies) 165

CHAPTER 7 Phylum Cnidaria: Anemones, Corals, Jellyfish, and Their Kin 185

CHAPTER 8 A Brief Introduction to the Bilateria and Its Major Clades 245

CHAPTER 9 Phylum Xenacoelomorpha: Basal Bilaterians 249

CHAPTER 10 Protostomia, Spiralia, and the Phylum Dicyemida 273

CHAPTER 11 Gnathifera: The Phyla Gnathostomulida, Rotifera (including Acanthocephala), Micrognathozoa, and Chaetognatha 281

CHAPTER 12 Platytrochozoa and Two Enigmatic Phyla: Entoprocta and Cycliophora 311

CHAPTER 13 Introduction to the Lophotrochozoa, and the Phylum Mollusca 321

CHAPTER 14 Phylum Nemertea: The Ribbon Worms 397

CHAPTER 15 Phylum Annelida: The Segmented (and Some Unsegmented) Worms 415

CHAPTER 16 The Lophophorates: Phyla Phoronida, Bryozoa, and Brachiopoda 487

CHAPTER 17 Rouphozoa: The Phyla Platyhelminthes (Flatworms) and Gastrotricha (Hairy-Bellied Worms) 519

CHAPTER 18 Introduction to Ecdysozoa: Scalidophora (Phyla Kinorhyncha, Priapula, Loricifera) 563

CHAPTER 19 Nematoida: Phyla Nematoda and Nematomorpha 579

CHAPTER 20 Panarthropoda and the Emergence of the Arthropods: Tardigrades, Onychophorans, and the Arthropod Body Plan 607

CHAPTER 21 Phylum Arthropoda—Subphylum Crustacea: Crabs, Shrimps, and Their Kin 659

CHAPTER 22 Phylum Arthropoda—Subphylum Hexapoda: Insects and Their Kin 735

CHAPTER 23 Phylum Arthropoda—Subphylum Myriapoda: Centipedes, Millipedes, and Their Kin 785

CHAPTER 24 Phylum Arthropoda: Subphylum Chelicerata 801

CHAPTER 25 Introduction to Deuterostomia, and the Phylum Hemichordata 857

CHAPTER 26 Phylum Echinodermata : Starfish, Sea Urchins, Sea Cucumbers, and their Kin 873

CHAPTER 27 Phylum Chordata: Cephalochordata and Urochordata 911

CHAPTER 28 Perspectives on Invertebrate Phylogeny 935

Contents

Classification of the Animal Kingdom (Metazoa) xx
A Phylogeny of Metazoa xxi
Geologic Time Scale xxii

CHAPTER 1 Introduction 1

Keeping Track of Life 3
Prokaryotes and Eukaryotes 7
Where Did Invertebrates Come From? 9
- The Dawn of Life 10
- The Ediacaran Period and the Origin of Animals 10
- The Paleozoic Era (541–251.9 Ma) 11
- The Mesozoic Era (251.9–66 Ma) 15
- The Cenozoic Era (66 Ma–present) 16

Where Do Invertebrates Live? 16
- Marine Habitats 16
- Estuaries and Coastal Wetlands 21
- Freshwater Habitats 21
- Terrestrial Habitats 22
- A Special Type of Environment: Symbiosis 22

Changing Views of Invertebrate Phylogeny 24
- Legacy Names 25
- Phylogenetics and Classification Schemes 25

A Final Introductory Message to the Reader 25

CHAPTER 2 Systematics, Phylogeny, and Classifications 27

Phylogeny, Monophyly, Paraphyly, and Polyphyly 28
Homology 29
Apomorphy and Plesiomorphy 32
Challenges of Phylogenetic Inference 32
Constructing Phylogenies 33
Biological Classification 35
Nomenclature 38

CHAPTER 3 Introduction to the Animal Kingdom: Animal Architecture and Body Plans 43

Body Symmetry 44
Cellularity, Body Size, Germ Layers, and Body Cavities 47
Locomotion and Support 49
- Reynolds Number 49
- Ameboid Locomotion 50
- Cilia and Flagella 50
- Muscles and Skeletons 52

Feeding and Digestion 56
- Intracellular and Extracellular Digestion 56
- Feeding Strategies 57

Excretion and Osmoregulation 65
- Nitrogenous Wastes and Water Conservation 66
- Osmoregulation and Habitat 66
- Excretory and Osmoregulatory Structures 67

Circulation and Gas Exchange 69
- Internal Transport 69
- Circulatory Systems 70
- Hearts and Other Pumping Mechanisms 71
- Gas Exchange and Transport 71

Nervous Systems and Sense Organs 75
- Sense Organs 76
- Independent Effectors 81

Bioluminescence 81
Nervous Systems and Body Plans 81
Hormones and Pheromones 84
Reproduction 84
- Asexual Reproduction 84
- Sexual Reproduction 86
- Parthenogenesis 88

CHAPTER 4 Introduction to the Animal Kingdom: Development, Life Histories, and Origin 91

Evolutionary Developmental Biology: Evo-Devo 92
- Developmental Tool Kits 92
- The Relationship Between Genotype and Phenotype 93
- The Evolution of Novel Gene Function 93
- Gene Regulatory Networks 93

Eggs and Embryos 95
- Eggs 95
- Cleavage 95
- Orientation of Cleavage Planes 96
- Radial and Spiral Cleavage 96
- Cell Fates 99
- Blastula Types 101
- Gastrulation and Germ Layer Formation 101
- Mesoderm and Body Cavities 103

Life Cycles: Sequences and Strategies 105
- Classification of Life Cycles 105
- Indirect Development 107
- Settling and Metamorphosis 107
- Direct Development 108
- Mixed Development 108
- Adaptations to Land and Fresh Water 109
- Parasite Life Cycles 109

The Relationships Between Ontogeny and Phylogeny 110
- The Concept of Recapitulation 110
- Heterochrony and Paedomorphosis 111

The Origin of the Metazoa 112
- Origin of the Metazoan Condition 112
- Historical Perspectives on Metazoan Origins 112
- The Origin of Multicellularity 114
- The Origin of the Bilateral Condition and the Coelom 115
- The Trochaea Theory 116

Closing Thoughts 117

CHAPTER 5 Phylum Porifera: The Sponges 119

Phylum Porifera: The Sponges 120

Taxonomic History and Classification 123

The Poriferan Body Plan 126
- Body Structure and the Aquiferous System 127
- More on Sponge Cell Types 132
- Support 136
- Nutrition, Excretion, and Gas Exchange 138
- Activity and Sensitivity 143
- Reproduction and Development 143

Some Additional Aspects of Sponge Biology 154
- Distribution and Ecology 154
- Biochemical Agents 154
- Growth Rates 155
- Symbioses 156

Poriferan Phylogeny 159
- The Origin of Sponges 159
- Evolution within the Porifera 160

CHAPTER 6 Two Enigmatic Phyla: Placozoa and Ctenophora (The Comb Jellies) 165

Phylum Placozoa 166

Phylum Ctenophora 167

Taxonomic History and Classification 169

The Ctenophoran Body Plan 172
- Support and Locomotion 175
- Feeding and Digestion 176
- Circulation, Excretion, Gas Exchange, and Osmoregulation 179
- Nervous System and Sense Organs 179
- Reproduction and Development 181

Ctenophoran Phylogeny 183

CHAPTER 7 Phylum Cnidaria: Anemones, Corals, Jellyfish, and Their Kin 185

Taxonomic History and Classification 190

The Cnidarian Body Plan 196
- The Body Wall 197
- Support 209
- Movement 212
- Cnidae 215
- Feeding and Digestion 218
- Defense, Interactions, and Symbiosis 220
- Circulation, Gas Exchange, Excretion, and Osmoregulation 227
- Nervous System and Sense Organs 227
- Reproduction and Development 231

Cnidarian Evolutionary History 240
- Earliest Cnidaria 240
- Cnidarian Phylogeny 241

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

CHAPTER 8 A Brief Introduction to the Bilateria and Its Major Clades 245

The Bilateria 245
Deuterostomes and Protostomes 246

CHAPTER 9 Phylum Xenacoelomorpha: Basal Bilaterians 249

The Basal Bilaterian 249
Phylum Xenacoelomorpha 250
Subphylum Acoelomorpha 252
Class Acoela 252
The Acoel Body Plan 255
- Body Wall and External Appearance 255
- Body Musculature, Support, and Movement 256
- Nutrition, Excretion, and Gas Exchange 257
- Nervous Systems and Sense Organs 258
- Reproduction and Development 259

Class Nemertodermatida 261
The Nemertodermatid Body Plan 263
- Body Structure 263
- Cell and Tissue Organization 263
- Support and Movement 263
- Nutrition, Excretion, Gas Exchange 264
- Nervous System 265
- Reproduction and Development 265

Subphylum Xenoturbellida 267
The Xenoturbellid Body Plan 268
- General Body Structure 268
- Support and Movement 269
- Nutrition, Excretion, and Gas Exchange 270
- Nervous System and Sense Organs 270
- Reproduction and Development 270

CHAPTER 10 Protostomia, Spiralia, and the Phylum Dicyemida 273

Protostomes and Deuterostomes 273
Spiralia and Ecdysozoa 274
The Phylum Dicyemida (= Rhombozoa) 275
Anatomy and Biology of Dicyemidans 275
Life Cycles 277

CHAPTER 11 Gnathifera: The Phyla Gnathostomulida, Rotifera (including Acanthocephala), Micrognathozoa, and Chaetognatha 281

Phylum Gnathostomulida: The Gnathostomulids 283
The Gnathostomulid Body Plan 284
- Body Wall, Support, and Locomotion 284
- Nutrition, Circulation, Excretion, and Gas Exchange 284
- Nervous System 284
- Reproduction and Development 284

Phylum Rotifera: The Free-Living Rotifers 284
The Rotifer Body Plan 286
- Body Wall, General External Anatomy, and the Corona 286
- Body Cavity, Support, and Locomotion 287
- Feeding and Digestion 288
- Circulation, Gas Exchange, Excretion, and Osmoregulation 289
- Nervous System and Sense Organs 290
- Reproduction and Development 290

Phylum Rotifera, Subclass Acanthocephala: The Acanthocephalans 292
The Acanthocephalan Body Plan 293
- Body Wall, Support, Attachment, and Nutrition 293
- Circulation, Gas Exchange, and Excretion 294
- Nervous System 294
- Reproduction and Development 294

Phylum Micrognathozoa: The Micrognathozoans 295
The Micrognathozoan Body Plan 296
- Epidermis, Ciliation, and Body Wall Musculature 296
- Locomotion 298
- Pharyngeal Apparatus, Feeding, and Digestion 298
- Circulation, Gas Exchange, and Excretion 298
- Nervous System and Sense Organs 301
- Reproduction and Development 301

Phylum Chaetognatha 301
The Chaetognath Body Plan 304
- Body Wall, Support, and Movement 304
- Feeding and Digestion 306
- Circulation, Gas Exchange, and Excretion 306
- Nervous System and Sense Organs 306
- Reproduction and Development 307

CHAPTER 12 Platytrochozoa and Two Enigmatic Phyla: Entoprocta and Cycliophora 311

Phylum Entoprocta: The Entoprocts 312
The Entoproct Body Plan 314
Body Wall, Support, and Movement 314
Feeding and Digestion 314
Circulation, Gas Exchange, and Excretion 314
Nervous System 315
Reproduction and Development 316
Phylum Cycliophora: The Cycliophorans 317

CHAPTER 13 Introduction to the Lophotrochozoa, and the Phylum Mollusca 321

Phylum Mollusca 322
Taxonomic History and Classification 322
The Molluscan Body Plan 344
The Body Wall 346
The Mantle and Mantle Cavity 346
The Molluscan Shell 347
Torsion, or "How the Gastropod Got its Twist" 353
Locomotion 356
Feeding 361
Digestion 370
Circulation and Gas Exchange 373
Excretion and Osmoregulation 377
Nervous System 378
Sense Organs 380
Cephalopod Coloration and Ink 384
Reproduction 385
Development 389
Molluscan Evolution and Phylogeny 392

CHAPTER 14 Phylum Nemertea: The Ribbon Worms 397

Taxonomic History and Classification 399
Classification 399
The Nemertean Body Plan 400
Body Wall 401
Support and Locomotion 402
Feeding and Digestion 402
Circulation and Gas Exchange 406
Excretion and Osmoregulation 406
Nervous System and Sense Organs 408
Reproduction and Development 409
Nemertean Phylogeny 411

CHAPTER 15 Phylum Annelida: The Segmented (and Some Unsegmented) Worms 415

Taxonomic History and Classification 416
The Annelid Body Plan 426
Body Forms 426
Body Wall and Coelomic Arrangement 428
Support and Locomotion 429
Feeding and Digestion 432
Circulation and Gas Exchange 441
Excretion and Osmoregulation 444
Nervous System and Sense Organs 446
Reproduction and Development 450
Sipuncula: The Peanut Worms 457
Classification of Sipuncula 459
The Sipunculan Body Plan 460
Body Wall, Coelom, Circulation, and Gas Exchange 460
Support and Locomotion 461
Feeding and Digestion 462
Excretion and Osmoregulation 462
Nervous System and Sense Organs 463
Reproduction and Development 463
Thalassematidae: The Spoon Worms 465
Body Wall and Coelom 465
Support and Locomotion 465
Feeding and Digestion 465
Circulation and Gas Exchange 469
Excretion and Osmoregulation 469
Nervous System and Sense Organs 469
Reproduction and Development 469
Siboglinidae: Vent Worms and Their Kin 470
Siboglinid Taxonomic History 473
The Siboglinid Body Plan 473
The Tube, Body Wall, and Body Cavity 473
Nutrition 474
Circulation, Gas Exchange, Excretion, and Osmoregulation 474
Nervous System and Sense Organs 474
Reproduction and Development 474
Hirudinea: Leeches and Their Relatives 476

The Hirudinean Body Plan 477
Body Wall and Coelom 477
Support and Locomotion 477
Feeding and Digestion 478
Circulation and Gas Exchange 479
Excretion and Osmoregulation 480
Nervous System and Sense Organs 480
Reproduction and Development 481
Orthonectida: Extremely Simplified Annelids 482
Annelid Phylogeny 483

CHAPTER 16 The Lophophorates: Phyla Phoronida, Bryozoa, and Brachiopoda 487

Taxonomic History of the Lophophorates 488
The Lophophorate Body Plan 489
Phylum Phoronida: The Phoronids 490
The Phoronid Body Plan 490
Body Wall, Body Cavity, and Support 490
The Lophophore, Feeding, and Digestion 494
Circulation, Gas Exchange, and Excretion 494
Nervous System 495
Reproduction and Development 495
Phylum Bryozoa: The Moss Animals 496
The Bryozoan Body Plan 499
The Body Wall, Coelom, Muscles, and Movement 501
Zooid Interconnections 502
The Tentacle Crown, Feeding, and Digestion 503
Circulation, Gas Exchange, and Excretion 504
Nervous System and Sense Organs 505
Reproduction and Development 506
Phylum Brachiopoda: The Lamp Shells 509
The Brachiopod Body Plan 512
The Body Wall, Coelom, and Support 512
The Lophophore, Feeding, and Digestion 513
Circulation, Gas Exchange, and Excretion 514
Nervous System and Sense Organs 515
Reproduction and Development 515

CHAPTER 17 Rouphozoa: The Phyla Platyhelminthes (Flatworms) and Gastrotricha (Hairy-Bellied Worms) 519

Introduction to Rouphozoa 519
The Phylum Platyhelminthes (Flatworms) 520
Taxonomic History and Classification 522
The Platyhelminth Body Plan 527
Body Wall 529
Support, Locomotion, and Attachment 532
Feeding and Digestion 533
Circulation and Gas Exchange 537
Excretion and Osmoregulation 538
Nervous System and Sense Organs 539
Reproduction and Development 541
Platyhelminth Phylogeny 554
Phylum Gastrotricha: The Gastrotrichs, or Hairy-Bellied Worms 556
The Gastrotrich Body Plan 558
Body Wall 558
Support and Locomotion 558
Feeding and Digestion 558
Circulation, Gas Exchange, Excretion, and Osmoregulation 558
Nervous System and Sense Organs 558
Reproduction and Development 560

CHAPTER 18 Introduction to Ecdysozoa: Scalidophora (Phyla Kinorhyncha, Priapula, Loricifera) 563

Introduction to Ecdysozoa 563
The Scalidophora 564
Phylum Kinorhyncha: The Kinorhynchs, or Mud Dragons 564
The Kinorhynch Body Plan 567
Body Wall 567
Support and Locomotion 567
Feeding and Digestion 567
Circulation, Gas Exchange, Excretion, and Osmoregulation 567
Nervous System and Sense Organs 568
Reproduction and Development 568
Phylum Priapula: The Priapulans, or Penis Worms 568
Priapulan Body Plan 570
Body Wall, Support, and Locomotion 570
Feeding and Digestion 571
Circulation, Gas Exchange, Excretion, and Osmoregulation 571
Nervous System and Sense Organs 572
Reproduction and Development 572
Phylum Loricifera: The Loriciferans 572

CHAPTER 19 Nematoida: Phyla Nematoda and Nematomorpha 579

Phylum Nematoda: Roundworms 581
Classification of Phylum Nematoda 582
The Nematode Body Plan 586
Body Wall, Support, and Locomotion 586
Feeding and Digestion 588
Circulation, Gas Exchange, Excretion, and Osmoregulation 590
Nervous System and Sense Organs 592
Reproduction, Development, and Life Cycles 594
Life Cycles of Some Parasitic Nematodes 597
Phylum Nematomorpha: Horsehair Worms and Their Kin 600
The Nematomorph Body Plan 601
Body Wall, Support, and Locomotion 601
Feeding and Digestion 603
Circulation, Gas Exchange, Excretion, and Osmoregulation 603
Nervous System and Sense Organs 604
Reproduction and Development 604

CHAPTER 20 Panarthropoda and the Emergence of the Arthropods: Tardigrades, Onychophorans, and the Arthropod Body Plan 607

Phylum Tardigrada 610
The Tardigrade Body Plan 613
Locomotion 615
Feeding, Digestion, and Excretion 616
Circulation and Gas Exchange 616
Nervous System and Sense Organs 616
Reproduction and Development 617
Phylum Onychophora 619
The Onychophoran Body Plan 622
Locomotion 623
Feeding and Digestion 624
Circulation and Gas Exchange 624
Excretion and Osmoregulation 625
Nervous System, Sense Organs, and Behavior 625
Reproduction and Development 626
Systematics and Biogeography 628
An Introduction to the Phylum Arthropoda 628
Taxonomic History and Classification 629
The Arthropod Body Plan and Arthropodization 630
The Body Wall 632
Arthropod Appendages 634
Support and Locomotion 636
Growth 639
The Digestive System 642
Circulation and Gas Exchange 644
Excretion and Osmoregulation 646
Nervous System and Sense Organs 647
Reproduction and Development 651
The Evolution of Arthropods 652
The Origin of Arthropods 652
Evolution within the Arthropoda 652

CHAPTER 21 Phylum Arthropoda—Subphylum Crustacea: Crabs, Shrimps, and Their Kin 659

Classification of the Crustacea 663
Synopses of Crustacean Taxa 666
The Crustacean Body Plan 699
Locomotion 703
Feeding 708
Digestive System 714
Circulation and Gas Exchange 717
Excretion and Osmoregulation 719
Nervous System and Sense Organs 720
Reproduction and Development 724
Crustacean Phylogeny 730

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

CHAPTER 22 Phylum Arthropoda—Subphylum Hexapoda: Insects and Their Kin 735

Classification of the Subphylum Hexapoda 738
Synopses of Hexapod Groups 739
The Hexapod Body Plan 751
- General Morphology 751
- Locomotion 758
- The Origin of Insect Flight 761
- Feeding and Digestion 762
- Circulation and Gas Exchange 767
- Excretion and Osmoregulation 770
- Nervous System and Sense Organs 771
- Reproduction and Development 775

Hexapod Evolution 780

CHAPTER 23 Phylum Arthropoda—Subphylum Myriapoda: Centipedes, Millipedes, and Their Kin 785

Myriapod Classification 787
The Myriapod Body Plan 789
- Head and Mouth Appendages 791
- Locomotion 791
- Feeding and Digestion 791
- Circulation and Gas Exchange 793
- Excretion and Osmoregulation 794
- Nervous System and Sense Organs 794
- Reproduction and Development 795
- Embryonic Development 798

Myriapod Phylogeny 798

CHAPTER 24 Phylum Arthropoda: Subphylum Chelicerata 801

Synopses of Living Chelicerate Groups 807
The Euchelicerate Body Plan 818
- Spinnerets, Spider Silk, and Spider Webs 819
- Locomotion 823
- Feeding and Digestion 826
- Circulation and Gas Exchange 831
- Excretion and Osmoregulation 834
- Nervous System and Sense Organs 834
- Reproduction and Development 837

The Class Pycnogonida 846
The Pycnogonid Body Plan 849
- External Anatomy 849
- Locomotion 850
- Feeding and Digestion 850
- Circulation, Gas Exchange, and Excretion 852
- Nervous System and Sense Organs 852
- Reproduction and Development 852

Chelicerate Phylogeny 854

CHAPTER 25 Introduction to Deuterostomia, and the Phylum Hemichordata 857

Introduction to the Deuterostomia 857
Phylum Hemichordata: Acorn Worms and Pterobranchs 859
The Hemichordate Body Plan 862
Class Enteropneusta (Acorn Worms) 863
- External Anatomy 863
- Support Structures 863
- Coelomic Cavities 863
- Musculature and Locomotion 865
- Feeding and Digestion 865
- Circulatory System 866
- Excretory System 866
- Gas Exchange 866
- Nervous System 866
- Reproduction and Development 866

Class Pterobranchia (Pterobranchs) 868
- Body Wall and Cavities 869
- Support, Muscles, and Movement 869
- Gut and Feeding 869
- Circulation and Gas Exchange 869
- Nervous System 870
- Reproduction and Development 870

Hemichordate Fossil Record and Phylogeny 870

CHAPTER 26 Phylum Echinodermata: Starfish, Sea Urchins, Sea Cucumbers, and their Kin 873

Taxonomic History and Classification 877
The Echinoderm Body Plan 881
Developmental Roots of the Echinoderm Body Plan 881
Body Wall and Coelom 883
Mutable Collagenous Tissue 885
Water Vascular System 885
Support and Locomotion 887
Feeding and Digestion 889
Circulation and Gas Exchange 896

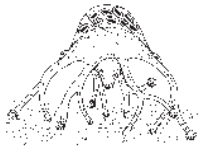
Foreword

Humans are well aware of the crushing tragedy of species loss among the grand mammals—the rhinoceroses, elephants, and even among our closest relatives, the primates—as well as among the birds, reptiles, fish, and amphibians. But meanwhile, though less often in the news, the invertebrate species and communities of the world have also been suffering. Insect populations are reduced globally to a fraction of former levels, many invertebrates are shifting their historical ranges, and invasive species are decimating indigenous ones, especially on islands and in freshwater environments. And we have barely begun to appreciate or document the impacts on marine invertebrates of global ocean warming and acidification and disruption of oceanic circulation patterns. The losses of these non-vertebrate species are already being felt and will become catastrophic in the not too distant future as insect-pollinated crops fail, soil ecosystems collapse, and marine food chains are disrupted.

Most humans think of invertebrates (when they think of them at all) as annoying pests or something to be afraid of, or, in the case of lobsters and prawns or oysters and mussels, as succulent mouthfuls. This book invites us, as it has for over three decades, to explore more deeply into the beautiful and fascinating diversity of our own family tree—our invertebrate cousins that dominate planet Earth. With this new, fourth edition, the account of the world of invertebrates is brought up to date with respect to the rapidly growing fields of molecular phylogenetics and evo-devo. New figures and color photographs add further appeal to this new edition, especially as they reflect some of the latest discoveries in invertebrates and the most up-to-date imaging techniques to capture the beauty of their whole bodies or their anatomy. The ever-useful, detailed classifications are updated to reflect the latest consensus in the field, with excellent synopses of the higher taxa making the book an enormously useful reference for any zoologist—not just students. And as with past editions, complicated ideas are presented accurately, clearly, and understandably.

Invertebrates has long been prestigious among invertebrate zoology texts, a reputation well earned. For coverage of some groups, such as the meiofaunal taxa, there is simply nothing comparable. Successive editions of this textbook have added newly discovered phyla. First, Loricifera (first edition), then Cycliophora (second edition), living on the mouthparts of lobsters, and finally Micrognathozoa (third edition), originally found at Disko Island, in Greenland but now known from several localities around the world. These discoveries should make us realize how much there remains to learn, as cycliophorans were discovered only relatively recently despite being ectocommensals on some of the most preferred foods of Europe and North America, the Norway lobster and the American and European lobsters of the genera *Nephrops* and *Homarus.* If we had only paid more attention to them before tossing them into the pot to be boiled! So, curl up in your favorite reading chair and enjoy a few pages when you're in the mood; you'll be surprised at how readable and fascinating the lives of invertebrates are.



Vicki Buchsbaum Pearse
Coauthor of *Animals Without Backbones* and *Living Invertebrates*, founding editor of *Invertebrate Biology*.

Reinhardt Møbjerg Kristensen
University of Copenhagen, Denmark.

Preface

This project began in 1980, when two California brothers who taught invertebrate biology courses at Humboldt State University and the University of Southern California sat down in front of their typewriters determined to write a "different invert textbook" in two or three years. It took them ten years. By the second edition personal computers were widely available, and in the early 1990s email further increased the efficiency and pace of the project. The success of the first edition led to the second (2003) being full color—a game changer. For the third edition (2016) Wendy Moore and Stephen Shuster joined the team, and a number of contributing specialists kindly agreed to revise or edit various sections of the book. For this fourth edition of *Invertebrates*, Gonzalo Giribet and Wendy Moore join as co-authors. In addition, 19 other specialists graciously agreed to revise selected chapters or chapter sections and we are deeply indebted to them (please see Guest Chapter Revisers). We have also had the good fortune to continue working with the highly professional team at Sinauer Associates, now an imprint of Oxford University Press. It truly does take a village.

The information explosion has continued since the third edition of this book, especially in the fields of molecular biology and phylogenetics. A fairly solid framework of the "new metazoan phylogeny" has emerged although some big questions still linger, such as the relationships of the four basal metazoan phyla and the internal relationships among the Platytrochozoa. Although the legacy names Protostomia and Deuterostomia (the later now with only three phyla) are retained, the composition and nature of these two animal clades has changed significantly since the first edition of this book. The enigmatic phylum Xenacoelomorpha remains supported as the sister group of the remaining Bilateria (aka the Nephrozoa). Protostomia comprises two well-supported clades, Spiralia and Ecdysozoa. There is support for the Ecdysozoa having three subclades—Nematoida, Panarthropoda, and Scalidophora—although the latter lacks strong molecular support. The sister group of Ecdysozoa, Spiralia (with 15 phyla), still remains only partly resolved, although the clades Gnathifera, Platytrochozoa, Rouphozoa and Lophotrochozoa have strong support. The Platyhelminthes, once thought to be primitive bilaterians, have been shown to be high up in the spiralian tree of life as a sister group to the hairy-bellied worms, Gastrotricha (together constituting the clade Rouphozoa). The sister group of Arthropoda is Onychophora, not Tardigrada as once thought. Among the Crustacea, the long-bodied forms (e.g., Cephalocarida, Branchiopoda, Remipedia) are no longer viewed as the most primitive living crustaceans, but rather form a clade called Allotriocarida that arises higher in the tree and that includes Hexapoda. Indeed, the sister group of the remipedes appears to be Hexapoda (insects and their kin). The two spiralian phyla Annelida and Mollusca are in the midst of major phylogenetic re-evaluation and for now their internal classification, while striving for monophyly, has many provisional rankings (the overall composition of Mollusca has been stable for decades, but that of Annelida continues to add taxonomic groups, the latest being the former phylum Orthonectida). As a result of recent molecular phylogenetic studies, some long-standing taxa have been abandoned (e.g., the phyla Sipuncula, Echiura and Orthonectida are now known to be clades of highly modified annelids), and other annelid and mollusc groups have been radically redefined (e.g., Polychaeta, Heterobranchia).

In addition to the revised phylogenetic trees and classifications, other major changes in this fourth edition include new summary boxes for each chapter, a revised and updated discussion of phylogenetic systematics (Chapter 2), and a shortening of the book's length. The chapter on protists has been deleted simply because surveys show they are not taught in any university courses that use this textbook (and protists are, of course, not invertebrates). As in previous editions, important new terms are printed in boldface when first defined (and these are noted in the Index). Specific gene names, like species names, are italicized, though note that their products (proteins) are not (nor are names for classes of genes, e.g., Hox and ParaHox genes).

Much of the art for this edition is new or has been updated. However, we continue to include diagrams that will be useful to students in the laboratory,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

including for animal dissections. We also continue to provide detailed classifications and taxonomic synopses within each phylum, and these have been thoroughly updated. We don't expect these to read in the same way as the rest of the chapter, but rather to be used as a reference to look up taxonomic names, understand the traits that distinguish groups, and get an overall sense of the scope of the higher taxa in each animal phylum.

We are delighted and honored that Vicki Buchsbaum Pearse and Reinhardt Møbjerg Kristensen wanted to write a Foreword for this edition of *Invertebrates*. Vicki, of course, has coauthored two very popular books on invertebrates herself, was a founding editor for the fine journal *Invertebrate Biology*, and has published extensively on everything from sponges to echinoderms (and is one of the few world experts on Placozoa). Reinhardt is a world expert on tardigrades and other meiofauna and microfauna, and he holds the distinguished honor of having discovered more animal phyla than any other modern biologist, three—Loricifera, Cycliophora, and Micrognathozoa! He has also been a leading expert in Arctic biology for the past forty years.

To say this book is a "labor of love" would be an understatement. Without a deep passion for invertebrates on the part of all the contributors it would not have been possible. Hopefully this book elevates in its readers their own passion and enthusiasm for that 95% of the animal kingdom that has so successfully flourished without backbones.

Acknowledgments

This edition of *Invertebrates* has again benefitted greatly from conscientious reviews provided by many specialists, and we extend to those wonderful professionals and friends our utmost gratitude. Special thanks to Judie Bronstein for discussions on symbiosis in its many forms. In addition, 19 specialists in various taxa generously agreed to revise chapters or sections of the book (see Guest Chapter Revisers). Thanks also to those guest revisers of the third edition who did not participate in this edition: S. Patricia Stock, C. Sarah Cohen, Joel W. Martin, Fernando Pardos, and Jesús Benito.

The highly talented staff at Sinauer Associates has always been a joy to work with, and for this edition we had the skills of their many professionals assisting us, including: Tracy Marton (Production Editor), Martha Lorantos (Lead Production Editor), Cailen Swain (Permissions Supervisor), Lou Doucette (Copyeditor), Sarah D'Arienzo (Editorial Assistant), Mark Siddall (Photo Researcher), Joan Gemme (Production Manager/Art Director), Meg Britton Clark (Production Specialist & Book Designer), Michele Ruschhaupt (freelance page layout assistance), Linda Hallinger (Indexer), and Jason Noe (Senior Acquisitions Editor, Oxford University Press). Most of the original artwork in this text was done from our own sketches or from other sources by the award-winning scientific illustrator Nancy Haver, supported by our publisher, Sinauer Associates. Thank you one and all; your technical skills are matched only by your patience and good humor. We are fortunate to have many of Larry Jon Friesen's splendid photographs once again adorning this edition of *Invertebrates*, including the cover photo.

Invertebrates is in four languages and enjoys a broad readership, notably in Europe and Latin America. Many students and professionals have written over the years expressing their support and encouragement and sending photographs or other material. To those loyal supporters of this long-standing project, we offer our most sincere thanks.

Digital Resources for *Invertebrates*, Fourth Edition

To learn more about any of these resources, or to get access, please contact your local OUP representative.

E-Book

(ISBN 9780197637173)

Invertebrates, Fourth Edition is available for purchase as an e-book via RedShelf, VitalSource, and other leading higher education e-book vendors. The e-book can be purchased as either a 180-day rental or a permanent (non-expiring) subscription. All major mobile devices are supported.

For the Instructor

(Available at oup.com/he/brusca4e)

Instructors using *Invertebrates*, Fourth Edition have access to an extensive collection of visual resources to aid in course planning, lecture development, and student assessment.

- **PowerPoint Presentations**: All of the textbook's figures, photos, and tables are provided for each chapter, with figure numbers and titles on each slide, complete captions in the Notes field, and alt text embedded for accessibility. All of the artwork has been reformatted and optimized for exceptional image quality when projected in class.

A phylogeny of Metazoa. This tree reflects a consensus view based primarily on recent molecular phylogenetic analyses. The 31 animal phyla are in boldface, whereas subphyla and other clades are in lightface. Spiralian lineages are in red, ecdysozoan lineages are in green, deuterostome lineages are in tan. Uncertainty still exists in several regions, and these are depicted as polytomies ("starbursts"). Thus, for example, the branching sequence for Placozoa, Cnidaria, and Bilateria is not yet resolved, so it is shown as an unresolved trichotomy. Similarly, two large polytomies exist among the Platytrochozoa, and the relationships of the three ecdysozoan clades are still unresolved, as are those of the three scalidophoran phyla. Due to uncertainty, Dicyemida is depicted in an unresolved trichotomy with Gnathifera and Platytrochozoa. See Chapter 28 for additional details.

CHAPTER 1

Introduction

The incredible diversity of extant (= living) invertebrates on Earth is the outcome of more than half a billion years of evolution. Indirect evidence of the first life on Earth, prokaryotic organisms, has been found in some of the oldest sedimentary rocks on the planet, suggesting that life first appeared in Earth's seas almost as soon as the planet cooled enough for life to exist. The Earth is 4.6 billion years old, and the oldest rocks found so far are about 4.3 billion years old. Although the precise date of the first appearance of life on Earth remains debatable, there are tantalizing 3.6- to 3.8-billion-year-old trace fossils from Australia that resemble prokaryotic cells—although these have been challenged, and opinion is now split on whether they are traces of early bacteria or simply mineral deposits. However, good evidence of prokaryotic life has been found in pillow lava that formed on the seabed 3.5 billion years ago, now exposed in South Africa. And 3.4-billion-year-old fossil cells (probably sulfur-oxidizing bacteria) have been found among cemented sand grains on an ancient beach in Australia.[1]

The next big step in biological evolution came about when prokaryotic cells began taking in guests. Around 2 to 2.5 billion years ago, one of these primitive prokaryotic cells took in a free-living bacterium that established permanent residency—giving rise to the cellular organelles we call mitochondria. And that was the origin of the eukaryotic cell. Mitochondria, you will recall from your introductory biology course, generate energy for their host cells by oxidizing sugars, and in this case they also equipped early life to survive in Earth's gradually increasing oxygen levels. Evidence suggests that mitochondria evolved just once, from a symbiotic α-proteobacterium, and then subsequently diversified broadly. Modern free-living relatives of this bacterium harbor about 2,000 genes across several million base pairs, but their mitochondrial descendants have far fewer, sometimes as few as three genes. And human mitochondrial DNA harbors only about 16,000 base pairs. On the other hand, some plants have greatly

[1]There are three popular theories on how life first evolved on Earth. The classic "primeval soup" theory, dating from Stanley Miller's work in the 1950s, proposes that self-replicating organic molecules first appeared in Earth's early atmosphere and were deposited by rainfall into the ocean, where they reacted further to make nucleic acids, proteins, and other molecules of life. More recently, the idea of the first synthesis of biological molecules by chemical and thermal activity at deep-sea hydrothermal vents has been suggested. Hydrothermal vents also spew out compounds that could have been incorporated into the first life forms. The third proposal is that organic molecules, or even prokaryotic life itself, first arrived on Earth from another planet (recently Mars has been at the forefront) or from deep space, on comets or meteorites. Meteorites that fall to Earth contain amino acids and organic carbon molecules such as formaldehyde. Clearly, raw materials were not the issue—the trick was assembling the organic compounds to create a living, reproducing system.

expanded their mitochondrial genome, the largest so far discovered in the genus *Silene*, with around 11 million base pairs. Another prokaryotic intracellular guest, a cyanobacterium, became the ancestor of chloroplasts through the same symbiogenic process; chloroplasts, of course, are the photosynthesizing organelles that made plants and algae possible. In some plant and algal lines, the original chloroplast was lost, and a new one was picked up when a host cell took in an alga and co-opted its chloroplast in another kind of symbiogenic event.

Controversial hydrocarbon biomarkers suggest that the first eukaryotic cells might have appeared as early as 2.7 billion years ago, late in the Archean, although the earliest fossils that have been proposed to be eukaryotes—based on cell surface features and their large size—are 1.6 to 1.8 billion years old (Paleoproterozoic). Multicelled algae (protists) date as far back as 1.2 billion years (in the Mesoproterozoic Era). Eukaryote-like microfossils have been described from 1-billion-year-old freshwater deposits, suggesting that the eukaryotes might have left the sea and invaded the terrestrial realm long ago. Even though the eukaryotic condition appeared early in Earth's history, it took a few hundred million more years for multicellular organisms to first evolve.

Molecular clock estimates put the origin of Metazoa at 875 to 650 million years ago. The oldest generally accepted metazoan fossils are from the Ediacaran Period (635–541 Ma), found in the Fermeuse Formation of Newfoundland (~560 Ma) and the Doushantuo Formation of southern China (600–580 Ma). A 560-million-year-old likely cnidarian (named *Haootia quadriformis*) has been described from Newfoundland, with quadraradial symmetry and clearly preserved bundled muscular fibers. *Haootia* appears to be a polyp nearly 6 cm long, or perhaps an attached medusa—it resembles modern species of Staurozoa. Cnidarians and other apparent diploblastic animals have been reported from the Doushantuo deposits, although these have been met with skepticism in some quarters. However, in 2015, a seemingly reliable 600-million-year-old fossil sponge (*Eocyathispongia qiania*) was described from the Doushantuo Formation. In 2009, Jun-Yuan Chen and colleagues reported on embryos of reputed bilaterians (triploblasts) in the Doushantuo deposits—32-cell-stage embryos with micromeres and macromeres, apparent anterior–posterior and dorsoventral patterning, and ectoderm-like cells around part of their periphery. This finding was challenged, and the fossils were variously declared prokaryotes or protists by other workers. However, further discoveries of additional embryos seemed to support the view that these were bilaterian embryos and, in some cases, perhaps diapause embryos ("resting eggs") of bilaterians. Good trace fossils (tracks) of a minute wormlike bilaterian animal, possibly with legs, have also been described from 585-million-year-old rocks in Uruguay. These fossils put the appearance of "higher metazoans" (i.e., bilaterians) millions of years before the beginning of the Cambrian period.

There is no argument that Metazoa are monophyletic (i.e., a clade), and the animal kingdom is defined by numerous apomorphies, including: gastrulation and embryonic germ layer formation; unique modes of oogenesis and spermatogenesis; a unique sperm structure; mitochondrial gene reduction; epidermal epithelia with septate junctions, tight junctions, or zonula adherens; striate myofibrils; actin-myosin contractile elements; type IV collagen; and the presence of a basal lamina/basement membrane beneath epidermal layers (of course, some of these features have been secondarily lost in some groups). In addition, there is a series of molecular apomorphies unique to metazoans, including signaling, adhesion, and transcriptional regulation factors (e.g., *Wnt*, *Frizzled*, *Hedgehog*, *EGFR*, classical cadherin, Hox, and others). Evidence is strong that Metazoa arose out of the protist group Choanoflagellata, or a common ancestor, and the two comprise sister groups in almost all recent analyses. They are, in turn, part of a larger clade known as Opisthokonta that also includes the Fungi and several small protist groups.

The three great lineages of life on Earth—Bacteria, Archaea, Eukaryota—are very different from one another. Bacteria and Archaea have their DNA dispersed throughout the cell, whereas in Eukaryota the DNA is enclosed within a membrane-bound nucleus. The cell lineages that gave rise to the Eukaryota are still unknown. The many millennia between the origin of Eukaryota and the explosive radiation that apparently began in the Ediacaran is sometimes called the "boring billion years," but the fossil record is fairly sparse for that time period, so we're not sure how "boring" it actually was. One popular hypothesis suggests that oxygen levels were too low during that time for larger organisms to evolve.

It seems likely that a significant portion of Earth's biodiversity, at the level of both genes and species, resides in the "invisible" prokaryotic world, and we have come to realize how little we know about this hidden world. About 10,300 species of prokaryotes have been described, but there are an estimated 10 million (or up to ~1 trillion) undescribed prokaryote species on Earth. Today, there are an estimated 2,064,967 described and named eukaryote species: about 200,000 protists, 375,000 plants (300,000 seed plants), 100,000 fungi, and 1,453,163 animals (Metazoa). And 15,000 to 20,000 new species are described every year. An estimated 135,000 more plant species remain to be described. Overall, estimates of undescribed eukaryotes range from lows of 3–8 million to highs of 100 million or more. Of the 1,453,163 described species of living animals, around 58,000 are vertebrates (4%), more than half of which are fishes,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and 1,395,163 (96%) are invertebrates (Table 1.1). This book attempts the audacious task of teaching you about those 1.4 million spineless wonders.

Keeping Track of Life

How can we possibly keep track of all these species names and information about each of them, and how do we organize them in a meaningful way? We do so with classifications. **Classifications** are lists of species, ranked in a subordinated fashion that reflects their evolutionary relationships and phylogenetic history. Classifications summarize the overarching aspects of the tree of life. At the highest level of classification, we can recognize two superkingdoms: Prokaryota (containing the kingdoms Archaea and Bacteria) and Eukaryota (containing the kingdoms Protista, Fungi, Plantae, and Animalia/Metazoa). Because "Protista" is not a monophyletic group, the protists are sometimes broken up into several kingdoms, or other classificatory ranks, but the relationships among some protist groups are still being debated.

One of the earliest and best-known evolutionary trees of life published from a Darwinian (genealogical) perspective was by Ernst Haeckel in 1866 (Figure 1.1). Haeckel coined the term "phylogeny," and his famous trees codified what became a tradition of depicting phylogenetic hypotheses as branching diagrams, a tradition that has persisted since that time. However, a hand-drawn sketch in Charles Darwin's field notebook (1837) clearly depicts his view of South American mammal evolution in a branching tree of extant and fossil species. And in his book *On the Origin of Species* (1859), Darwin presented an abstract branching diagram of a theoretical tree of species as a way of illustrating his concept of descent with modification. The famous French zoologist Jean Baptiste P. A. de Lamarck probably presented the first historical trees of animals in his *Philosophie Zoologique* in 1809, and the French botanist Augustin Augier published a tree showing the relationships among plants in 1801 (perhaps the first evolutionary tree ever published)—even

TABLE 1.1 Numbers of Described Living Species in the 31 Animal Phyla, 1,453,163 total[a,b]

Taxon	Number of Described and Valid Living Species	Percent of Total Described Animal Species
Phylum Porifera	9,300	0.67
Phylum Placozoa	4	0.0003
Phylum Ctenophora	130	0.009
Phylum Cnidaria	13,300	0.95

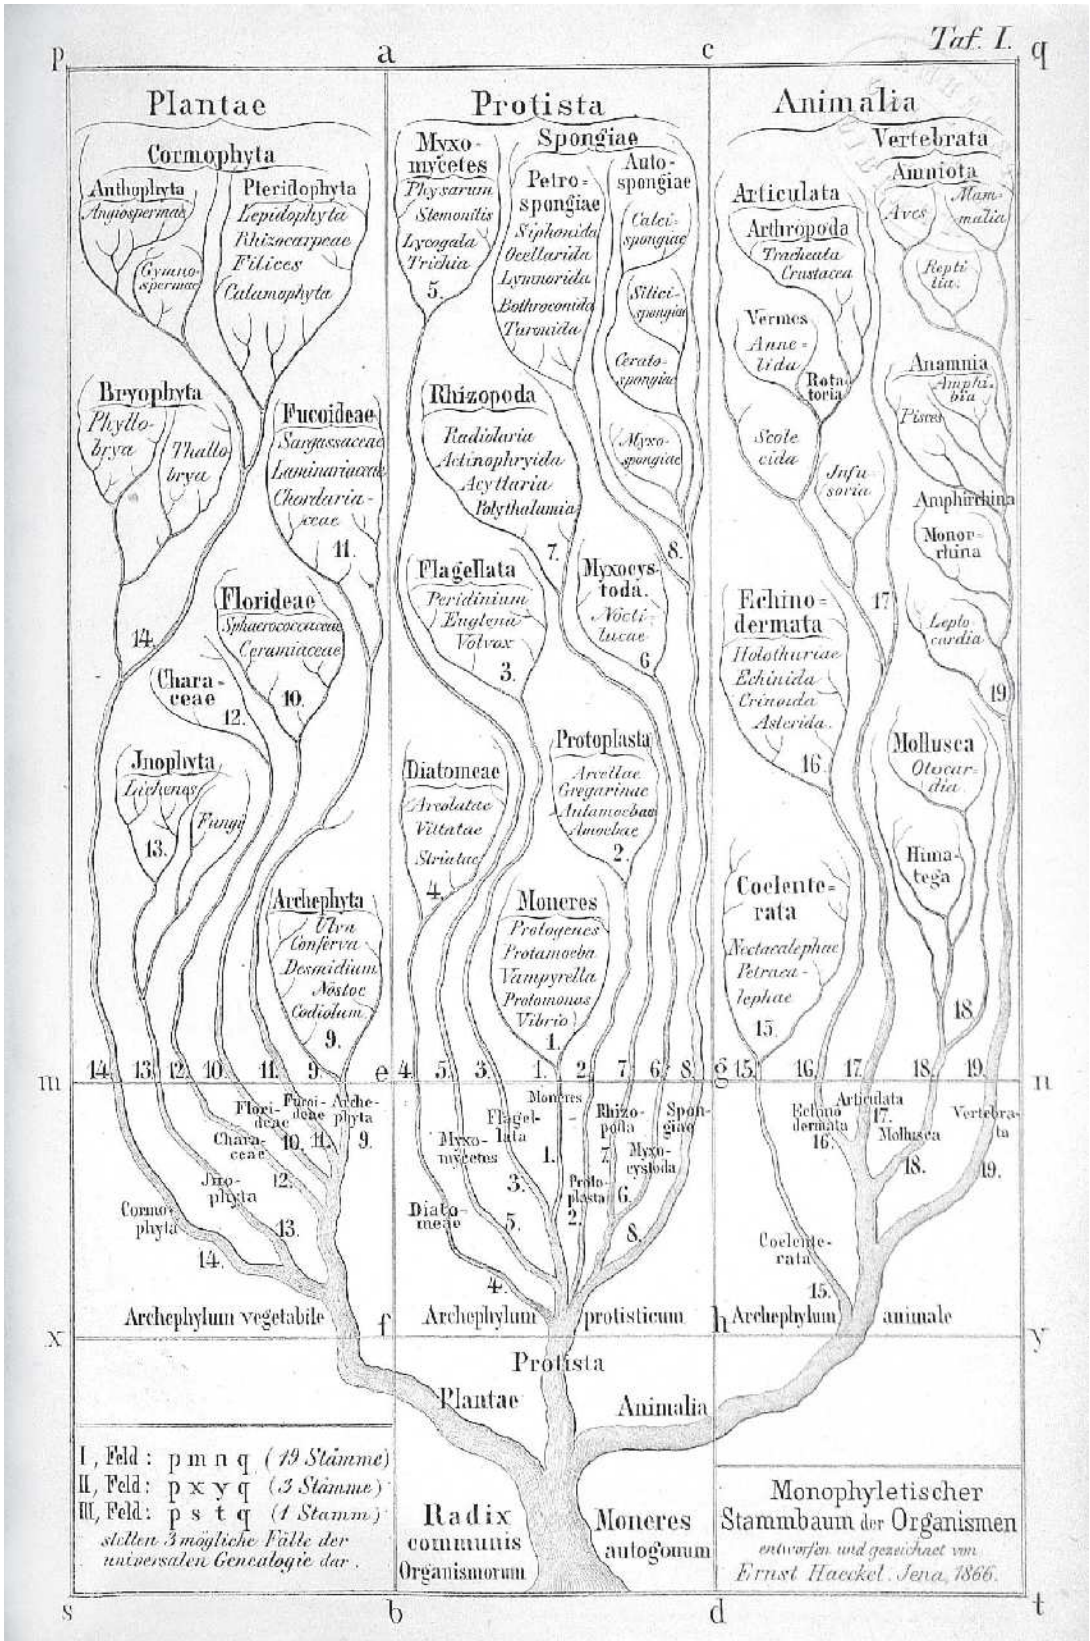
Phylum Rotifera	3,350	0.23
Phylum Micrognathozoa	1	0.00007
Phylum Chaetognatha	130	0.009
Phylum Entoprocta	200	0.014
Phylum Cycliophora	2	0.0001
Phylum Mollusca	73,000	5.02
Phylum Nemertea	1,300	0.09
Phylum Annelida	20,000	1.38
Phylum Phoronida	15	0.001
Phylum Bryozoa (= Ectoprocta)	6,300	0.43
Phylum Brachiopoda	440	0.03
Phylum Gastrotricha	860	0.06
Phylum Platyhelminthes	30,000	2.06
Phylum Kinorhyncha	300	0.02
Phylum Priapula	22	0.0016
Phylum Loricifera	38	0.0027
Phylum Nematoda	27,000	1.86
Phylum Nematomorpha	365	0.026
Phylum Tardigrada	1,300	0.09
Phylum Onychophora	200	0.014
Phylum Arthropoda (TOTAL)	**1,196,521**	**82.3**
Subphylum Chelicerata	113,000	7.8
Subphylum Myriapoda	16,000	1.10
Subphylum Crustacea	72,000	5.00
Subphylum Hexapoda	995,521	68.51
Phylum Chordata (TOTAL)	**61,035**	**4.20**
Subphylum Cephalochordata	35	0.003
Subphylum Urochordata	3,000	0.21
Subphylum Vertebrata	58,000	4.0
Phylum Hemichordata	130	0.009
Phylum Echinodermata	7,300	0.5

[a]1,395,163 (96%) are invertebrates. 82% of all known animals belong to just one phylum, Arthropoda; 87% belong to two phyla (Arthropoda + Mollusca); 92% belong to three phyla (Arthropoda + Mollusca + Chordata). 25 phyla each contain fewer than 1% of the known animal species, including some that may seem quite diverse to the casual seashore visitor, such as sponges, cnidarians, bryozoans, and echinoderms.

[b]Estimated numbers of other described (living) species: Prokaryota = 10,300; Protista = 200,000; Plantae = 315,000; Fungi = 100,000.



From E. H. P. A. Haeckel.1866. *Generelle Morphologie der Organismen: allgemeine Grundzüge der organischen Formen-Wissenschaft, mechanisch begründet durch die von C. Darwin reformirte Decendenz-Theorie.* Georg Reimer, Berlin

FIGURE 1.1 **Haeckel's Tree of Life (1866).**

though both Lamarck's and Augier's trees were produced before the modern concept of evolution had been clearly articulated. We discuss various ways in which phylogenetic trees are developed in Chapter 2.

Since Haeckel's day, many names have been coined for the branches that sprout from these trees, and in recent years a glut of new names has been introduced to label various new clades nested within the tree of

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

life, many of which have been proposed based on molecular data. We will not burden you with all of these names, but a few of them need to be defined here before we launch into our study of the invertebrates. Most of these names refer to groups of organisms that are thought to be natural phylogenetic lineages (i.e., groups that include all the descendants of a stem species, known as **monophyletic** groups, or **clades**). Examples of such natural, or monophyletic, groups are the superkingdom Eukaryota, kingdom Metazoa (the animals), and kingdom Plantae (the lower and higher plants).[2] All three of these large groupings are thought to have had a single origin, and they each include all of the species descended from that original ancestor. Some other named groups are natural, having a single evolutionary origin, but the group *does not contain all of the members* of the lineage. Such groups are said to be **paraphyletic**, and they are often the basal or deep lineages of a much larger clade. Paraphyletic groups comprise some, but not all, descendants of a stem species. The Protista are paraphyletic because the grouping excludes three large multicelled lineages that evolved out of it (e.g., Metazoa, Plantae, Fungi). Another well-known paraphyletic group is Crustacea (which excludes the Hexapoda/Insecta, a clade that evolved from a crustacean ancestor). The clade that includes both Crustacea and Hexapoda is called Pancrustacea. Classifications of life are ideally derived from evolutionary or phylogenetic trees and thus generally include only monophyletic groups. However, sometimes paraphyletic taxa are also used because they had been recognized historically and, if they are unambiguous, they can be important in facilitating meaningful communication among scientists and between the scientific community and society (e.g., Protista and Crustacea).

Some names refer to unnatural, or composite, groupings of organisms, such as "microbes" (i.e., all organisms that are microscopic in size, such as bacteria, archaeans, yeasts, unicellular fungi, and some protists). These unnatural groups are **polyphyletic**. For example, yeasts are unicellular fungi that evolved several times independently from multicellular filamentous ancestors; today they are assigned to one of three higher fungal phyla, so the concept of "yeast" represents a polyphyletic, or unnatural, grouping. The name "slugs" (or "sea slugs") also refers to a group of animals that do not share a single ancestry (the slug form has evolved many times among gastropod molluscs), so slugs are polyphyletic. We explore these concepts more fully in Chapter 2.

We know approximately how many genes are in organisms from yeast (about 6,000 genes) to humans (about 25,000 genes), but we don't know how many living species inhabit our planet, and the range in estimates is surprisingly broad. How many undescribed species are lingering out there, waiting for names and descriptions? However derived, predictions of global species diversity rely on extrapolations from existing real data. Methods of estimation have included rates of past species descriptions, expert opinion, the fraction of undescribed species in samples collected, and ratios between taxa in the taxonomic hierarchy. Each method has its limitations. Two recent estimates of undescribed marine animals (Mora et al. 2011 and Appeltans et al. 2012) concluded that 91% or 33%–67% (respectively) of the world's eukaryotic marine fauna is still undescribed. More recently, a large research program sampling the Western Australian upper continental slope for Crustacea and Polychaeta found 95% of the species to be undescribed (with the rate of new species obtained by the sampling program not even leveling off). Given the vast extent of the poorly sampled world's continental slopes, not to mention the deep sea, rain forests, and other little-sampled habitats, these data suggest that estimates that over 90% of eukaryotes on Earth are undescribed are not unreasonable.

Our great uncertainty about how many species of living organisms exist on Earth is unsettling. At our current rate of species descriptions, it might take us 10,000 years or more to describe just the rest of Earth's eukaryotic life forms. Not all of the species remaining to be described are invertebrates—between 1990 and 2002 alone, 38 new primate species were discovered and named. And if prokaryotes are thrown into this mix, the numbers become even larger. Recent gene-sequence surveys of the world's oceans (based largely on DNA "barcodes"—16S ribosomal RNA gene sequences for Bacteria and Archaea, 18S ribosomal RNA gene sequences for eukaryotes) have revealed a massive undescribed biota of microbes in the sea. Similar discoveries have been made with genetic searches for soil microbes, and a handful of soil can contain more than 5,000 species of prokaryotes and eukaryotes combined. For example, there are about 30,000 formally named bacterial varieties that are in pure culture, but estimates of undescribed species range from 10 million to a billion or more! And thousands of bacterial species inhabit the human body, almost all of which are not yet even named and described. Viruses still lack a universal molecular identifier, and the world scope of viral biodiversity is essentially unknown, despite the impact many of these undiscovered viruses may have on us.

[2] For decades, taxonomists have debated the boundary between protists and Plantae. We accept the view that it should be placed just prior to the evolutionary origin of chloroplasts and that Plantae should comprise all eukaryotes with plastids directly descending from the initially enslaved cyanobacterium, i.e., Rhodophyta (red algae), Glaucophyta (glaucophyte algae), and Viridiplantae ("green plants"), but exclude those like chromists that obtained their chloroplasts from plants secondarily by subsequent eukaryote-to-eukaryote lateral transfers. The structure of plastid genomes and the derived chloroplast protein-import machinery support a single origin of these closely related groups. Thus, Plantae is a monophyletic group containing two subkingdoms, Biliphyta (phyla Glaucophyta and Rhodophyta) and Viridiplantae (the phyla Chlorophyta, Charophyta, Anthocerotophyta, Bryophyta, Marchantiophyta, and Tracheophyta). In the past, some workers have restricted Plantae to land plants (embryophytes, or higher plants) and included the other Viridiplantae with the Protista in a larger group called Protoctista (which also included the lower fungi).

There are currently several attempts to compile a list of all *known* species on Earth. The United States Geological Survey (USGS) has hosted ITIS—the Integrated Taxonomic Information System. The goal of ITIS is to create an easily accessible database with reliable information on species names and their classification. Recently, ITIS and several other initiatives turned their data over to the Catalogue of Life (CoL) project, which is building the species list and maintaining a "consensus classification" of all life (see www.catalogueoflife.org and Ruggiero et al. 2015). The Encyclopedia of Life (EOL) project is building a website that offers not just species names, but also ecological information about each species; it currently contains more than 200,000 vetted species pages. WoRMS (the World Register of Marine Species) is an open-access online database with the goal of listing all described eukaryotic species, including their higher taxonomy.

However, at our current rate of anthropogenically driven extinction, a majority of Earth's species will go extinct long before they are ever described. In the United States alone, at least 5,000 named species are threatened with extinction, and an estimated 500 known species have already gone extinct since people first arrived in North America. Globally, the United Nations Environment Programme estimates that by 2030 nearly 25% of the world's mammals could go extinct, and recent counts indicate over 325 vertebrate species have already become extinct since 1500. Some workers now refer to the time since the start of the Industrial Revolution as the Anthropocene—a geologic period marked by humanity's profound global transformation of the environment. More than half of Earth's terrestrial surface is now plowed, pastured, fertilized, irrigated, drained, bulldozed, compacted, eroded, reconstructed, mined, logged, or otherwise converted to new uses. Human-driven deforestation removes 15 billion trees per year. E. O. Wilson once estimated that about 25,000 species are going extinct annually on Earth (we just don't know what they are!).

Even though invertebrates make up 95% of the described animal kingdom (Table 1.1), they account for only 38% of the 500 or so species now under protection by the U.S. Endangered Species Act. NatureServe has argued that more than 1,800 invertebrate species need protection, while the IUCN Red List of Threatened Species documents the extinction risk of nearly 50,000 species of animals and plants. In 2002, the U.N. Convention on Biological Diversity committed nations to significantly reduce rates of biodiversity loss by 2010, and in 2010 this call was renewed with a set of specific targets for 2020. However, several recent studies have shown that the convention has so far failed dismally and rates of biodiversity loss do not appear to be slowing at all; in fact, they are likely accelerating.

The single greatest threat to species survival for the past 200 years has been habitat loss, although over the past 75 years or so, loss of keystone predators has also been a major perturbation to ecosystems (including in the sea, where only 7% of the world's ocean has any form of protection, and only 2.5% is highly protected). More recently, invasive species are becoming an increasing threat, especially in the time of globalization. We hear mostly about deforestation, but as much as 50% of the Earth's coastal environments have also been degraded during past decades, at rates exceeding those of tropical forest loss. And, it is now clear that the damaging effects of habitat loss will be escalated by anthropogenically driven global climate change. The concentration of carbon dioxide (CO_2) in Earth's atmosphere has risen by about 40% since the start of the industrial era, as a result of fossil fuel burning and land use change, and nearly a third of all the CO_2 emitted through human activities has been absorbed by the ocean, resulting in acidification of surface waters, although much of this carbon is eventually transported to the isolated deep sea as plankton and nekton die and sink. In fact, the oceans overall are now about 30% more acidic than they were 100 years ago. This drastic drop in ocean pH is creating hardships on animals with calcium carbonate skeletons, and damage has been documented in everything from corals to sea butterflies (pteropod molluscs). In May 2019, the concentration of CO_2 in the atmosphere reached 415 ppm, the highest it has been over the past 2 million years (since well before our species evolved). One recent study suggests that the same amount of CO_2 may be emitted over the twenty-first century as was released in pulses of volcanic eruptions during the end-Triassic mass extinction event 200 million years ago, which is enough to warm the planet by around 2°C. Rising concentrations of greenhouse gases in the atmosphere are leading to increasing global temperatures and changes in precipitation regimes, and these changes are impacting the distribution of biota across the planet. Globally, average air temperatures have risen about 0.8°C since 1880, mean land surface temperature has warmed 0.27°C per decade since 1979, and projections from global climate models predict global atmospheric temperatures to increase by about 4°C by the end of this century.

The global human population is 7.6 billion and expected to rise to 10 billion by the middle of this century. Humans now constitute 36% of the mammalian biomass, and livestock another 60%, leaving just 4% for the more than 5,000 species of wild mammals. Climate warming is leading to marine "heat waves" that result in mass killings of shallow-water animals and not-too-gradual shifts in species ranges. These are also compromising the health of or even outright destroying the world's kelp forests, the most productive ecosystems on the planet, rich in invertebrate diversity. Melting polar ice and glaciers, combined with expansion of warming ocean waters, are driving up sea level, which is expected to be as much as 2 m higher by the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

end of this century. Even the accumulation of plastics has become a major threat to animals in the sea, where massive concentrations of large plastics occur on the surface and microplastics are entering marine food webs and even accumulating on the seafloor of the deep ocean. An estimated 311 million tons of plastic are produced annually worldwide, 90% of these being derived from petrol (and less than 15% being recycled). And growth of coastal cities, sewage discharge, and agriculture are leading to massive increases in nitrogen and phosphorus being delivered to coastal waters. These are stimulating rapid increases in primary production and, in warm, stratified, and/or poorly mixed waters, resulting in hypoxia—depletion of dissolved oxygen—and acidification, both of which individually can have adverse effects on sea life. Industrial fishing occurs in over 55% of the ocean's area and has a spatial extent more than four times that of agriculture. On land, increasing frequency of unusually hot days is creating stress on many insects, as is decreasing precipitation and the use of pesticides. Reports of insect declines, best documented in Europe and North America, suggest that as much as 40% of insect species in temperate countries may face extinction over the next few decades. Recent studies suggest a 30% drop in the number of North American birds since 1970.

Prokaryotes and Eukaryotes

The discovery that organisms with a cell nucleus constitute a natural (monophyletic) group divided the living world neatly into two categories, the **prokaryotes** (Archaea and Bacteria: those organisms lacking membrane-enclosed organelles and a nucleus, and without linear chromosomes) and the **eukaryotes** (those organisms that do possess membrane-bound organelles, a nucleus, and linear chromosomes). Investigations by Carl Woese and others, beginning in the 1970s, led to the discovery that the prokaryotes themselves comprise two distinct groups, called **Bacteria** (= Eubacteria) and **Archaea** (= Archaebacteria), both quite distinct from eukaryotes (Box 1A). Bacteria correspond more or less to our traditional understanding of bacteria. Archaea strongly resemble Bacteria, but they have genetic and metabolic characteristics that make them quite unique. For example, Archaea differ from both Bacteria and Eukaryota in the composition of their ribosomes, in the construction of their cell walls, and in the kinds of lipids in their cell membranes. Some Bacteria conduct chlorophyll-based photosynthesis, a trait that is never present in Archaea (photosynthesis is the harvesting of light to produce energy/sugars and oxygen). Current thinking favors the view that prokaryotes ruled Earth for about a billion years before the eukaryotic cell appeared.

As the prokaryotes evolved, they adapted to colonize every conceivable environment on Earth. During their early evolution, Earth's air had almost no oxygen, consisting primarily of CO_2, methane, and nitrogen. The metabolism of the earliest prokaryotes relied on hydrogen, methane, and sulfur and did not produce oxygen as a by-product. It was the appearance of the first oceanic photosynthesizing prokaryotes that led to increased atmospheric oxygen concentrations, setting the stage for the evolution of complex multicellular life. And aquatic species were probably able to colonize land only because the oxygen helped create the ozone layer that shields against the sun's ultraviolet radiation. Just *when* oxygen-producing photosynthesis began is still being debated, but when it happened, most of the early chemoautotrophic prokaryotes were likely poisoned by the "new gas" in the environment. A large body of evidence points to a sharp rise in the concentration of atmospheric oxygen between 2.45 and 2.32 billion years ago (this is sometimes called the "great oxidation event"), around the same time the eukaryotic cell first appeared. This evidence includes red beds or layers tinged by oxidized iron (i.e., rust) and oil biomarkers that may be the remains of Cyanobacteria (photosynthetic true Bacteria). However, in western Australia, thick shale deposits that are 3.2 billion years old have bacterial remains that hint at oxygen-producing photosynthesis. These ancient oxygen levels might have reached around 40% of present atmospheric levels. There is also evidence in the geological record that atmospheric oxygen did not steadily increase, but fluctuated wildly, dropping at times to a mere 0.1% of current levels. It may not have been until around 800 million years ago that high oxygen levels stabilized, and it might have been around then, in the Neoproterozoic, that multicelled animals made their first appearance.

Terrestrial photosynthesis has little effect on atmospheric O_2 because it is nearly balanced by the reverse processes of respiration and decay. By contrast, marine photosynthesis is a net source of O_2 because a small fraction (~0.1%) of the organic matter synthesized in the oceans is buried in sediments. It is this small "leak" in the marine organic carbon cycle that is responsible for most of our accumulated atmospheric O_2. Cyanobacteria are thought to have been largely responsible for the initial rise of atmospheric O_2 on Earth, and even today *Prochlorococcus* can be the numerically dominant phytoplankton in tropical and subtropical oceans, accounting for 20% to 48% of the photosynthetic biomass and production in some regions. Overall, this cyanobacterium may be responsible for about 5% of global photosynthesis, and it thrives from the sunlit sea surface to a depth of 200 m, where light is minimal. Today most marine photosynthesis is performed by Cyanobacteria and single-celled protists, such as diatoms and coccolithophores. Cyanobacteria are nearly unique among the prokaryotes in performing oxygenic photosynthesis, often together with nitrogen fixation, and thus they are major primary producers in both marine and terrestrial ecosystems.

BOX 1A The Six Kingdoms of Life*

PROKARYOTES (Superkingdom Prokaryota)*

Kingdom Bacteria (= Eubacteria)
The "true" bacteria, including Cyanobacteria (blue-green algae), Proteobacteria, Spirochaetae, and numerous other phyla; never with membrane-enclosed organelles or nuclei, or a cytoskeleton; none are methanogens; some use chlorophyll-based photosynthesis; with peptidoglycan in cell wall; with a single known RNA polymerase.

Kingdom Archaea (= Archaebacteria)
Anaerobic or aerobic, largely methane-producing microorganisms; never with membrane-enclosed organelles or nuclei, or a cytoskeleton; none use chlorophyll-based photosynthesis; without peptidoglycan in cell wall; with several RNA polymerases.

EUKARYOTES (Superkingdom Eukaryota)

Cells with a variety of membrane-enclosed organelles (e.g., mitochondria, lysosomes, peroxisomes) and with a membrane-enclosed nucleus. Cells gain structural support from an internal network of fibrous proteins called a cytoskeleton.

Kingdom Protista
Largely unicellular eukaryotes that do not undergo tissue formation through the process of embryological layering. A paraphyletic grouping of many phyla, including euglenids, diatoms and some other brown algae, ciliates, dinoflagellates, foraminiferans, amebas, and others (Chapter 3). Protists descended from bacteria by the acquisition of a nucleus, endomembrane, cytoskeleton, and mitochondria. The 200,000 or so described living species probably represent about 10% of the actual protist diversity on Earth today.

Kingdom Fungi
The fungi. Probably a monophyletic group that includes molds, mushrooms, yeasts, and others. Saprobic, heterotrophic, multicellular organisms. We view the demarcation between Protista and Fungi as lying immediately before the origin of the chitinous wall around vegetative fungal cells and the associated loss of phagotrophy. The earliest fossil records of fungi are from the Middle Ordovician, about 460 million years ago. The 100,000 described species are thought to represent only a small percentage of the actual diversity, and estimates of total fungal biodiversity range from 3 to 10 million. The detection of fungal species by molecular soil surveys has suggested that only 1% to 17% of soil fungi have so far been described and named.

Kingdom Plantae (= Archaeplastida)
Unicellular and multicellular, photosynthetic, chlorophyll-bearing eukaryotes with plastids directly descended from an initially enslaved cyanobacterium. About 400,000 named living species. Includes Glaucophyta (glaucophyte algae), Rhodophyta (red algae), and Viridiplantae (green plants). Viridiplantae includes the phyla Chlorophyta (green algae), Charophyta (freshwater green algae), Anthocerotophyta (hornworts and their kin), Marchantiophyta (liverworts), Bryophyta (other nonvascular plants), and Tracheophyta (the vascular plants, about 260,000 of which are flowering plants). Tracheophytes develop through embryonic tissue layering, in a manner analogous to animal embryogeny. The described species of Plantae are thought to represent about half of Earth's actual plant diversity.

Kingdom Animalia (= Metazoa)
The multicellular animals. A monophyletic taxon, containing 31 phyla of ingestive, heterotrophic, multicellular organisms that develop by tissue layering during embryogenesis. About 1,398,696 species of living metazoans have been described; estimates of the number of undescribed animal species range from lows of 3–8 million to highs of over 100 million.

*Portions of the old "kingdom Monera" are now included in the Bacteria (Eubacteria) and the Archaea. Viruses (about 5,000 described "species") and subviral parasites such as viroids and prions, which are all regarded as laterally transmissible parasitic genetic elements, are not included in this classification. Prions are infectious proteins, devoid of a nucleic acid genome but subject to mutation and thus evolution. Viruses comprise an ancient, polyphyletic group of stripped-down parasitic genetic fragments. Recent work suggests that they might have played important roles in major evolutionary transitions, such as the emergence of DNA and DNA replication mechanisms, the formation of the major "superkingdoms" of life, and perhaps even the origin of the eukaryotic nucleus. Viral classification is standardized by the ICTV (International Committee on Taxonomy of Viruses).

Many Archaea live in extreme environments, and this pattern is often interpreted as a refugial lifestyle—in other words, such creatures tend to live in places where they have been able to survive without confronting dangerous environments or competition from more highly derived life forms. Many of these "extremophiles" are anaerobic chemoautotrophs, and they have been found in a variety of habitats, such as deep-sea hydrothermal vents, benthic marine cold seeps, hot springs, saline lakes, sewage treatment ponds, subglacial lakes beneath the ice of Antarctica (where the water is liquid due to a combination of geothermal heating and pressure), and the guts of humans and other animals. Hydrothermal vents on the seafloor and hydrothermal pools (geothermal hot springs on land) have both been implicated in the origin of life on the planet, and today both harbor extensive mats of microbial life. But one of the most astonishing discoveries of the 1980s was that extremophile Archaea (and some fungi) are widespread in the deep rocks of Earth's crust. Since then, a community

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

of hydrogen-eating Archaea has been found living in a geothermal hot spring in Idaho, 600 feet beneath Earth's surface, relying on neither sunshine nor organic carbon. Archaea are known to grow at temperatures up to 121°C in deep-sea hydrothermal vents. Archaea have been found at depths as great as 2.8 km, living in igneous rocks with temperatures as high as 75°C. Recently, a diverse microbial biota (Bacteria, Archaea, and even eukaryotes) has been found to live as deep as 2.5 km beneath the seafloor, in ancient buried sediments, and is remarkably abundant in coal bed layers. And in the early part of this century, thanks to new high-throughput sequencing technologies, it was discovered that there are massively more species of prokaryotes in the environment than had been thought. Even deep within sediments, at least 800 m below the seafloor, huge populations of prokaryotes have been discovered.

We are now realizing that the 10,000 or so described species of Bacteria and Archaea are barely the tip of the iceberg. Extremophiles include **halophiles** (which grow in the presence of high salt concentrations, in some cases as high as 35% salt); **thermophiles** and **psychrophiles** (which live at very high or very low temperatures); **acidophiles** and **alkaliphiles** (which are optimally adapted to acidic or alkaline pH environments); and **barophiles** (which grow best under pressure). Molecular phylogenetic studies now suggest that some of these extremophiles, particularly the thermophiles, might be very similar to the "universal ancestor" of all life on Earth.[3]

The vast majority of species that have been described are animals. The kingdom Animalia, or **Metazoa**, is usually defined as the ingestive, heterotrophic, sexual, multicellular eukaryotes that undergo embryonic tissue formation.[4] The process of embryonic tissue formation takes place through a major reorganization and differentiation process called **gastrulation**. However, metazoans possess other unique attributes as well, such as an acetylcholine/cholinesterase-based nervous system, special types of cell–cell junctions, and a unique family of connective tissue proteins called collagens. Metazoans have also been shown to possess a distinctive set of insertions and deletions in genes coding for proteins in the mitochondrial genome. Among the Metazoa are some species that possess a backbone (or vertebral column), but most do not. Those that possess a backbone constitute the subphylum Vertebrata of the phylum Chordata, and they account for only about 4% (about 58,000 species) of all described animals. Those that do not possess a backbone (the remainder of the phylum Chordata, plus 30 additional animal phyla) constitute the invertebrates. Thus, we see that the division of animals into invertebrates and vertebrates is based more on tradition and convenience, reflecting a dichotomy of interests among zoologists, than it is on the recognition of natural biological groupings. About 15,000 to 20,000 new species are named and described by biologists each year, most of them invertebrates (especially insects).

Not only are invertebrates diverse and numerous, they span over six orders of magnitude in size. Many species are microscopic (even though they may have thousands of cells in their bodies). Some of the smallest are cycliophorans (350 μm, or 0.35 mm), loriciferans (as small as 85 μm, or 0.085 mm), and the coral reef nematode *Greeffiella minutum*, which is only 80 μm (0.08 mm) long. However, species with bodies smaller than 1 mm occur in many other phyla. Invertebrates can also be quite large. Some jellyfish reach 25 m including the tentacles, the giant squid (*Architeuthis dux*) reaches 13 m including the tentacles, a sperm whale nematode parasite (*Placentonema gigantisima*) can exceed 8 m, and some earthworms can reach 3 m in length. There is a record of a nemertean reaching 60 m, but this lacks reliable verification. Giant clams (*Tridacna*) can exceed 400 kg in weight, and the terrestrial coconut crab (*Birgus latro*) can exceed 4 kg—perhaps the heaviest land invertebrate.

Where Did Invertebrates Come From?

Evolutionary analyses confirm that the ancestors of plants and animals (and fungi) were protists, and the phenomenon of multicellularity arose independently in these three groups, although in different ways. Genetic and developmental data confirm that the basic mechanisms of pattern formation and cell–cell communication during development were independently derived in animals and in plants. In animals, segmental identity is established by the spatially specific transcriptional activation of an overlapping series of master regulatory genes, the homeobox (Hox) genes. The master regulatory genes of plants are not members of the homeobox gene family, but members

[3]One of the most striking examples of a thermophile is *Pyrolobus fumarii*, a chemolithotrophic archaean that lives in oceanic hydrothermal vents at temperatures of 90°C–113°C. (Chemolithotrophs are organisms that use inorganic compounds as energy sources.) On the other hand, *Polaromonas vacuolata* grows optimally at 4°C. *Picrophilus oshimae* is an acidophile whose growth optimum is pH 0.7. (*P. oshimae* is also a thermophile, preferring temperatures of 60°C.) The alkaliphile *Natronobacterium gregoryi* lives in soda lakes where the pH can rise as high as 12. Halophilic microorganisms abound in hypersaline lakes such as the Dead Sea and Great Salt Lake and in solar salt evaporation ponds, and the green alga *Dunaliella salina* lives in the Dead Sea at salinities of 23% salt. Hypersaline lakes are often colored red by dense microbial communities (e.g., *Halobacterium*). *Halobacterium salinarum* lives in the salt pans of San Francisco Bay and colors them red. Barophiles have been found living at all depths in the sea, and one unnamed species from the Mariana Trench (the deepest part of the ocean) has been shown to require at least 500 atmospheres of pressure in order to grow.

[4]Heterotrophic organisms are those that derive their nutritional requirements from complex organic substances (i.e., by consuming other organisms or organic materials as food). In contrast, autotrophs are able to form nutritional organic substances from simple inorganic matter such as carbon dioxide (e.g., plants).

of the MADS-box family of transcription factor genes. There is no evidence that the animal homeobox and MADS-box transcription factor genes are homologous.

Although the fossil record is rich with the history of many early animal lineages, many others have left few or no fossils. Many ancient animals were very small, many were soft-bodied and did not fossilize well, and others lived where conditions were not suitable for the formation of fossils. However, highly fossilizable groups such as the echinoderms (starfish, urchins), molluscs (clams, snails), arthropods (crustaceans, insects), corals, bryozoans, brachiopods, and vertebrates have left a rich fossil record. In fact, for some groups (e.g., echinoderms, brachiopods, bryozoans, molluscs), the number of extinct species known from fossils exceeds the number of known living forms. Of course, this makes sense given the long history of animal life on Earth and that representatives of about 60% the extant animal phyla were present in the Cambrian Period. Life on land, however, did not appear until later, and terrestrial radiations probably began only about 470 million years ago. The following account briefly summarizes the early history of life and the rise of the invertebrates.

The Dawn of Life

It used to be thought that the Proterozoic Eon, 2.5 billion to 541 million years ago, was a time of only a few simple kinds of life; hence the name. However, recent discoveries have shown that life on Earth began early and had a very long history throughout the Proterozoic. As noted above, some of the oldest rocks known on Earth have markings suspected to represent anaerobic sulfur-reducing prokaryotes and perhaps even cyanobacterial stromatolites, which may be Earth's first photosynthetic organisms. Undisputed cyanobacterial fossils 3.5 billion years of age are known, and older ones have been suggested. The first actual traces of eukaryotic life (benthic algae) are 1.6 to 1.8 billion years old, whereas the first certain eukaryotic fossils (phytoplankton) are 1.2 billion years old. Together, these prokaryotes and protists appear to have formed diverse communities in shallow marine habitats throughout the Proterozoic. Living stromatolites (compact layered colonies of Cyanobacteria and mud) are still with us and can be found in certain high-evaporation/high-salinity coastal environments in places such as Shark Bay (Western Australia), Scammon's Lagoon (Baja California), salt ponds on islands in the Sea of Cortez, the Persian Gulf, the Paracas coast of Peru, the Bahamas, and Antarctica. Living stromatolites also occur in some isolated inland waters, such as the famous Cuatro Ciénegas Oasis, Coahuila, Mexico.

In the end era of the Proterozoic (the Neoproterozoic Era, 1 billion years ago to 541 Ma) the world was different from what it is today. Atmospheric oxygen levels were much lower. The deep ocean was especially oxygen poor. Three ice-covered Earth events are hypothesized to have occurred during the Neoproterozoic Era, based on the occurrence of multiple glaciations at sea level in low latitudes in the geological record. These "Snowball Earth" events, which might have lasted up to 10 million years each, are thought to have been interrupted by periods of rapid warming and global greenhouse conditions. The causes of these wide climatic swings during the Neoproterozoic are still unclear, although there is evidence that the world oceans lacked the $CaCO_3$-based carbon stabilization chemistry we have today. Indeed, major carbon precipitators such as foraminiferans and coccolithophores had probably not yet evolved in the world's oceans. It seems likely that buildup of atmospheric CO_2 generated by massive volcanic eruption periods drove the warming events. All these changes were taking place during the breakup of a supercontinent known as Rodinia (about 750 Ma)—the supercontinent that preceded Pangaea. It was against this backdrop that the Metazoa first arose, perhaps 875 to 650 million years ago. Around 800 million years ago, atmospheric oxygen seems to have stabilized at a relatively high level, setting the stage for the rapid evolution of eukaryotes. Oxygen, of course, was critical to the diversification of large and metabolically active, complex life.

The prevailing view is that Metazoa arose in the Neoproterozoic (latest Precambrian), began to diversify, and then radiated rapidly in the Cambrian—the "Cambrian Explosion"—when there was a rapid increase in animal diversity and abundance, as manifest in the fossil record, between around 541 and 520 million years ago. However, during the Neoproterozoic these early animal lineages must have survived some extreme climate swings on Earth, including profound changes in ocean and atmospheric chemistry and widespread global glacial events.

The Ediacaran Period and the Origin of Animals

One of the most perplexing unsolved mysteries in biology is the origin and early radiation of Metazoa (the animal kingdom). Fossil evidence suggests that by the end-Proterozoic Ediacaran Period a worldwide marine invertebrate fauna was already well established, and this coincides roughly with molecular estimates for the origin of animals. Although the animals that existed during this time left few records, the fauna of the Ediacaran (635–541 Ma) contains the first evidence of many, possibly modern phyla. Living phyla thought to be represented among the Ediacaran fauna include Porifera, Cnidaria, Mollusca, possibly Annelida, and others. Some authors have even suggested the presence of Onychophora, Arthropoda, and Echinodermata, although these are more controversial. The Ediacaran *Dickinsonia* has been said to represent a "placozoan-grade" or "Cnidarian-grade animal," *Kimberella* may be a mollusc, *Eoandromeda* a ctenophore, and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Thectardis a sponge (although all of these classifications are debatable). Over 100 Ediacaran animal genera have been described from around the world. However, most Ediacaran animals cannot be unambiguously assigned to any living phylum, and these animals may represent phyla or other high-level taxa that went extinct at the Proterozoic–Cambrian transition.

Early reports of Ediacaran fossils are from sites in Newfoundland and Namibia, but the name is derived from the superb assemblages of these fossils discovered at Ediacara in the Flinders Ranges of South Australia. Most of the Ediacaran organisms were preserved as shallow-water impressions on sandstone beds, but some of the 25 or so worldwide sites probably represent deep-water and continental slope communities. The Ediacaran fauna was mostly soft bodied, and there have been no heavily shelled creatures reported from these deposits. Even the alleged molluscs and arthropod-like creatures from this fauna are thought to have had soft (unmineralized or lightly mineralized) skeletons. A few chitinous structures probably developed during this time, such as the sabellid-like tubes of worms and the radulae of early molluscs.[5] Siliceous spicules of hexactinellid sponges have been reported from Australian and Chinese Ediacaran deposits. In 2014, Ediacaran-age metazoan reefs were discovered in Namibia that were built by skeletonized creatures named *Cloudina*. Resembling cnidarians, these are the oldest known structural reef-building animals although their phylogenetic affinities are uncertain.

Many of these Ediacaran animals appear to have lacked complex internal organ structures, and none have yet shown clear evidence of having a mouth or anus. Many were small and possessed radial symmetry. However, at least by late in the Ediacaran Period, large animals with bilateral symmetry seem to have appeared, such as the segmented, sheetlike *Dickinsonia* (which reached 1 m in length; Figure 1.2), which led some workers to infer they might have had internal organs. Some workers have questioned whether or not Ediacaran life even included any animals, suggesting that it might be represented only by protists, algae, fungi, lichens, and microbial colonies and mats. However, some Ediacaran fossils seem to be unmistakably Porifera and Cnidaria, and others (e.g., *Kimberella*) show strong similarity to molluscs. *Kimberella* has been associated with scratch marks reminiscent of radula scrapings. Still others are thought to possess bilateral symmetry, an idea once controversial but now gaining traction. Among the bilaterian fossils are *Kimberella*, the "small shelly fossils" (e.g., the enigmatic *Cloudina*), and embryos of probable bilaterian origin from the Doushantuo Formation of south China, although these bilaterian records have their detractors. Other evidence of bilaterians in these deposits includes what appear to be predatory bore holes in the small shelly fossils, and a variety of horizontal and vertical burrows that were perhaps made by motile animals.

The beginning of the Ediacaran Period coincides with the end of the last "Snowball Earth" event of the Precambrian, when most of Earth's land, and perhaps much of its ocean, was frozen over. And at the end of the Ediacaran many living creatures seem to have gone extinct.[6] The Ediacaran Period was followed by the Cambrian Period (541–485 Ma) and the great "explosion" of skeletonized metazoan life associated with that time. Life quickly got very interesting and very complicated in the Cambrian! Why large, skeletonized animals appeared at that particular time, and in such great profusion, remains a mystery, but the fossil record clearly informs us that by the early Cambrian a good number of the major animal phyla we recognize today had come into being. Certainly, great changes were occurring at the end of the Precambrian and the start of the early Cambrian—the breakup of the supercontinents, rising sea levels, fluctuations in atmospheric composition (including oxygen and CO_2 levels), changes in ocean chemistry—and these likely played a role in the demise of the Ediacaran fauna and the rise of Cambrian life.

The Paleozoic Era (541–251.9 Ma)

The Phanerozoic Eon (the time of abundant life on Earth that encompasses the Paleozoic, Mesozoic and Cenozoic Eras) was ushered in with the almost simultaneous appearance in the early Cambrian of well-developed, large, calcareous body skeletons in numerous groups, such as archaeocyathans (coral-like organisms that may have been early sponges), molluscs, bryozoans, brachiopods, crustaceans, chaetognaths (represented by fossils long called protoconodonts), and trilobites. It used to be that the first appearance of these well-mineralized animal skeletons was used to define the beginning of the Cambrian. However, the dating of the Precambrian-Cambrian boundary has changed considerably in the past decades. In the 1970s, with the discovery of small shelly fossils *below* the oldest Cambrian trilobites—a fauna composed of spicules, sclerites,

[5]Chitin is a cellulose-like family of compounds that is widely distributed in nature, especially in invertebrates, fungi, and many protists, but it is apparently uncommon in deuterostome animals and higher plants, perhaps due to the absence of the chitin synthase enzyme.

[6]The largest mass extinctions recorded in the fossil record occurred at the ends of the Precambrian (the Ediacaran–Cambrian transition), Ordovician, Devonian, and Permian and in the Early Triassic, Late Triassic, and end-Cretaceous. Most of these extinction events were experienced by both marine and terrestrial organisms. The Triassic events and the end-Devonian event have recently been shown to be less severe extinction events than once thought. And a relatively little-studied mass extinction event in the Late Permian, about 260 million years ago, has recently begun to emerge as a much larger extinction event than previously thought, with perhaps 56% of plant species and 58% of marine invertebrate genera disappearing. Earth is today entering a sixth great mass extinction, driven entirely by humans.

(B) A bushlike fossil of uncertain affinity (suggestive of a cnidarian). (C) *Ediacara*, a cnidarian medusa. (D) The enigmatic *Dickinsonia*. (E) One of the many soft-bodied trilobite-like creatures known from the Ediacaran Period. (some of which also occurred in the Early Cambrian). (After R. J. F. Jenkins 1992. In J. H. Lipps and P. W. Signor [Eds.], *Origin and Early Evolution of the Metazoa*, pp. 131–178. Plenum, New York. https://link.springer.com/chapter/10.1007/978-1-4899-2427-8_5)

and ossicles of animals plausibly interpreted as sponges, molluscs (including extinct scleritome-bearing groups such as halkieriids), stem-group brachiopods, and so on—the base of the Cambrian was revised. Today, the Precambrian-Cambrian boundary is defined by the first occurrence of the trace fossil *Treptichnus pedum* (Figure 1.3), one of the first putative, penetrative animal burrows, suggesting a metazoan capable of causing a good deal of bioturbation that oxygenated and mixed the sediment at depths not previously attained. This sediment mixing is sometimes called the "agronomic revolution," and it provides one of the possible ecological explanations for the Cambrian "explosion" of animal life. The nature of the animal that left the *T. pedum* trace fossil has been a matter of speculation, but it must have been relatively large, based on the size of the burrows. Comparisons with the feeding traces of extant priapulans are consistent with *T. pedum*. The burrow traces of *T. pedum* have also been associated with the presence of some sort of hydrostatic skeleton, such as a coelomic or a large pseudocoelomic cavity that allowed the animals to burrow. In an event, the newly skeletonized animals of the Paleozoic radiated quickly and filled a multitude of ecological roles in shallow-water marine environments, and by the early Cambrian most living phyla possessing hard parts had appeared. The earliest land plants appeared about 470 million years ago.

Evidence suggests that in the Early Cambrian the world ocean increased its calcium content dramatically, which coincided with the proliferation of skeletonized animals. Climates were warm, and shallow epicontinental seas covered broad regions of Paleozoic continents. The explosion of bilaterally symmetrical animals, the Bilateria, also began around the Proterozoic–Cambrian transition. Seed ferns and other gymnosperms also arose during the Paleozoic, perhaps a bit more than 400 million years ago, whereas angiosperms may have arisen around 200 million years ago, as suggested by molecular data (although the oldest undisputed angiosperm fossils are from about 175 Ma).

Did all the metazoan lineages arise quickly, during the first 10 million years or so of the Cambrian? Or

were many (or most) of them already getting established in the Ediacaran but we have yet to find evidence of this, perhaps because they lacked hard skeletons or were very small? This latter idea, sometimes called the "phylogenetic fuse" hypothesis, is supported by the discovery of undisputed and modern-appearing crustaceans in the earliest Cambrian, as well as many creatures from the Ediacaran that resemble modern phyla (or their embryos). Given that advanced phyla like arthropods were already well established in the earliest Cambrian, it seems likely that earlier-derived phyla of ecdysozoans must have been alive and thriving in the Ediacaran. Indeed, apparent phosphatized bilaterian animal embryos from the Ediacaran provide evidence of the cryptic roots of Metazoa and the likelihood that the evolutionary fuse of modern animal phyla was lit well before the Cambrian began.

Geological evidence tells us that Earth's earliest atmosphere lacked free oxygen, and the radiation of the animal kingdom could not have begun under those conditions. Free oxygen probably accumulated over many millions of years as a by-product of photosynthetic activity in the oceans, particularly by the cyanobacterial stromatolites and planktonic species. A long-standing hypothesis suggests that the beginning of an oxygenated atmosphere was around 2.4 billion years ago, and it was then that "modern life" began to evolve (at the beginning of the Proterozoic). However, evidence for free oxygen levels in the Proterozoic is still unclear, and there are some data that suggest an oxygenated atmosphere might have evolved even earlier than that. Proterozoic seas might have been oxic near the surface, but anoxic in deep waters and on the bottom. Some workers suggest that the absence of metazoan life in the early fossil record is due to the simple fact that the first animals were small, lacked skeletons, and did not fossilize well. The discovery of highly diverse communities of metazoan meiofauna in the Proterozoic strata of south China and in deposits from the middle and upper Cambrian (e.g., the Swedish Orsten fauna) lends support to the idea that many of the first animals were microscopic.[7] However, large animals also are not uncommon among the Ediacaran and early Cambrian faunas.

It has also been proposed that the advent of predatory lifestyles, early in the Cambrian, was the key that favored the first appearance of animal skeletons (as defensive structures), leading to the Cambrian Explosion. The rapid appearance and spread of diverse metazoan skeletons in the early Cambrian certainly heralded the beginning of the Phanerozoic Eon (i.e., all time after the Precambrian). The Ediacaran fauna seems to have included primarily passive suspension and detritus feeders; very few of these animals appear to have been active carnivores or herbivores. Early Cambrian animal communities, on the other hand, included most of the trophic roles found in modern marine communities, including giant predatory arthropods.

Much of what we know about earliest Cambrian life comes from the early Cambrian Chengjiang fossil deposits of the Yunnan Province in southern China and similarly aged (although less well preserved) deposits spread across China and the Siberian Platform. The Chengjiang deposits are the oldest Cambrian occurrences of well-preserved soft-bodied and hard-bodied animals, and although they are dominated

[7] Orsten-type preservation entails the phosphatization of cuticles with almost no deformation. It preserves the finest details of organisms, including setae, and such deposits have yielded three-dimensional fossils at the scale of 0.1–2.0 mm. First discovered in Sweden, Orsten-type deposits are now known from several continents, from the early Cambrian (520 Ma) to the middle Cretaceous (100 Ma). Most of the earliest "Orsten fossils" are undisputed arthropods.

by arthropods, they also include a rich assemblage of exquisitely preserved lobopodians, medusae (Cnidaria), and brachiopods, many of which appear closely related to Ediacaran species.

In the middle Cambrian fossil record (e.g., the 508 Ma Burgess Shale fauna of western Canada, 518 Ma Qingjiang biota of China, and similar deposits elsewhere; Figure 1.4), cnidarians, annelids, and tardigrades make their first positive appearance and the first complete echinoderm skeletons appear. Twelve million years younger than the Chengjiang fauna, the Burgess Shale material is also dominated by arthropods (and their allies), including the infamous *Opabinia* and *Anomalocaris*. Most of the Burgess Shale fauna can also be assigned to living phyla. There are numerous other (less famous) Cambrian fossil sites, such as the Sirius Passet fauna in Greenland, the Emu Bay Shale in Australia, the Sinsk biota in Russia, and the Kaili and Guanshan biotas in China. In the upper Cambrian fossil record (e.g., the Orsten deposits of southern Sweden and similar strata), the first pentastomid Crustacea and the first agnathan fishes make their appearances. By the end of the Cambrian, nearly all of the major, modern animal phyla had appeared. The Burgess Shale–like assemblage in Lower Ordovician rocks of Morocco tells us that many of the Cambrian lineages survived for tens of millions of years (Figure 1.4).

The driving force for this Cambrian explosion has perplexed scientists since Darwin's day. In fact, it has been referred to as "Darwin's dilemma," because he could not reconcile such rapid origination and diversification of major animal groups with his view of gradual evolution driven only by natural selection. Some analyses have suggested that rates of phenotypic and genomic evolution might have been many times faster during the Cambrian than in the rest of the Paleozoic. One popular notion is that atmospheric oxygen reached a critical level around 580 million years ago, in the Ediacaran, and it allowed for larger animals and skeletonized animals to begin to evolve. This might have led to the appearance of large carnivores, which rely on oxygen for high-energy pursuits. Once the carnivores proliferated, a predator-prey arms race ensued,

driving the rapid evolution of never-ending new body forms. However, some other evidence suggests that high oxygen levels existed well before that date.

In addition to the agronomic revolution mentioned previously, another explanation for the explosive radiation of Metazoa in the Cambrian is a rapid increase in nutrient supplies to the world's oceans, especially phosphorus (P) and potassium (K). This is hypothesized to have occurred as the Earth cooled enough for subducting mantle to hydrate with seawater about 600 million years ago, thus moving water from the oceans into the lower mantle and lowering sea level, which in turn exposed great swaths of new landmasses that underwent erosion of P and K, which in turn were transported to the sea as fertilizers. In addition, massive uplift of mountains and plume-driven doming of landmasses also might have added new nutrient-erosion sources around the Precambrian–Cambrian transition.

The early Paleozoic also saw the first xiphosurans, eurypterids, and teleost fishes (in the Ordovician). The first land animals (arachnids, myriapods) appeared in the upper Silurian. By the Devonian Period, life on land had begun to proliferate. Forest ecosystems became established and began reducing atmospheric CO_2 levels (eventually terminating an earlier Paleozoic greenhouse environment). The first insects also appeared in the early Paleozoic (see Chapter 22). Insects probably developed flight in the Lower Devonian (~406 Ma), and they began their long history of coevolution with plants shortly thereafter (at least by the mid-Carboniferous, when tree fern galls first appeared in the fossil record).[8] During the Carboniferous Period, global climates were generally warm and humid, and extensive coal-producing swamps existed.

The late Paleozoic witnessed the formation of Earth's most recent supercontinent Pangaea, in the Permian Period (about 270 Ma). The end of the Paleozoic Era/Permian Period (251.9 Ma) was marked by the largest mass extinction known, in which an estimated 90% of Earth's marine species (and 70% of the terrestrial vertebrate genera) were lost over a brief span of a few million years. The Paleozoic reef corals (Rugosa and Tabulata) went extinct, as did the once-dominant trilobites, never to be seen again. The driving force of the massive Permian extinction is a hotly debated subject, and hypotheses range from rapid global warming to rapid global cooling! Either might have been driven by a huge asteroid impact, perhaps coupled with massive Earth volcanism, and perhaps also degassing of methane from stagnant ocean basins. Some evidence suggests that toxic waters decimated shallow bottom marine communities at that time. All of these might have created a large and rapid global warming (or cooling) event, depending on how things played out. The trillions of tons of carbon released into the atmosphere and oceans from enormous volcanism events likely also led to ocean acidification and a drop in dissolved oxygen in the oceans, further possible causes of oceanic extinction events. A volcanism event at this time was likely the one that created the massive flood basalts known as the Siberian Traps in Asia. Volcanism at this time could have led to atmospheric "pollution" in the form of dust and sulfur particles that cooled Earth's surface and/or massive gas emissions that led to a prolonged greenhouse warming and ocean acidification.

[8]Coevolution is the reciprocal adaptation that occurs over time between closely interacting species. One classic example is plants and their pollinators, which have evolved in lockstep since the late Paleozoic to form remarkably finely tuned anatomies, physiologies, and behaviors, among willing (or unwilling) partners.

The Mesozoic Era (251.9–66 Ma)

The Mesozoic Era is divided into three broad periods: Triassic, Jurassic, and Cretaceous. The Triassic began with the continents joined together as Pangaea. The land was high, and few shallow seas existed. Global climates were warm, and deserts were extensive. Although the Triassic is perhaps best known for the emergence of the dinosaurs, vertebrate diversity in general exploded during this period, as the first land mammals made their appearance. In Triassic seas, modern-looking scleractinian corals appeared, and the diversity of predatory invertebrates and fishes increased dramatically, although the paleogeological data suggest that deeper marine waters might have been too low in oxygen to harbor much multicellular life. The end of the Triassic witnessed a global extinction event that resulted in the disappearance of around half of all the living species. This was perhaps driven by the combination of asteroid impact and widespread volcanism that created the Central Atlantic Magmatic Province of northeastern South America 200 million years ago, although there is considerable disagreement about the extent and cause of this extinction event. Recent studies suggest elevated atmospheric CO_2 was the culprit behind the end-Triassic extinction event, possibly caused by high rates of magmatic CO_2 degassing. Certainly, it's possible that all these events took place.

The Jurassic saw a continuation of warm, stable climates, perhaps with little latitudinal or seasonal variation and probably little mixing between shallow and deep oceanic waters. Pangaea split into two large landmasses, a northern Laurasia and southern Gondwana, separated by a circumglobal tropical seaway known as the **Tethys Sea**. Many tropical marine families and genera today are thought to be direct descendants of lineages inhabiting that pantropical Tethys Sea. On land, modern genera of many gymnosperms and advanced angiosperms appeared, and the first birds begin to evolve (e.g., *Archaeopteryx*, ~150 Ma). Leaf-mining insects (lepidopterans) appeared by the Upper Jurassic (150 Ma), and other leaf-mining orders appeared through the Cretaceous, coincident with the radiation of the vascular plants.

In the Cretaceous, large-scale fragmentation of Gondwana and Laurasia took place, resulting in the formation of the Atlantic and Southern Oceans. During this period, landmasses subsided and sea levels were high; the oceans sent their waters far inland, and great epicontinental seas and coastal swamps developed. As land masses fragmented and new oceans formed, global climates began to cool and oceanic mixing began to move oxygenated waters to greater depths in the sea.

The end of the Cretaceous, 66 million years ago, was marked by the Cretaceous-Paleocene mass extinction, in which an estimated 75% of Earth's species were lost, including the (nonavian) dinosaurs and all of the sea's rich Mesozoic ammonite diversity. There is strong evidence that this extinction event was driven by a combination of two factors: massive Earth volcanism associated with the great flood basalts of western India known as the Deccan Traps, combined with a major meteor impact (documented by the Chicxulub Crater in the Yucatán region of modern Mexico). The Deccan Traps flood basalts, a result of two different deep mantle hotspots joining forces, comprise an almost unimaginable 1.3 million cubic kilometers of erupted lava, 3,000 m thick in some places. The main eruptions were initiated about 250,000 years before the Cretaceous-Paleocene boundary, and overall the lava might have flowed for over 750,000 years. However, an estimated 90% of the eruptive flow took place rapidly, coincident with the Cretaceous-Paleocene boundary. The sulfur dioxide gas injected into the atmosphere from this massive volcanic event would have converted to sulfate aerosols that caused climate cooling, and when these aerosols washed out (as acid rain), they would have acidified the oceans. The scale of biological turnover between the Cretaceous and Paleocene is nearly unprecedented in Earth history. All the nonavian dinosaurs, marine reptiles, ammonites, and reef-forming rudistid clams went extinct. Planktonic foraminiferans and land plants were devastated. There is recent evidence suggesting that the full strength of the end-Cretaceous mass extinctions might not have kicked in until about 300,000 years after the Chicxulub impact. If comet impacts are beginning to sound like a recurring theme in the history of life on Earth, it's because so many large impact craters have been found (at least 70 that are larger than 6 km in diameter), and many of these coincide with major transitions in the fossil record.

The Cenozoic Era (66 Ma–present)

The Cenozoic Era dawned with a continuing worldwide cooling trend. As South America decoupled from Antarctica, the Drake Passage opened to initiate the circum-Antarctic current, which eventually drove the formation of the Antarctic ice cap, which in turn led to our modern cold ocean bottom conditions (in the Miocene). India moved north from Antarctica and collided with southern Asia (in the early Oligocene). Africa collided with western Asia (late Oligocene/early Miocene), separating the Mediterranean Sea from the Indian Ocean and breaking up the circumtropical Tethys Sea. Around 56 million years ago, the Earth warmed rapidly as greenhouse gasses spiked in the atmosphere and global oceans warmed all the way down to the deep sea. The cause of this Paleocene–Eocene Thermal Maximum is uncertain, but massive volcanic eruptions that could have cooked CO_2 out of organic seafloor sediments have been suggested, as have wildfires burning through Paleocene peat deposits, and another meteor impact (that could have released large deposits of methane hydrate from the seafloor). Relatively recently (in the Pliocene), the Arctic ice cap formed, and the Isthmus of Panama rose, separating the Caribbean Sea from the Pacific and breaking up the last remnant of the ancient Tethys Seaway, probably about 3 million years ago. Modern coral reefs (scleractinian-based reefs) appeared early in the Cenozoic, reestablishing the niche once held by the rugose and tabulate corals of the Paleozoic.

This textbook focuses primarily on invertebrate life at the very end of the Cenozoic, in the Quaternary Period (Pleistocene + Holocene). However, evaluation of the present-day success of animal groups also involves consideration of the deeper history of modern lineages, the diversity of life over time (numbers of species and higher taxa), and the abundance of life in various environments. The predominance of certain kinds of invertebrates today is unquestionable. For example, of the estimated 1,398,696 named and described species of living animals (1,340,696 of which are invertebrates), 82% are arthropods (and 82% of arthropods are insects). It would be hard to argue that insects are not the most successful group of animals on Earth today. And the fossil record tells us that arthropods have always been key players in the biosphere, even before the appearance of the insects. Table 1.1 conveys a general idea of the levels of diversity among the animal phyla today. Note that 82% of all known animals belong to just one phylum, Arthropoda; 87% belong to two phyla (Arthropoda + Mollusca); 91% belong to three phyla (Arthropoda + Mollusca + Chordata). Also, 25 phyla each contain fewer than 1% of the known animal species, including some that may seem quite diverse to the casual seashore visitor, such as sponges, cnidarians, bryozoans, and echinoderms.

Where Do Invertebrates Live?

Marine Habitats

The global ocean is Earth's largest biome. In fact, it is fair to say Earth is a marine planet—salt water covers 71% of its surface. And the vast three-dimensional

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

world of the seas contains 99% of Earth's inhabited space. Life almost certainly evolved in the sea. The major events, described in the "Where Did Invertebrates Come From?" section, that led to the diversification of invertebrates occurred in late Proterozoic and early Cambrian shallow seas. Many aspects of the marine world minimize physical and chemical stresses on organisms. The challenge of evolving gas exchange and osmotic regulatory structures that can function in freshwater and terrestrial environments are formidable, and relatively few lineages were able to do so and fully escape their marine origin. Thus, it is not surprising to find that the marine environment continues to harbor the greatest diversity of higher taxa and major body plans—13 of the 31 living animal phyla are strictly marine (e.g., Placozoa, Ctenophora, Chaetognatha, Dicyemida, Cycliophora, Gnathostomulida, Phoronida, Brachiopoda, Kinorhyncha, Priapula, Loricifera, Echinodermata, Hemichordata), and many others have barely penetrated the terrestrial or freshwater realm. Productivity in the world's oceans is very high (representing about half of global primary production), and this also contributes to the high diversity of animal life in the sea. The total primary productivity of the seas is about 48.7×10^9 metric tons of carbon per year. Perhaps the most significant factor, however, is the special nature of seawater itself.

Water is a very efficient thermal buffer. Because of its high heat capacity, it is slow to heat up or cool down. Large bodies of water, such as oceans, absorb and lose great amounts of heat with little change in actual water temperature. In fact, the oceans store over 90% of the excess heat accumulating in the world's atmospheric climate system today. Thus, oceanic temperatures are very stable in comparison with those of freshwater and terrestrial environments. Short-term temperature extremes occur only in intertidal and estuarine habitats, and invertebrates living in such areas must possess behavioral and physiological adaptations that allow them to survive these temperature changes, which are often combined with aerial exposure during low tide periods.

The saltiness, or salinity, of seawater averages about 3.5% (often expressed as parts per thousand, 35‰). This property, too, is quite stable, especially in areas away from shore and the influence of rivers. The salinity of seawater gives it a high density, which enhances buoyancy, thereby minimizing energy expenditures for flotation. Furthermore, the various ions that contribute to the total salinity occur in fairly constant proportions. These qualities result in a total ionic concentration in seawater that is similar to that in the body fluids of most animals, minimizing the problems of osmotic and ionic regulation (see Chapter 3). The pH of seawater is also quite stable throughout most of the ocean. Naturally occurring carbonate compounds participate in a series of chemical reactions that buffer seawater at about pH 7.5–8.5. However, today's anthropogenic-driven increase in atmospheric CO_2 threatens to alter the carbonate buffering capacity of the world's seas. A large fraction (over 25%) of the CO_2 added to the atmosphere by burning of fossil fuels enters the ocean. Seawater reacts with CO_2 to form carbonic acid, decreasing the pH of ocean surface waters. The lowering of sea surface pH disrupts formation of calcium carbonate skeletons in both animals and protists.

In shallow and nearshore waters CO_2, various nutrients, and sunlight are generally available in quantities sufficient to allow high levels of photosynthesis, either seasonally or continuously (depending on latitude and other factors). Dissolved oxygen levels rarely drop below those required for normal respiration, except in stagnant waters, such as might occur in certain estuarine or ocean basin habitats, or where anthropogenic activities have created eutrophic conditions that can result in oxygen minimum zones (OMZs), hypoxic regions, or even anoxic seafloor conditions. Hypoxia occurs when dissolved oxygen falls below 2 ml of O_2/liter. The size and number of OMZs, defined by O_2 concentrations below 20 μM and sometimes called "dead zones," in the world oceans have been growing rapidly in recent decades as a result of humans releasing huge quantities of organic waste and fertilizers into the sea. Deep-sea ecosystems contain the largest hypoxic and anoxic regions of the biosphere. Permanently anoxic conditions in the oceans are present in certain seafloor locations and, among other areas, in the interior of the Black Sea[9] and in the deep (>3,000 m) hypersaline anoxic basins of the Mediterranean Sea, where it has long been thought that no metazoans could live. However, recently several species of Loricifera were discovered living in the anoxic Mediterranean basins (perhaps the only animals able to live permanently in anoxic conditions).

Because the marine realm is home to most of the animals discussed in this book, some terms that describe the subdivisions of that environment and the categories of animals that inhabit them will be useful. Figure 1.5 illustrates a generalized cross section through an ocean. The shoreline marks the littoral region, where sea, air, and land meet and interact (Figure 1.6A). Obviously, this region is affected by the rise and fall of the tides, and we can subdivide it into zones or shore elevations relative to the tides. The **supralittoral zone**, or splash zone, is rarely covered by water, even at high tide, but it is subjected to storm surges and spray from waves. The **eulittoral zone**, or true intertidal zone, lies between the levels of the highest and lowest tides. It can be subdivided by its flora and fauna, and by mean monthly hours of aerial exposure, into high, mid, and low intertidal zones. The **sublittoral zone**, or subtidal

[9]Despite its large surface area (423,500 km2), the Black Sea has only a thin surface layer that supports eukaryotic life. The water mass below about 175 m is devoid of dissolved oxygen, making this the largest anoxic body of water in the world.

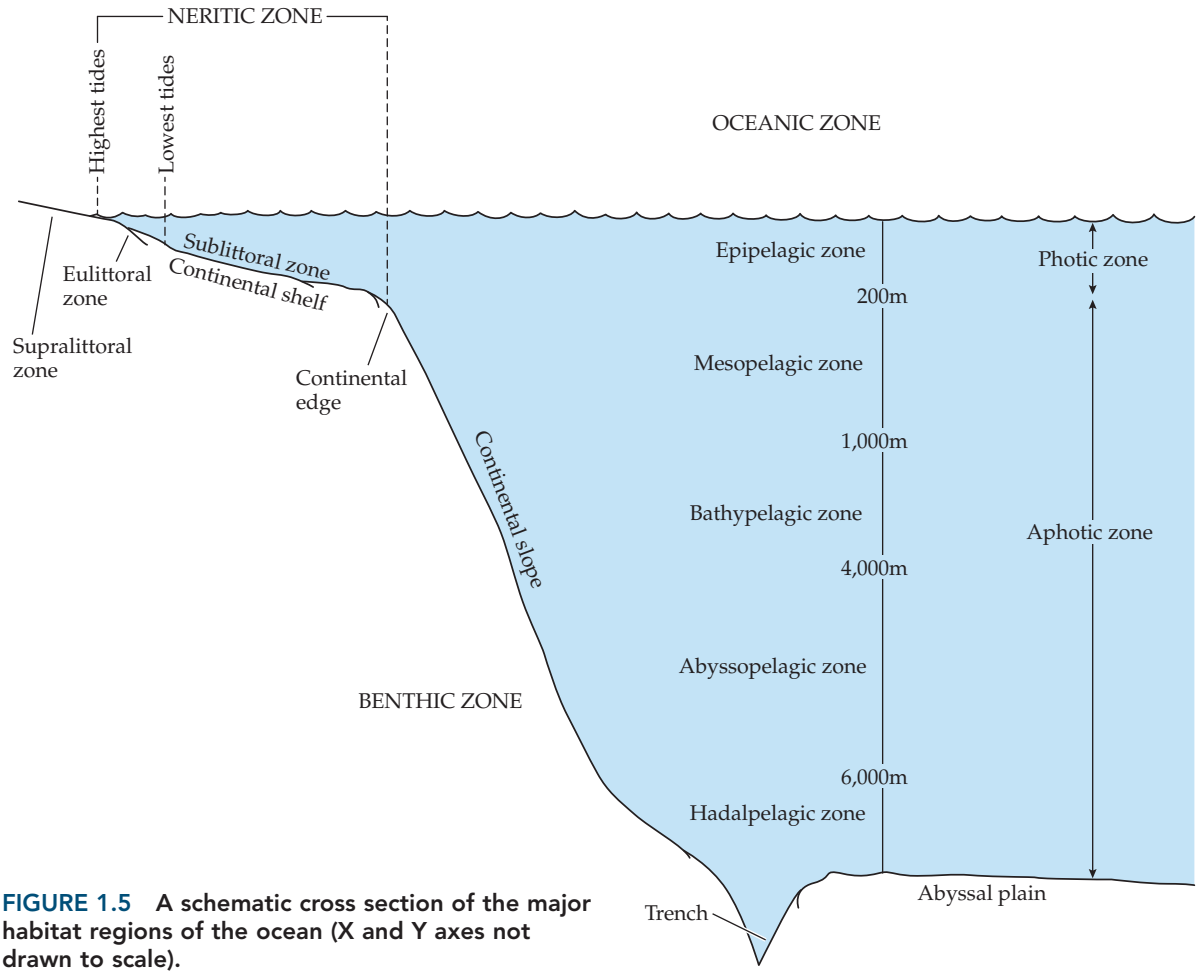

FIGURE 1.5 **A schematic cross section of the major habitat regions of the ocean (X and Y axes not drawn to scale).**

zone, is never uncovered, even at very low tides, but it is influenced by tidal action (e.g., by changes in turbulence, turbidity, and light penetration).

Organisms that inhabit the world's littoral regions are subjected to dynamic and often demanding conditions, and yet these areas commonly are home to exceptionally high numbers of species. Most animals and plants are more or less restricted to particular elevations along the shore, a condition resulting in the phenomenon of zonation. Such zones are visible as distinct bands or communities of organisms along the shoreline. The upper elevational limit of an intertidal organism is commonly established by its ability to tolerate conditions of exposure to air (e.g., desiccation, temperature fluctuations), whereas its lower elevational limit is often determined by biological factors (competition with or predation by other species). There are, of course, many exceptions to these generalizations.

Extending seaward from the shoreline is the **continental shelf**, a feature of most large landmasses. The continental shelf may be only a few kilometers wide, or it may extend up to 1,000 km from shore (50 to 100 km is average for most areas). It usually reaches a depth of 150–200 m. These nearshore shelf areas are among the most productive environments of the ocean, being rich in nutrients and shallow enough to permit photosynthesis from surface to seafloor.

The outer limit of the continental shelf—called the **continental edge**—is indicated by a relatively sudden increase in the steepness of the bottom contour. The "steep" parts of the ocean floor, the **continental slopes**, actually have slopes of only 4%–6% (although the slope is much steeper around volcanic islands). The continental slope continues from the continental edge to the deep ocean floor, which forms the expansive, relatively flat **abyssal plain**. The abyssal plain is an average of about 4 km below the sea's surface, but it is interrupted by a variety of ridges, seamounts, mountain ranges, trenches, and other formations. The bottom of some deep-sea trenches exceed 10 km in depth.

Organisms that inhabit the water column are known as **pelagic** organisms, whereas those living on the sea bottom anywhere along the entire contour shown in Figure 1.5 are referred to as **benthic** organisms. Organisms living in the water *near* the seafloor are **demersal**. Both the variety and the abundance of life tend to decrease with increasing depth, from the rich littoral and continental shelf environments to the deep abyssal plain. However, an overgeneralization of this relationship can be misleading. For example, although pelagic biomass

FIGURE 1.6 A few of Earth's major ecosystems. (A) Exposed rocks and algae in the intertidal zone, northern California. (B) A tidal flat in a salt marsh, New York. (C) A mangrove forest at low tide, in Mexico. (D) A freshwater stream in a tropical wet forest ("rain forest"), Costa Rica. (E) Flowering trees in a tropical dry forest, Costa Rica. (F) The Sonoran Desert in Arizona. Fully a third of the land on our planet is desert or semidesert, and this ecosystem is predicted to grow with global warming.

declines exponentially with depth, both diversity and biomass increase again near the bottom, in a thick layer of resuspended sediments called the **benthic boundary layer**. Also, shelf and slope habitats in temperate regions are often characterized by low animal density but high species diversity. In many areas, benthic diversity increases abruptly below the continental edge (100–300 m depth), peaks at 1,000 to 2,000 m depth, and

then decreases gradually. Species diversity in the benthic abyssal region itself may be surprisingly high. The first impression of early marine scientists—that the deep seabed was an environment able to sustain only a few species in impoverished simple communities—was long ago shown to be incorrect, and it is now known that deep-sea biodiversity in some regions is quite high, in some areas even rivaling tropical rain forests. Much of the discovery of high deep-sea biodiversity can be traced back to the pioneering work of Howard Sanders (1921–2001), of Woods Hole Oceanographic Institution. Additionally, the deep ocean covers more than half the planet!

Benthic animals may live on the surface of the substratum (**epifauna**, or **epibenthic** forms, such as most sea anemones, sponges, many snails, and barnacles) or burrow within soft substrata (**infauna**). Infaunal forms include many relatively large invertebrates, such as clams and various crustaceans and worms, as well as some specialized, very tiny forms that inhabit the spaces between sand grains, termed **interstitial** organisms (the smallest of which are **meiofauna**, usually defined as animals smaller than 0.5 mm). Five phyla of metazoans are exclusively meiofaunal (the first four being found only in the sea): Gastrotricha, Gnathostomulida, Kinorhyncha, Loricifera, Micrognathozoa. Benthic animals may also be categorized by their locomotor capabilities. Animals that are generally quite motile and active are described as being **errant** (e.g., crabs, many worms), whereas those that are firmly attached to the substratum are called **sessile** (e.g., sponges, corals, barnacles). Others are unattached or weakly attached but generally do not move around much (e.g., crinoids, solitary anemones, most clams); these animals are said to be **sedentary**.

The region of water extending from the surface to near the bottom of the sea is called the **pelagic zone**. The pelagic region over the continental shelf is called the **neritic zone**, and that over the continental slope and beyond is called the **oceanic zone**. The pelagic region can also be subdivided into increments on the basis of water depth (Figure 1.5) or the depth to which light penetrates. The latter factor is, of course, of paramount biological importance. Only within the **photic zone** does enough sunlight penetrate that photosynthesis can occur, and (except in a few special circumstances) all life in the deeper, **aphotic zone** depends ultimately upon organic input from the overlying sunlit layers of the sea. Notable exceptions are the restricted deep-sea hydrothermal vent and benthic cold seep communities in which sulfur-fixing microorganisms serve as the basis of the food chain.[10] The photic zone can be up to 200 m deep in the clear waters of the open ocean, decreasing to about 40 m over continental shelves and to as little as 20 m in some coastal waters. Phytoplankton in the photic zone of the world's oceans account for about half the production of organic matter on Earth. Note that some oceanographers restrict the term "aphotic zone" to mean depths below 1,000 m, where absolutely no sunlight penetrates; the region between this depth and the photic zone is then called the **disphotic, twilight, or mesopelagic zone**. Nearly 64% of the surface of planet Earth—over 200 million km^2—lies in the sea below the photic zone (below 200 m depth), and in this region it is estimated that 16 gigatons of carbon fixed by phytoplankton sink to the ocean interior ever year as the only food source for the majority of organisms in the deep sea (1 gigaton is 1 billion tons).

Organisms that inhabit the pelagic zone are often described in terms of their relative powers of locomotion. Pelagic animals that are strong swimmers, such as fishes and squids, constitute the **nekton**. Those pelagic forms that simply float and drift, or generally are at the mercy of water movements, are collectively called **plankton**. Many planktonic animals (e.g., small crustaceans) actually swim very well, but they are so small that they are swept along by prevailing currents in spite of their swimming movements, even though those movements may serve to assist them in feeding or escaping predators. Both photosynthetic organisms (**phytoplankton**) and animals (**zooplankton**) are included among the plankton, the latter being represented by invertebrates such as jellyfish, comb jellies, arrow worms, many small crustaceans, and the pelagic larvae of many benthic adults. Planktonic animals that spend their entire lives in the pelagic realm are called **holoplanktonic** animals; those whose adult stage is benthic are called **meroplanktonic** animals.

The oceans hold some unique habitats. Perhaps the most well known are coral reefs, which comprise one of the world's most diverse ecosystems. In 1997, Marjorie Reaka-Kudla estimated there were about 93,000 described animal species living in the world ocean's coral reefs but that this was only 10% of the actual diversity (due to all of the undescribed species). Since then, some workers have suggested the number of coral reef animals might be three times, or more, than Reaka-Kudla estimated.

Another well-known ocean ecosystem comprises the hydrothermal vent communities. These are abundant in the world's oceans and tend to occur in areas where tectonic plates are moving apart and near plate hotspots (the land equivalents are geysers, fumaroles, and hot springs). Oceanic hydrothermal vents have in common an abundance of reduced chemicals, such as sulfides and methane. Chemosynthetic bacteria and archaeans form the base of the food chain in these ecosystems. One of the signature animals of hydrothermal vents is the tubeworm annelid *Riftia pachyptila*, which has no mouth, gut, or anus and cannot feed by normal means (see Chapter

[10] In addition to deep-sea hydrothermal vents, nonphotosynthetic chemoautotroph-based communities have recently been discovered in a cave, Movile Cave in Romania. The base of the food chain in this unique cave ecosystem is autotrophic microorganisms (bacteria and fungi) thriving in thin mats in and near-geothermal waters that contain high levels of hydrogen sulfide. This community sustains dozens of microbial and invertebrate species. It is thought that the hydrogen sulfide originates from a deep magmatic source, similar to that seen in deep-sea vents.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

14). Instead, *Riftia* depends on intracellular chemoautotrophic symbionts—which fill a large internal organ called the trophosome—for nutrition. The symbionts are Proteobacteria, which are functionally analogous to plant chloroplasts in that they generate organic carbon as a food source for their worm hosts.

Another unique marine habitat consists of large vertebrate carcasses that sink to the bottom in deep waters, especially cetaceans (whales, dolphins, and porpoises). Unlike in shallower waters, where a large carcass will be consumed by scavengers over a relatively short period of time, these "whale falls" can last for several years and allow for the establishment of an entire food web, characterized by a specific assemblage of species, especially crustaceans, annelids, bivalve molluscs, and fishes. Some of the more famous members of the whale fall community are species of *Osedax*, the so-called zombie worms, which consume the bones of dead cetaceans in these communities (see Chapter 15).

One of the most unusual marine environments inhabited by invertebrates are the pockets of concentrated brines that are encased in the ice matrix of Earth's polar regions (brines are generally considered to be 5% or more dissolved salts; ocean water is 3.4%–3.5% salt). At very low temperatures (to –20°C) and light levels, a food web in miniature exists, including photosynthetic bacteria and protists (especially diatoms), heterotrophic protists, flatworms, small crustaceans, etc. These are highly adapted, normally planktonic species that get trapped, and survive, when winter sea ice forms.

Estuaries and Coastal Wetlands

Estuaries usually occur along low-lying coasts and are created by the interaction of fresh and marine waters, typically where rivers meet the sea. Here one finds an unstable blending of freshwater and saltwater conditions, moving water, tidal influences, and drastic seasonal fluctuations. Estuaries usually receive high concentrations of nutrients from terrestrial runoff in their freshwater sources and are typically highly productive environments. Temperature and salinity vary greatly with tidal activity and with season. Depending on tides and turbulence, the waters of estuaries may be relatively well mixed and more or less homogeneously brackish, or they may be distinctly stratified, with fresh water floating on the denser salt water below.

The amount of dissolved oxygen in an estuary may also change markedly throughout a 24-hour cycle as a function of temperature and the metabolism of photosynthetic organisms. In many cases, hypoxic (very low oxygen) conditions may occur on a daily basis, especially in the early morning hours. Animals inhabiting these areas must be capable of migrating to regions of higher oxygen levels, be able to store oxygen bound to certain body fluid pigments, or be able to switch temporarily to metabolic processes that do not require oxygen-based respiration. Furthermore, vast amounts of silt borne by freshwater runoff are carried into the waters of estuaries; most of this silt settles out and creates extensive tidal flats or deltaic regions (Figure 1.6B). In addition to the natural stresses common to estuarine existence, the inhabitants of estuaries are also subject to stresses resulting from human activity—pollution, thermal additions from power plants, dredging and filling operations, excessive siltation resulting from coastal and upland deforestation and development, and storm drain discharges are some examples.

Most coastal wetlands and estuaries, such as salt marshes and mangrove forests, are characterized by stands of halophytes (flowering plants that flourish in saline conditions; Figure 1.6B,C). Salt marshes and mangrove swamps are alternately flooded and uncovered by tidal action within the estuary and are thus subjected to the fluctuating conditions just described. The dense halophyte stands and the mixing of waters of different salinities create an efficient nutrient trap. Instead of being swept out to sea, most dissolved nutrients entering an estuary (or generated within it) are utilized there, yielding some of the most productive regions in the world. This great productivity does eventually enter the sea in two principal ways: as plant detritus (mainly from halophyte debris), and via the nektonic animals that move into and out of the estuary. The contribution of estuaries to general coastal productivity can hardly be exaggerated. The organic matter produced by plants of the Florida Everglades, for example, forms the base of a major detritus food web that culminates in the rich fisheries of Florida Bay. Furthermore, 60%–80% of the world's commercial marine fishes rely on estuaries directly, either as homes for migrating adults or as protective nurseries for the young. Estuaries and other coastal wetlands are also of prime importance to both resident and migratory populations of water birds.

A large number of invertebrates have adapted to life in these dynamic environments. In general, animals have but two alternatives when encountering stressful conditions: either they migrate to more favorable environments, or they remain and tolerate (accommodate to) the changing conditions. Many animals migrate into estuaries to spend only a portion of their life cycle, whereas others move in and out on a daily basis with the tides. Other species remain in estuaries throughout their lives, and these species show a remarkable range of physiological adaptations to the environmental conditions with which they must cope (see Chapter 3).

Freshwater Habitats

Most of the world's unfrozen fresh water is stored beneath the land surface. It is groundwater, stored in aquifers and out of sight. Although the world's aquifers are environmentally stable, humans are depleting more than half of them at an alarming rate. Because surface bodies of fresh water are so much smaller than both aquifers and the oceans, surface water is much

more readily and drastically influenced by extrinsic environmental factors and thus is a relatively unstable environment (Figure 1.6D). Changes in temperature and other conditions in ponds, streams, and lakes may occur quickly and be of a magnitude never experienced in most marine environments. Seasonal changes are even more extreme and may include complete freezing during the winter and complete drying in the summer. Ponds that hold water for only a few weeks during and after rainy seasons are called **ephemeral pools** (or vernal pools). They typically contain a unique and highly specialized invertebrate fauna capable of producing resting, or diapause, stages (usually eggs or embryos) that can survive for months or even years without water. As stressful as this sounds, ephemeral pools contain rich communities of plant and animal life, especially endemic species of crustaceans. **Diapause** is a form of dormancy in which invertebrates in any stage of development before the adult, including the egg stage, cease their growth and development. Diapause is genetically determined. Some species are programmed to enter diapause when certain environmental conditions provide the proper cues (often a combination of temperature and length of daylight). Hibernation and aestivation are two other types of dormancy, but they are not genetically programmed and may occur irregularly, or not at all, during any stage of an animal's development. **Hibernation** is a temporary response to cold, while **aestivation** is a temporary response to high temperatures and arid conditions.

Because the internal milieu of animals is typically close to that of sea water, the very low salinity of fresh water (rarely more than 1‰) and the lack of constant relative ion concentrations subject freshwater inhabitants to severe ionic and osmotic stresses. These conditions, along with other factors such as reduced buoyancy, less stable pH, and rapid nutrient input and depletion, produce environments that support far less biological diversity than the ocean does. Nonetheless, many different invertebrates do live in fresh water and have solved the problems associated with this environment. Special adaptations to life in fresh water are summarized in Chapter 3, and they are discussed in later chapters in relation to the groups of invertebrates that have such adaptations.

Stygobionts are aquatic obligates in subterranean ground waters, including streams and underground lakes that often connect to the sea. Aquatic creatures that inhabit subterranean alluvial waters and karst ecosystems also fall into this category, and many have been shown to be highly endemic and vulnerable to changing environmental conditions.

Freshwater habitats (including wetlands) are some of the most threatened environments on Earth. Throughout the United States, people destroy 100,000 acres of wetlands annually. Rare aquatic habitats such as ephemeral pools and subterranean rivers are disappearing faster than they can be studied. Underground, or hypogean, habitats are often aquatic, and these habitats are quickly being destroyed by pollution and groundwater overdraft. In California, 96% of the historic wetlands have been lost to agriculture and development, and globally wetland loss is three times as high as forest loss. The 2018 Living Planet Index (www.livingplanetindex.org) showed that populations of freshwater species had declined by an average of 83% since 1970, a far steeper drop than for terrestrial or marine species.

Terrestrial Habitats

Life on land is in many ways even more rigorous than life in fresh water. Temperature extremes are usually encountered on a daily basis, water balance is a critical problem, and just physically supporting the body requires major expenditures of energy. Water provides a medium for support; for dispersing gametes, larvae, and adults; and for diluting waste products and is a source of dissolved materials needed by animals. Animals living in terrestrial environments do not enjoy those benefits of water, and they must pay the price. The hottest terrestrial habitat on Earth may be the Lut Desert in southeast Iran, where soil surface temperatures can reach nearly 71°C (160°F). But even this desert has a vibrant ecosystem, supported in part by bird carcasses and a "hidden sea"—a surprising shallow layer of salty groundwater.

Relatively few phyla have successfully invaded the terrestrial world. Invertebrate success on land is exemplified by the arthropods, notably the terrestrial isopods, insects, and spiders, mites, scorpions, and other arachnids. These arthropod groups include truly terrestrial species that have invaded even the most arid environments (Figure 1.6F). Except for some snails and nematodes, all other land-dwelling invertebrates, including such familiar animals as earthworms, are largely restricted to relatively moist areas.

Terrestrial environments are commonly described in terms of moisture availability. **Xeric** habitats are dry, **mesic** environments have a moderate amount of moisture, and **hydric** habitats are very wet. Adaptations of terrestrial invertebrates to these various conditions are described in Chapter 3 and, for individual taxa, in subsequent chapters.

A Special Type of Environment: Symbiosis

Many invertebrates live in intimate association with other animals or plants. And, of course all Metazoa (and the eukaryotes in general) share an ancient genetic relationship with prokaryotes. An intimate association between two different species is termed a symbiotic relationship, or **symbiosis**. Symbiosis was first defined in 1879 by German mycologist H. A. DeBary as "unlike organisms living together." In most symbiotic

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

relationships, a larger organism (called the host) provides an environment (its body, burrow, nest, etc.) on or within which a smaller organism (the symbiont) lives. Some symbiotic relationships are rather transient—for example, the relationship between ticks or lice and their vertebrate host—whereas others are more or less permanent. Some symbionts are opportunistic (**facultative**), whereas others cannot survive without their host (**obligatory**). And, importantly, some symbioses evolve such intimacy that, over time, genes of the smaller symbiont may get incorporated into the genome of the "host."

Symbiotic relationships can be subdivided into several categories based on the nature of the interaction between the symbiont and its host (although in many cases the exact nature of the relationship is unknown). Perhaps the most familiar type of symbiotic relationship is **parasitism**, in which the symbiont (a parasite) receives benefits at the host's expense. Parasites may be external (**ectoparasites**), such as lice, ticks, and leeches; or they may be internal (**endoparasites**), such as liver flukes, some roundworms, and tapeworms. Other parasites may be neither strictly internal nor strictly external; rather, they may live in a body cavity or area of the host that communicates with the environment, such as the gill chamber of a fish or the mouth or anus of a host animal (**mesoparasites**). Some parasites live their entire adult lives in association with their hosts and are permanent parasites, whereas temporary, or intermittent, parasites such as bedbugs feed on the host and then leave it. There are even nest parasites, such as ant-nest beetles (Carabidae: Paussini) that inhabit the nests of host ants and feed on them, apparently by tricking the ants into thinking they are one of them. In some of these cases, the line between parasitism and predation becomes blurred. Temporary parasites, such as mosquitoes and aegiid isopods, are often referred to as **micropredators**, in recognition of the fact that they usually "prey" on several different host individuals (that happen to be much larger than themselves).

Parasites that parasitize other parasites are **hyperparasitic**. **Parasitoids** are insects, usually flies or wasps, whose immature stages feed on the bodies of their hosts, usually other insects, and ultimately kill the host. A **definitive host** is one in which the parasite reaches reproductive maturity. An **intermediate host** is one that is required for a parasite's development but in which the parasite does not reach reproductive maturity. Multiple hosts are more common than not in the world of parasites. Even most human pathogens circulate in other animals (or else originated in nonhuman hosts); influenza, plague, and trypanosomiasis all transmit from animals to humans. Over half of all human pathogens are **zoonotic** (have animal hosts, other than humans, in their life cycle). Every species probably serves as host to several (or many) parasites. It has been suggested that parasitism is the most popular lifestyle on Earth! Since insects are the most diverse group of organisms on Earth, and since all insects harbor numerous parasites, it is fair to say that the most common mode of life on Earth is that of an insect parasite. Most parasites have yet to be described, and as species go extinct, so, often, do their parasites (when the passenger pigeon was eliminated in 1914, it took two species of parasitic lice with it).

A few groups of invertebrates are predominantly or exclusively parasitic. Many texts and courses on parasitology pay particular attention to the effects of these animals on humans, crops, and livestock. Here we also try to focus on parasitism from "the parasite's point of view," that is, as a particular lifestyle suited to a specific environment, requiring certain adaptations and conferring certain advantages.

The term **mutualism** was introduced into biology in 1873 by Pierre van Beneden to recognize "mutual aid" between species. Mutualism is generally defined as cooperation between species, an association in which both host and symbiont benefit. Such relationships may be extremely intimate and important for the survival of both parties; for example, the bacteria in our own large intestine are important in the production of certain vitamins and in processing material in our gut. In fact, beneficial associations with specific bacterial symbionts characterize many, if not all, animal species, although most of these relationships have not been well studied. Another example is the relationship between termites and certain protists that inhabit their digestive tracts and are responsible for the breakdown of cellulose into compounds that can be assimilated by the insect hosts. In nature, 90% of land plants are mycorrhizal, and virtually all mammalian and insect herbivores would starve without their cellulose-digesting symbionts. Other mutualistic relationships may be less binding on the organisms involved. Cleaner shrimps, for example, inhabit coral reef environments, where they establish "cleaning stations" that are visited regularly by reef-dwelling fishes that present themselves to the shrimps for the removal of parasites. Obviously, even this rather loose association results in benefits for the shrimps (a meal) as well as for the fishes (removal of parasites). The mutualistic relationships between flowering plants (which have been around for over 100 million years) and their pollinators are essential to the survival of the plants and their insect partners (and, in some cases, their nectar-feeding bird or bat partners).

There are many types of mutualism, and Bronstein (2015) has categorized them as **transportation mutualism** (e.g., pollination, fig–fig wasp, yucca–yucca moth, seed dispersal), **protection mutualism** (e.g., ant-plant, bioluminescence, cleaning), and **nutritional mutualism** (e.g., legume-rhizobium, mycorrhizal, fungus-growing ants, bark beetle–fungus, coral-algae symbioses, gut microbiomes). Mutualistic relationships may be extremely intimate and important for the survival of both parties. Mutualism can be

obligate (neither population, or species, can survive without the other, such as fig pollination mutualism or yucca pollination mutualism), or it can be **facultative** (under certain conditions, the populations, or species, can survive without the other although they may not perform as well as when partnered). Some workers have noted that not all mutualisms are necessarily symbiotic, and thus the more specific term "symbiotic mutualism" can be used to describe those in which there is prolonged physical intimacy between partner species. Another form of interaction is known as "facilitation"—an interaction in which the presence of one species alters the environment in a way that enhances the growth, survival, or reproduction of a second, neighboring species (although the two may not share physical intimacy). In cases where each species facilitates the other, the interaction is a mutualism, usually a nonsymbiotic mutualism.

Mutualisms are some of the most threatened ecological relationships on Earth. For example, as we lose pollinator species, the plants they rely on suffer and begin to decline. In some cases, plants rely on single species for pollination. For example, each of the 900 or so species of giant fig trees of the tropics (*Ficus* is the most widespread plant genus in the tropics) is pollinated by a single variety of wasp. Imagine what would happen to the trees if they lost their very specific pollinators. Imagine what would happen to the rest of the community. Of immediate concern is colony collapse disorder (CCD), a syndrome that is killing honeybees worldwide. Bees pollinate 71% of the crops that provide 90% of human food; but since 2006, U.S. beekeepers have seen honeybee colony loss rates increase to 35% per year. The causes for CCD have yet to be fully elucidated, but overuse of pesticides in the environment appears to play a key role. In the European Union, about 500 active substances used in pesticides are approved.

A third type of symbiosis is called **commensalism**. This category is something of a catchall for associations in which neither significant harm nor mutual benefit is obvious. Commensalism is usually described as an association that is advantageous to one party (the symbiont) but leaves the other (the host) unaffected. For instance, among invertebrates there are numerous examples of one species inhabiting the tube or burrow of another (**inquilism**); the former obtains protection, food, or both with little or no apparent effect on the latter. A special type of commensalism is **phoresis**, wherein the two symbionts "travel together," but there is no physiological or biochemical dependency on the part of either participant. Usually one phoront is smaller than the other and is mechanically carried about by its larger companion.

There is a good deal of overlap among the categories of symbiosis just described, and many animal relationships have elements of two or even of all the categories, depending on life history stage or environmental conditions. Taken in its broad sense, the concept of symbiosis has profound implications for understanding Earth's biodiversity.

Changing Views of Invertebrate Phylogeny

Significant changes in our view of animal phylogeny have come about over the past three decades, primarily from the rapidly expanding field of molecular phylogenetics and also from new paleontological work and new ultrastructural and embryological studies. Broadly speaking, the 31 phyla of Metazoa are now classified into four basal, nonbilaterian phyla (the diploblastic phyla: Porifera, Cnidaria, Ctenophora, Placozoa) and the Bilateria (the 27 triploblastic phyla). The Bilateria comprise two long-recognized clades, Protostomia and Deuterostomia, but four phyla once regarded as deuterostomes are now recognized as protostomes (Chaetognatha, Phoronida, Bryozoa, Brachiopoda), leaving only three phyla of Deuterostomia—Echinodermata, Hemichordata, and Chordata. The newly created phylum Xenacoelomorpha, housing taxa formerly allied with the Platyhelminthes (Acoela, Nemertodermatida, and *Xenoturbella*), remains somewhat enigmatic, but most analyses place this phylum as sister group to Nephrozoa—the remaining bilaterians.

Among the protostomes, molecular phylogenetic research identifies two major clades, Ecdysozoa and Spiralia. However, despite great efforts to date, the specific relationships of the phyla within Ecdysozoa and Spiralia also remain somewhat elusive, although some strongly supported internal clades have been identified. These ideas are more fully discussed in Chapter 8. Among the deuterostomes, Echinodermata and Hemichordata form a well-supported clade (Ambulacraria), and this is the sister group to Chordata. Within Chordata, the long-standing idea that lancelets (Cephalochordata) are the sister group to the Vertebrata (Craniata) has been overturned, and strong evidence now supports the tunicates (Urochordata) as the sister group to the vertebrates. A summary classification and geologic time scale are provided on the front inside cover of this book.

Teasing apart the evolutionary relationships of the metazoan phyla has been challenging because of their ancient roots, and it has required finding informative phylogenetic markers for groups that are hundreds of millions of years old. One challenge has been that different regions of the genome have experienced different evolutionary histories, thus producing conflicting phylogenetic signals. Not only has this required using multiple genes, and even genome-level analyses, it has also led to the development of sophisticated algorithms that model the evolution of individual amino

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

acids. Those phyla still stubbornly resisting phylogenetic understanding will probably require new and even more sophisticated analysis protocols. One of the important things that has been revealed over the past couple of decades through the work of molecular phylogenetics and developmental biology is that there is far more homoplasy in the animal world than we suspected, even in such complex features as segmentation and nervous systems. For example, one surprising discovery of the early days of molecular systematics is that Annelida (considered spiralians) and Panarthropoda (Onychophora, Tardigrada, Arthropoda—placed within Ecdysozoa) are far more distantly related than was previously thought. And another, only distantly related phylum, the Kinorhyncha, also show segmentation. We still have much to learn about these new twists in animal phylogeny. Even spiral cleavage, once thought to be a largely immutable aspect of animal development (due to "developmental constraints"), has been shown to be flexible—to the point of being greatly altered or even lost in some lineages. Further, we now know that many genes once thought to be specific to particular innovations actually appeared in the tree of life much earlier than did the features themselves; so we can no longer necessarily expect to find novel genes associated with novel morphological or developmental features. For example, cellular adhesion and transcriptional regulation genes essential to animal multicellularity also occur in the protistan ancestral line leading to Metazoa. And we now know that many genes once thought to be specific to vertebrates can be found as far down the tree of life as Cnidaria (but have been lost in many lineages in between). Many novel phenotypes have arisen by way of modification of gene function and by interactions between existing genes.

Legacy Names

As you might have guessed by now, some of the names in use today for higher taxa were created before biologists achieved their current understanding of animal phylogeny, and due to more recent reassignments of phyla, these names are no longer fully descriptive. As noted, the two great clades of Bilateria have long been called Protostomia and Deuterostomia. The names were originally based on what was known at the time about early embryonic development, especially the fate of the blastopore. Deuterostomia were those animals in which the blastopore became the adult anus, the mouth thus forming de novo, secondarily. Hence the name: *deutero* = "second," *stome* = "mouth." In Protostomia (*proto* = "first"), on the other hand, the blastopore gave rise to the mouth, and the anus formed elsewhere. However, we now know that some members of the clade Protostomia have deuterostomous development (e.g., nematomorphs, priapulans), and in some Deuterostomia the anus does not originate from the blastopore. In fact, it seems that the blastopore, the mouth, and the anus have a degree of developmental independence. Similarly, the name Spiralia was created by Waldemar Schleip in 1929, after the stereotypical spiral cleavage seen in most member phyla, but even this name is not fully descriptive, because several phyla of Spiralia lack this developmental pattern (e.g., Bryozoa, Brachiopoda, Gastrotricha). These kinds of names for higher taxa, that are no longer fully descriptive based on their original intent, are **legacy names**. To fully appreciate them, one needs to understand a bit of their history; otherwise they can seem illogical. Again, these ideas are explored more fully in Chapter 8.

Phylogenetics and Classification Schemes

As noted previously, the rapidly growing number of molecular phylogenetic studies, especially genomic-scale phylogenetics, has changed many of our views on animal relationships and classifications. This work is also generating large and highly resolved phylogenetic trees, with detailed branching patterns depicting the history of life on Earth. Such detail creates challenges for biologists who strive to produce classifications that accurately reflect phylogeny, because the traditional Linnean hierarchical ranks are too few in number to capture the great depth and detail of these trees. Many of the new trees have scores of branching points, or even hundreds of branches that appear as long comblike topologies. But the standard Linnean ranks number only 30 or so. There are a few solutions to this dilemma, such as using unranked classifications, but none of the solutions is perfect. We briefly discuss these in Chapter 2. In this book, we mostly use ranked classifications that mirror, or at least do not conflict with, the phylogeny of the groups in question. In a few instances, we have had to use fully or partly unranked subordinated classifications (e.g., annelids and molluscs). Again, this is all explained in more detail in Chapter 2. But the upshot is, things are changing and the "traditional" classification schemes many students are used to seeing are beginning to look rather different these days.

A Final Introductory Message to the Reader

Because of our comparative approach, it is important that you become familiar with Chapters 1 through 4 before attempting to study and comprehend the sections dealing with individual animal groups. These four chapters are designed to accomplish several goals: (1) to define some basic terminology, (2) to introduce a number of important concepts, and (3) to describe in detail the themes that we use throughout the rest of the book. They also offer students a bit of a "refresher course" in general biology.

The fundamental theme of this book is evolution, and we approach invertebrate evolution primarily through the field of comparative biology. In Chapter 2 we provide an explanation of how biologists derive evolutionary schemes and classifications, how theories about the phylogeny of animal groups grow and change, and how the information presented in this text has been used to construct theories on how life evolved on Earth. In Chapters 3 and 4 we lay out the fundamental anatomical and morphological designs and developmental strategies of metazoans. Like all features of organisms, these designs and strategies are not random, but form patterns. Recognition and analysis of these patterns constitute the basic building blocks of this book. We then proceed in the "animal chapters" to explore the evolution of the invertebrates in light of various combinations of these basic functional body plans and lifestyles. With this background, you should be able to follow the evolutionary changes and branchings among the invertebrate phyla, their body systems, and their various pathways to success on Earth. Note that chapters treating large phyla (e.g., molluscs, annelids, the arthropods) have rather lengthy taxonomic synopsis sections. We don't expect students to read every word of these synopses; they are provided more as a reference source for readers to look up taxa within the context of our current state of knowledge for the groups.

Through our approach, we hope to add continuity to the massive subject of invertebrate zoology, which is often covered (in texts and lectures) by a sort of "flash card" method, in which the primary goal is to have the student memorize animal names and characteristics and keep them properly associated, at least until after the examination. Thus, we urge you to look back frequently at these first few chapters as you read ahead and explore how invertebrates are put together, how they live, and how they evolved.

Chapter Summary

Are you ready to join us on this journey through the diversity of animal life on planet Earth? Good! In this introductory chapter we provide you with some background material for what lies ahead. We start with a brief overview of the history of life on Earth, especially the large clade Metazoa (= Animalia). Although the oldest generally accepted animal fossils are from the Ediacaran Period (635–541 Ma), molecular clock estimates have suggested that Metazoa might have arisen much earlier (875–650 Ma). On land, however, animals may not have begun to radiate until around 470 million years ago. Approximately 2 million living eukaryote species, about 1.45 million of which are animals, have so far been described, but estimates of undescribed/unnamed eukaryote species range from 3 to 100 million (or more). Species are not evenly distributed among the 31 animal phyla (Table 1.1). Of the 1.4 million named living animal species, 1.2 million (82.3%) belong to one phylum, Arthropoda, and 1.33 million (92%) belong to just three phyla (Arthropoda, Mollusca, and Chordata). And seven animal phyla each contain fewer than 100 named species.

We organize our knowledge of these species through classifications, which are based upon our current understanding of the one great tree of life. Our understanding of the topology of that tree is always being refined as new data and new ways of analyzing our data appear. But our principal goal is always to recognize natural, or monophyletic, groups (which are also called clades); these are groups of species that have descended from a single common ancestor and that include all the descendants of that ancestor. In this way, our classifications reflect our understanding of the tree of life, the evolutionary history of life on Earth. However, many previously recognized taxa have been shown to be paraphyletic or polyphyletic, basically representing mistakes made by previous systematists that have been revealed in light of new information. In contrast to monophyletic groups, paraphyletic groups have a common ancestor, but they do not contain all of the descendants of that ancestor. An example of a paraphyletic group is Crustacea; while crustaceans are all descended from an immediate common ancestor, one group is traditionally excluded—the insects and their kin (Hexapoda). Polyphyletic groups contained species that are not all descended from an immediate common ancestor. An example of a polyphyletic group was Vermes, and old name used for many wormlike animals, that included representatives of many current animal phyla.

Significant changes in our view of animal phylogeny have come about over the past three decades, primarily from the rapidly expanding field of molecular phylogenetics, and also from new paleontological work and new ultrastructural and embryological studies. Broadly speaking, the 31 currently recognized phyla of Metazoa are today classified into four basal, nonbilaterian phyla (the diploblastic phyla: Porifera, Cnidaria, Ctenophora, Placozoa) and the Bilateria (the 27 triploblastic phyla).

Marine, freshwater, and terrestrial environments present different kinds of challenges for animals, especially in terms of water balance, excretion, reproduction, support, and locomotion; this is briefly reviewed in this chapter.

CHAPTER 2

Systematics, Phylogeny, and Classifications

The affinities of all the beings of the same class have sometimes been represented by a great tree. . . . As buds give rise by growth to fresh buds, and these, if vigorous, branch out and overtop on all sides many a feebler branch, so by generation I believe it has been with the great Tree of Life, which fills with its dead and broken branches the crust of the earth, and covers the surface with its ever branching and beautiful ramifications.

Charles Darwin, *The Origin of Species*, 1859

Systematics is the study of biological diversity and its origins. Systematists identify and distinguish species, describe and name new taxa, provide tools to aid others in identifying specimens, infer the evolutionary relationships among species and higher taxa, undertake biogeographic analyses, and produce classification systems that reflect evolutionary history. These stages in systematic research overlap and cycle back on themselves in a highly iterative fashion. In sum, the role of systematics is to document and understand Earth's biological diversity, to reconstruct the history of that biodiversity, and to develop natural (evolutionary) classifications of living and extinct organisms.

Just as your own family has grown through time and you are connected to your parents and your grandparents, all organisms that have ever lived on Earth are related to one another through genetic descent. **Phylogenetic trees** are diagrams comprising branches and nodes that depict this flow of genetic information over time to illustrate how organisms are related. Since all organisms are kin to one another, there is a single tree of life, whose branching pattern reflects the evolutionary relationships among all species on Earth (Darwin's "great Tree of Life"). However, because multicellular life has been evolving on Earth for hundreds of millions of years, and we cannot time travel, we don't know for certain how all of the branches of the tree are connected to one another. That is, there is not a universal record of the pattern of genetic decent since life began. But, there are *traces* of that pattern embedded in the anatomy and genomes of all of the organisms roaming the Earth today and even in some that are no longer among us (e.g., fossils can be studied anatomically, and ancient DNA allows us to study the genomes of some organisms that died more than one million years ago). Systematists seek to uncover those traces to generate hypotheses of how organisms and species are related to one another. They do this by creating and analyzing data matrices of homologous anatomical or genetic traits, formally called **characters**, among

The chapter opener photo shows representatives of two phyla that are only distantly related, deeply in time: sponges (Porifera) and crabs (Arthropoda). Both are ancient phyla that arose in Precambrian seas more than 550 million years ago.

organisms. As new data become available and are added to the analysis, trees are revised and updated. As we will see throughout this book, many long-held ideas about animal relationships have recently been altered (or even overturned) by analyses of DNA sequence data. In this chapter, we will present the underpinnings of phylogenetic analysis and the construction of classifications.

Phylogeny, Monophyly, Paraphyly, and Polyphyly

A **phylogenetic tree** is a branching diagram that depicts how organisms are related to one another (Figure 2.1). It is a graphical means of expressing relationships (or genetic connectivity) among species or other taxa and is, in fact, a nested set of clades. Understanding the concept of a clade (or monophyletic group) is critical to being able to read a tree correctly. A **monophyletic group, or clade,** is a group of species that includes a common ancestor and all of the descendants of that common ancestor—that is, it is a unique branch in the tree of life. Monophyletic groups can be separated from the rest of the tree of life by cutting a single branch once. If you were able to walk up to the tree of life and cut off one branch, any branch, and hold that trimming in your hand, you would be holding a monophyletic group (Figure 2.1). A monophyletic group is a group of taxa that are one another's closest relatives. You and your immediate family (you, your parents, and your siblings) is one example of a monophyletic group.

Most trees published in the literature (and in this text) are rooted, and rooted trees not only show a pattern of relationship but also indicate the direction in which time is moving along the branches—always from the root (oldest) to the tips (youngest) of the tree, no matter how the tree is drawn (Figure 2.2). Thus, rooted trees depict ancestor-descendant relationships.

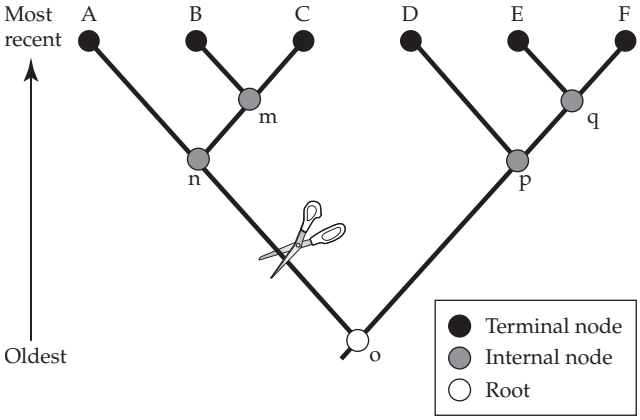

FIGURE 2.1 Learning to read trees. This phylogeny depicts the relationships among six taxa (A–F). Phylogenetic trees are always composed of nodes and branches, but the nodes are usually not indicated. In this tree, the terminal nodes are solid black circles (A–F), and they represent the extant species. The internal nodes are gray or open circles (m–q), and they represent the most recent common ancestors (MRCA) of their descendants. Node o is the root node; it indicates where this tree would attach to the rest of the tree of life, and it tells us the direction in which time moves along the branches of the tree (from bottom to top). Time always moves from the root node toward the terminal nodes, as indicated by the arrow to the left. A monophyletic group (or clade) is a group of taxa that includes the MRCA and the descendants of that ancestor. You could cut this tree along any single branch and hold the trimming in your hand, and that would be a monophyletic group. Trees are nested sets of monophyletic groups (or clades). Sister groups are two monophyletic groups that are more closely related to one another than they are to any other groups. Sister groups share a most recent common ancestor. The sister group of taxon A in this tree is m + B + C, and their MCRA is represented by node n. The sister group of the clade that includes A + B + C is the clade composed of p + q + D + E + F. These two clades share a MRCA depicted by node o.

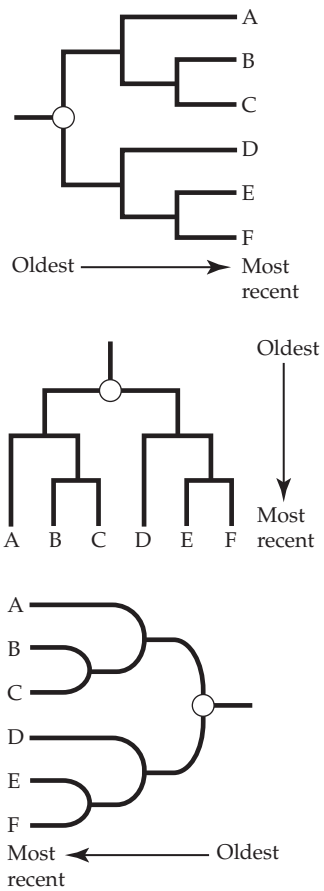

FIGURE 2.2. Trees, the root node, and direction of time. These three trees depict the same pattern of relationship between taxa A–F as the tree shows in Figure 2.1. In each tree the root node is indicated by a circle, and an arrow depicts the direction in which time moves along the branches, from the root node to the terminal nodes (sometimes called "leaves").

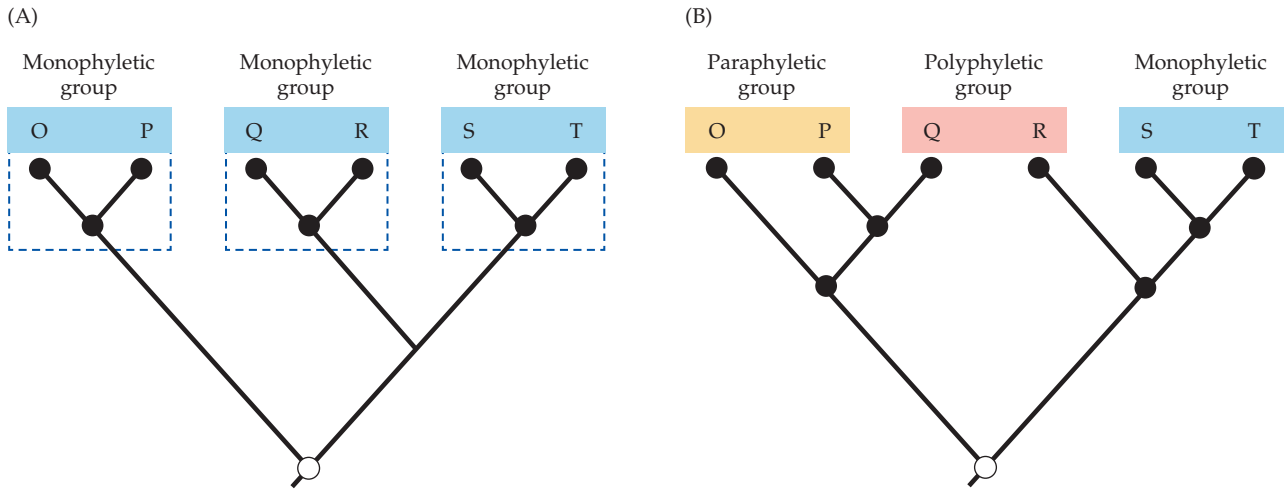

FIGURE 2.3. Monophyly, paraphyly, and polyphyly. Trees A and B depict two different, but potentially correct, phylogenies of six living species (O–T). In both scenarios a systematist proposed to classify the six extant species into three groups: O + P, Q + R, and S + T. If the evolutionary relationships among these taxa are correctly depicted in tree A, then all three groups the systematist erected are monophyletic. However, if the evolutionary relationships among these taxa are correctly depicted by tree B, then only S + T would be a monophyletic group. O + P would be a paraphyletic group since it excludes species Q, and Q + R would be a polyphyletic group because these two species evolved from more than one most recent common ancestor. If we knew the shape of the tree of life with certainty, systematists would erect only monophyletic groups. Paraphyletic and polyphyletic groups are erected due to a lack of knowledge of the evolutionary relationships among taxa (or the shape of the underlying tree).

If we knew for certain what the shape of the tree of life looked like, then systematists would erect only monophyletic groups (Figure 2.3A). But because we do not yet fully know the shape of the tree, sometimes systematists mistakenly create paraphyletic or polyphyletic groups. These kinds of nonmonophyletic taxa or species groups are illustrated in Figure 2.3B.

A group whose member species are all descendants of a common ancestor but that does *not* contain all the species descended from that ancestor is called a **paraphyletic group** (Figure 2.3B, O + P group). Paraphyly implies that for some reason one or more members of a natural group have been separated out and placed in a different group. As we will see, many paraphyletic groups exist within animal classifications today.[1]

A **polyphyletic group** is a group whose member species arose from two or more, different immediate ancestors. Such composite groups are proposed due to insufficient knowledge concerning how the taxa in question are related to other taxa (Figure 2.3B, Q + R group). Polyphyletic groups are usually established because the features or characters used to recognize and diagnose the group are not homologous but rather are the result of evolutionary convergence.[2] One of the principal goals of systematists is to discover such polyphyletic or "artificial" taxa and, through careful study, reclassify their members into appropriate monophyletic taxa.

Homology

As mentioned earlier, systematists infer phylogenies by comparing heritable traits, formally called **characters**, which they break down into **character states** to capture the variation in form of that character among the taxa they are studying. In practical usage, the terms "character" and "character state" are often used interchangeably. This practice can be a bit confusing. When the term "character" is used in a discussion of two or more homologues, it is typically being used in the same sense as "character state." Characters and character states

[1]Some biologists consider paraphyly a subset of monophyly, using the term "holophyly" to denote the strictly monophyletic groups. However, this alternative use of these terms is not common, and we do not use it in this book.

[2]There are many examples of previously established groups which are now known or suspected to be polyphyletic. For example, the old phylum Gephyrea contained species that we now classify into three distinct taxa that are only distantly related to one another—Sipuncula, Thalassematidae, and Priapula (the first two are now in the phylum Annelida but are not closely related). Another example is the old group Radiata, which included all animals possessing radial symmetry (e.g., Cnidaria, Ctenophora, and Echinodermata). Most recently, the group called Articulata, containing the Annelida and the Arthropoda (and their kin), has been shown by molecular phylogenetics to be polyphyletic. Polyphyletic taxa usually are established because the features or characters used to recognize and diagnose them are the results of evolutionary convergence in different lineages. Convergent evolution can often be understood only by careful comparative embryological or anatomical studies, sometimes requiring the efforts of several generations of specialists. The complex nature of the probable convergence between annelid and arthropod segmental development, for example, is yet to be fully worked out.

(A)

Characters	Crustacea	Springtails	Silverfish	Dragonflies	Crickets	Beetles	Butterflies
	Taxa						
1. Thorax of only 3 segments, each bearing one pair of legs	No	Yes	Yes	Yes	Yes	Yes	Yes
2. Mouthparts external, not embedded within head	No	No	Yes	Yes	Yes	Yes	Yes
3. Wings present	No	No	No	Yes	Yes	Yes	Yes
4. Wing base with 3rd auxiliary sclerite, allowing wings to fold flat over the abdomen	No	No	No	No	Yes	Yes	Yes
5. Pupal stage present	No	No	No	No	No	Yes	Yes

(B)

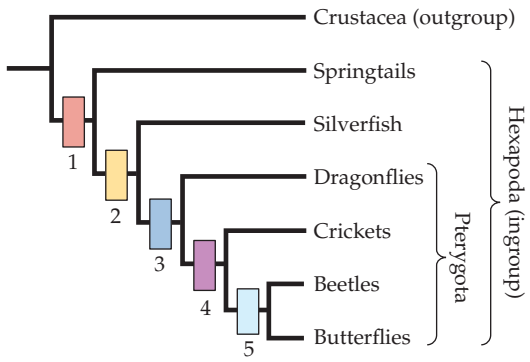

FIGURE 2.4. Example of a data matrix of five characters and seven taxa. The character states for each of the seven taxa are coded in the matrix. If the character is not present within a taxon, the matrix is coded with "no"; if it is present in that taxon, the matrix is coded with "yes" (systematists often use "absence" and "presence" instead of "no" and "yes," and these are represented in matrices as "0" and "1," but additional states may exist in the so-called multistate characters, as opposed to binary ones). These character states are plotted on the corresponding tree to the right along the branch where they change from no to yes. The place where the character state first appears represents an apomorphy for the corresponding ancestral node to the right, and that character state occurs in all the descendants of the ancestor. Among the descendants, manifestations of this character are called homologues, or homologous features. Homologues share a common developmental and evolutionary origin. For example, the presence of wings is an apomorphy of clade Pterygota (and wings are homologous throughout the Pterygota), but the presence of wings is a plesiomorphy of the clade containing only beetles and butterflies. The clade containing only beetles and butterflies is defined by the apomorphy of a pupal stage (representative of complete metamorphosis).

(which are usually either morphological or molecular) are assembled into data matrices (Figure 2.4) in which every character amounts to a hypothesis of homology.

Homologous characters have *shared ancestry.* That is, they are traits that are present in two or more taxa and inherited from their common ancestor. Homologous characters share an evolutionary history. The process of evolutionary descent with modification has produced a hierarchical pattern of homologies that can be traced through lineages of living organisms. It is this pattern that we use to reconstruct the history of life. The functions of homologous structures may be similar or different, but this has no bearing on the underlying homology of the structures involved. Our ability to recognize anatomical homologues often depends on developmental or embryological evidence and on the relative position of the anatomical structure or the nucleotide or amino acids in nucleotide or protein sequences.

Homology is a concept that is applicable to anatomical structures, to genes, and to developmental processes. However, homology at one of these levels does not necessarily indicate homology at another. Biologists should always be clear regarding the level at which they are inferring homology: genes, their expression patterns, their developmental roles, or the structures to which they give rise. Researchers sometimes assume similar patterns of regulatory gene expression are also evidence of homology among structures. This can result in mistakes because it ignores the evolutionary histories of the genes and of the structures in which they are expressed. The functions of homologous genes (orthologues or paralogues), just like those of homologous structures, can diverge from one another over evolutionary time. Similarly, the functions of nonhomologous genes can converge over time. Therefore, similarity of function is not a valid criterion for the determination of homology of either genes or structures. For example, the phenomenon of gene recruitment (co-option) can lead to situations in which truly orthologous genes are expressed in nonhomologous structures during development. Most regulatory genes play several distinct roles during development, and homologous genes can be independently recruited to superficially similar roles. A classic example is the regulatory gene *Distal-less*, which is expressed in the distal portion of appendages of many animals during their embryogeny (e.g., arthropods, echinoderms, chordates). Although the domains of *Distal-less* gene expression might reflect a homologous role in specifying proximodistal axes of appendages, the appendages themselves are clearly not homologous.

Characters are the attributes, or features, of organisms or groups of organisms (clades, taxa) that biologists rely on to indicate their relatedness to other similar organisms and to distinguish them from other groups.

for more ebook/ testbank/ solution manuals requests: email P6012673@qq.com

Characters are the observable features and expressions of the genotype, and they can be anything from the actual amino acid sequences of the genes themselves to the phenotypic expressions of the genotype. A character can be any genetically inherited trait that systematists can examine and measure; it can be a morphological, anatomical, developmental, or molecular feature of an organism, its chromosomal makeup (karyotype) or biochemical "fingerprint," or even a physiological, or ethological (behavioral), attribute—the webs of spiders are a classic example of behavioral traits relatively easy to document. A large number of biochemical, molecular, and bioinformatics techniques for measuring similarity and inferring relationships among organisms have been developed over the past few decades. Thus, a variety of kinds of data are available that provide systematists with homologous characters needed to define and compare species and infer phylogenies.

With the advent of technology for rapid amplification of DNA fragments and sequencing of the nucleic acids, the field of systematics has undergone dramatic change.[3] Questions of evolutionary relationship, which had traditionally been addressed only by comparative anatomy, can now be tested by an independent source of data. Since the 1990s, **molecular phylogenetics** has swept the literature with evolutionary trees built by analyses of gene sequences. Trees built from DNA sequence data have corroborated some relationships previously inferred by analyses of morphological traits, but they also provided support for novel relationships never predicted.[4] In molecular-based data matrices, every column in the aligned matrix represents a character, or a hypothesis of a homologous position in the alignment, and the character states are the specific nucleotides (A, adenine; T, thymine; C, cytosine; and G, guanine) or amino acids that occur in those taxa at those sites, or their inferred insertions or deletions.[5] Every character in a phylogenetic character matrix, whether built from anatomical or genetic data, is a hypothesis of homology.

[3]On February 12, 1988 (by appropriate coincidence, Charles Darwin's birthday), a paper published by Katherine Field, Rudy Raff, and others presented the first credible molecular analysis of metazoan phylogeny based on sequences from the small ribosomal subunit RNA gene (SSU or 18S rRNA). This work initiated a paradigm shift in phylogenetic analysis, and today the field of molecular phylogenetics is rooted in the methods pioneered in that important paper. In 1997, Anna Marie Aguinaldo and colleagues also published a revolutionary paper, proposing a radical new view of animal phylogeny—one that hypothesized the Protostomia to comprise two distinct clades, a "molting clade" (called Ecdysozoa) and a nonmolting clade (called Spiralia in this book).

The first molecular phylogenies were constructed from analyses of ribosomal genes, which code for RNA that forms the 3-D structure of ribosomes (the large ribosomal subunit or 28S rRNA, and the small subunit or 18S rRNA). However, the number of genes used to infer phylogenies increased quickly to include both nuclear and mitochondrial protein-coding genes. Whereas analyses of single genes were the standard only a few years ago, most molecular phylogenetic analyses today use multiple, preferably unlinked, genes concatenated together into one supermatrix. In fact, new and relatively inexpensive DNA sequencing technology, high-throughput sequencing, is allowing for molecular phylogenies to be constructed from larger portions of the genome, up to tens of thousands of genes. Specific regions of the genome can be targeted a priori through methods such as anchored hybrid enrichment or ultraconserved elements, or novel genes of phylogenetic significance can be discovered after shotgun sequencing of all DNA molecules (genomes) or RNA molecules (transcriptomes). No matter what type of genetic data are selected or how they are sequenced, these methods result in rich multigene data sets for phylogenetic inference. Resulting trees are therefore inferred from a larger portion of the genome than previous methods that relied on only a handful of genes, whose history may or may not precisely reflect the history of the taxa being analyzed.

[4]Equally exciting are techniques being developed to extract DNA from fossilized bone, tissue, or dung. In 2003, scientists managed to extract DNA from Siberian permafrost sediments and soils of caves in New Zealand. The Siberian sediments yielded the oldest reliable ancient DNA up to that time, from plants as much as 400,000 years old (angiosperms, gymnosperms, and mosses) as well as from numerous animals, including both living and extinct species up to 30,000 years old. In 2008, the entire genome of the extinct woolly mammoth (*Mammuthus primigenius*) from Siberia was sequenced, showing a sequence identity of over 98% with modern African elephants (the two diverged from one another about 6 million years ago). Also in 2008, DNA was sequenced from lice (Insecta: Phthiraptera: *Pediculus humanus*) preserved in the scalps of 1,000-year-old Peruvian mummies. The lice belonged to a subtype of head and body lice found all over the world, thus proving that human lice were in the New World well before Columbus. Since then, scientists have begun sequencing DNA from even older animals—the oldest so far is from two mammoths older than 1 million years, perhaps pushing the limits of how long DNA can actually survive. By extracting fragments of DNA from ancient soils and sediments (known as "environmental DNA") in North America, scientists have begun to reconstruct Pleistocene and early Holocene ecosystems. The extraction of DNA from 2,000- to 4,000-year-old cores from the Arctic region has yielded a variety of plants, bison, horses, bears, mammoths, and lemmings. Environmental DNA comes from urine, feces, hair, skin, eggshells, feathers, and even the saliva of animals, as well as from the decaying leaves and fine rootlets of plants. Ancient DNA analyses have led to the discovery of new types of ancient humans and revealed interbreeding between our ancestors and our archaic cousins, which left a genetic legacy that shapes who we are today. Much of the genome of Neanderthal has now been sequenced. As a result, we now know that modern *Homo sapiens* carry a remnant of Neanderthal DNA from interbreeding events that have been postulated to have occurred as humans migrated out of Africa and into Eurasia, at least 80,000 years ago.

[5]Not long after the first molecular-based trees were published, it was recognized that analyses of molecular sequence data are prone to predicting erroneous relationships under certain circumstances. Rapidly evolving lineages were inferred to be closely related, regardless of their true evolutionary relationships, due to a phenomenon known as long branch attraction (LBA). Since there are only four possible character states in molecular sequence data (the four nucleotides), when DNA substitution rates are high, there is a high probability that two lineages will *independently* evolve the same nucleotide at the same site by chance alone. In these circumstances, phylogenetic algorithms (especially parsimony methods) erroneously interpret these convergences to be signs of shared ancestry (synapomorphies) and therefore misinterpret taxa on long branches to be close relatives.

Using phylogenetic algorithms that incorporate models of evolution can minimize the LBA problem. These models include three components: (1) models of DNA substitution, which describe the rates at which one nucleotide replaces another over evolutionary time; (2) the relative nucleotide base frequency in a data set; and (3) the relative rates at which sites in an alignment evolve in a data set. Things get more complicated in analysis of data as amino acids, as typically done in many phylogenomic analyses, especially those using transcriptomes, and models become more complex and computationally intensive. Popular evolutionary-model-based algorithms include maximum likelihood and Bayesian methods of phylogenetic estimation.

Apomorphy and Plesiomorphy

Monophyletic groups (or clades) are defined only by apomorphies. **Apomorphies** are shared, derived character states, and they stand in opposition to **plesiomorphies**, which are relatively older states (or forms) of that character.[6] An apomorphy is only an apomorphy *at one specific place* in a phylogeny, along the branch in the tree in which the character state evolved. At the specific point on a phylogenetic tree where such a transformation takes place, the new (derived) character state is called an **apomorphy** and the former (ancestral) state is called a **plesiomorphy**. Character states can be apomorphic in one place in the tree and plesiomorphic in another. Within Arthropoda, for example, having just three thoracic segments, each bearing one pair of legs, is a derived character state whose evolutionary appearance marked the origin of the Hexapoda (thus distinguishing them from all other arthropods) (Figure 2.4). But for groups or lineages *within* the Hexapoda, such as the Pterygota, these same features represent retained ancestral features (plesiomorphies), whereas having wings is a shared, derived trait (or apomorphy) for the clade Pterygota. In the most general sense, so-called **primitive character states** are attributes of lineages that are relatively older and have been retained from some more distant ancestor; in other words, they have been around for a longer time relative to the apomorphic state, geologically or genealogically speaking.

In sum, systematists aim to document biodiversity by recognizing the boundaries of natural lineages and describing them by inferring the shape of the tree of life and building systems to classify species that reflect that evolutionary history. They do this by analyzing homologous characters to build a phylogeny, with each clade in that phylogeny defined by at least one apomorphy, or shared derived character state. It seems fairly straightforward, so why is this process so difficult? The answer to that question boils down to the fact that we cannot always recognize homologous characters, so there are many chances for error as we seek to obtain the shape of the one true tree of life.

Challenges of Phylogenetic Inference

Attempts to relate two taxa by comparing nonhomologous characters will result in errors. For example, the hands of chimpanzees and humans are homologous characters (i.e., homologues) because they have the same evolutionary and developmental origin; the wings of bats and insects, although similar in some ways, are not homologous characters because they have completely different origins. In a strict sense, the concept of homology has nothing to do with similarity or degree of resemblance. Some homologous features look very different in different taxa (e.g., the pectoral fins of whales and the arms of humans; the forewings of beetles and those of flies). Again, the concept of homology is related to the level of analysis being considered. The wings of bats and birds are homologous as tetrapod forelimbs, but they are not homologous as "wings," because wings evolved independently in these two groups (i.e., the wings of bats and birds do not share a common ancestral wing). Homology is a powerful concept, but it is important to remember that homologies are really hypotheses, open to testing and possible refutation.

Through **convergent evolution**, similar-appearing (but nonhomologous) structures may evolve in distantly related groups of organisms in quite different ways; that is, they have separate genetic and developmental origins. For example, early biologists were misled by the superficial similarities between the vertebrate eye and the cephalopod eye, the bivalve shells of molluscs and of brachiopods, and the sucking mouthparts of true bugs (Hemiptera) and of mosquitoes (Diptera). Structures such as these, which appear superficially similar but that have arisen independently and have separate genetic and phylogenetic origins, are called **convergent characters**. There are both ecological and genomic explanations for the evolution of morphological similarity. Through the phenomenon of convergent evolution, similar-appearing structures may arise independently, with separate genetic and developmental origins, in response to the same ecological factors. Convergent traits (among both animals and plants) have been recognized at nearly all levels of biological organization, ranging from molecules to morphology to behavior.

One of the most interesting cases of convergent evolution is the recently discovered analogies between voice and vocal learning in some mammals and birds (vocal learning is the ability to imitate sounds). Not only have the vocal regions of certain bird and mammal brains converged in their anatomy, but more than 50 genes have contributed to their convergent specialization—convergent behavior and neural circuits for vocal learning are accompanied by convergent molecular changes of multiple genes in species separated by millions of years from a common ancestor.

Convergence is often confused with **parallelism**. **Parallel characters** are similar features that have arisen more than once in different species but that share a common genetic and developmental basis. Parallel evolution is the result of "distant" or underlying homology; for parallel evolution to occur, the genetic potential for certain features must persist within a group, thus allowing the feature to appear and reappear in various related species or groups of species. Parallelism might be thought of as a kind of "evolutionary repeatedness."[7] Failure to

[6] Apomorphies that are shared by two or more taxa are sometimes referred to as synapomorphies; plesiomorphies shared by two or more taxa are sometimes referred to symplesiomorphies.

[7] Parallelism in this context is not to be confused with the evolution of species (or characters within species) "in parallel," that is, when two species (or characters) change more or less together over time. Host-parasite coevolution is an example of "evolution in parallel."

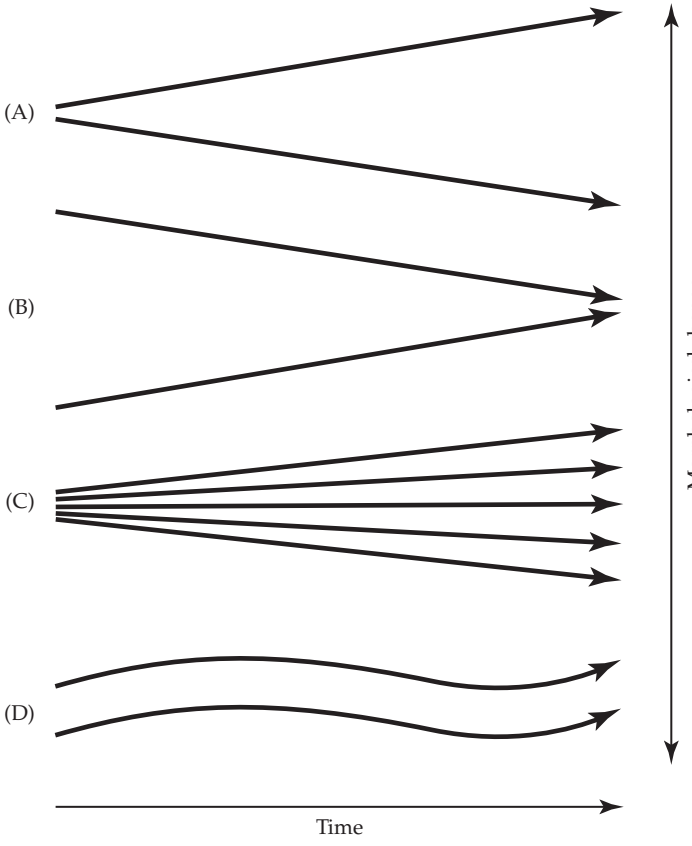

FIGURE 2.5 Common patterns of evolution displayed by independent lineages. (A) Divergence occurs when two or more lineages (or characters) evolve independently to become less similar. (B) Convergence occurs when two or more lineages (or characters) evolve independently toward a similar state. Convergence generally refers to very distantly related taxa and to characters sharing no common genetic (phylogenetic or ontogenetic) basis. (C) Radiations occur when a species gives rise to more than two descendant lineages. (D) Parallel evolution occurs when two or more species (or lineages) change similarly so that, despite evolutionary activity, they remain similar in some ways. Parallelism generally refers to closely related taxa, usually species, within which the characters or structures in question share a common genetic basis.

recognize convergences (and parallelisms) among different groups of organisms has led to the creation of "unnatural," or polyphyletic, taxa in the past (Figure 2.3). For example, the intracellular parasites known as Myxozoa were long thought to be protists, but they have recently been shown to be highly specialized parasitic cnidarians. These and some other groups (e.g., yeasts) mistakenly classified among the Protista made protists a polyphyletic group; removal of those nonprotistan taxa has left the Protista a paraphyletic group (a natural group, with a single origin, but from which animals, plants and fungi, which are nested within, are excluded). Parallelism is commonly encountered in characters of morphological "reduction," such as reduction in the number of segments, spines, fin rays, and so on or in the loss of vision and pigmentation in many different kinds of animals.

Another phenomenon complicating phylogenetic inference is **evolutionary reversal**, wherein a feature reverts back to a previous, ancestral condition. Together, these three evolutionary processes (convergence, parallelism, reversal) constitute the phenomenon known as **homoplasy**—the recurrence of similarity in evolution (Figure 2.5). As you might guess, for systematists, homoplasy can be both fascinating and frustrating!

When comparing homologues among species, one quickly sees that variation in the expression of a character is the rule, rather than the exception. A character may have only two contrasting character states, or it may have several different states. A simple example is hair color in humans; black, brown, red, and blond are all discrete states of the character "hair color" (to make things more complicated, we could treat the character as a "continuous character," with an infinite number of states reflecting all possible colors from white to black). Not only can characters vary within a species, they also typically have several states among groups of species within higher taxa, such as patterns of body hair among various primates or the spine patterns on the legs of crustaceans.

It is important to understand that what we designate a "character" is really a hypothesis that the attributes that appear different in different organisms are simply alternative states of the same feature (i.e., they are homologues). Note that convergences are not homologies, whereas parallelisms and reversals do represent an underlying genetic homology. In other words, some kinds of homoplastic characters are homologues, and others are not. The recognition and selection of proper characters is clearly of primary importance in systematics and phylogenetics, and a great deal has been written on this subject. Systematics is, to a great extent, a search for the homologues that define natural evolutionary lineages. Most recently, great efforts have been made to define homologous gene sequences that can serve as reliable characters to infer relationships among species.

Constructing Phylogenies

Our classifications will come to be, as far as they can be so made, genealogies.

Charles Darwin, *The Origin of Species*, 1859

From what you have read so far in this chapter, it should be evident that comparative biologists, particularly systematists, spend a great deal of their time seeking to identify and unambiguously define two natural entities: homologous characters and monophyletic groups (i.e., clades). Biologists may present their ideas on such matters of relationship in the form of trees, classifications, or narrative discussions (evolutionary scenarios). In all three contexts, these presentations represent sets of evolutionary hypotheses—hypotheses of common ancestry (or ancestor-descendant relationships).

Patterns of relatedness are usually displayed by biologists in branching diagrams called trees, and these are the least ambiguous (most testable) way to present evolutionary hypotheses, although it is now recognized that for some organisms networks may be better representations of relationships than trees, especially in organisms with rampant genome recombination. Once constructed, such trees can then be converted into classification schemes, which are dynamic ways of representing our understanding of the history of life on Earth. Thus, trees and classifications are actually hypotheses of the evolution of life and the natural order it has created. Although classification schemes are ultimately derived from phylogenetic trees, they do not always reflect precisely the arrangement of natural groups in the trees. Discrepancies between phylogenetic trees and classifications derived from them most commonly occur when biologists choose to establish or recognize paraphyletic taxa. Thus, to recognize the protists as a distinct taxon (the kingdom Protista) would be to recognize a paraphyletic group (because it excludes three large lineages that descended from it—animals, plants, and fungi). Whereas most systematists advocate that only monophyletic taxa be recognized in a formal classification, many paraphyletic taxa persist in animal classification, for convenience or tradition or because they are simply not yet known to be paraphyletic (there are probably thousands of taxa for which we do not yet know whether they are monophyletic or paraphyletic). For example, the long-recognized group Reptilia is paraphyletic because it excludes one of that group's most distinct lineages, the birds. The subphylum Crustacea is paraphyletic because it omits the Hexapoda (insects and their kin), which evolved from within the crustaceans long ago. And, of course, the group "Invertebrata" is a paraphyletic group—it is Metazoa excluding the vertebrates. Even Prokaryota is a paraphyletic group (the Eukaryota evolved out of it). In fact, taxonomic groups at all levels are likely to have been derived from within other taxonomic groups, leaving the latter paraphyletic, and we are beginning to discover that paraphyly abounds in the Linnean hierarchy of life that has been built over the past centuries. The issue of how to deal with such long-standing, well-known paraphyletic taxa in classification schemes is still being debated. One way of doing this might be to indicate their paraphyletic status by a code in the classification scheme (e.g., some type of notation beside the name). This code would inform readers that to view the precise phylogenetic relationships of such taxa, they must look to the phylogenetic tree.

Biologists today use a method known as **phylogenetic systematics** (or **cladistics**) when inferring patterns of evolutionary relationships. Phylogenetic systematics had its origin in 1950 in a book by the German biologist Willi Hennig; the English translation (with revisions) appeared in 1966. Its popularity has grown steadily since that time. Through the years, **phylogenetic systematics** has evolved well beyond the framework Hennig originally proposed. Its detailed methodology has been formalized and expanded and will certainly continue to be elaborated for some time to come. The goal of phylogenetic systematics is to produce explicit and testable hypotheses of genealogical relationships among monophyletic groups of organisms. As a systematic methodology, it is based entirely on recency of common descent (i.e., genealogy). The trees used by phylogenetic systematists are constructed to depict only genealogy, or ancestor-descendant relationships. The term **cladogenesis** refers to splitting; in the case of biology, this means the splitting of one species (or one lineage) into two or more species (or lineages). It is this splitting process that produces genealogical (ancestor-descendant) relationships.

Phylogenetic inference can be a time-consuming process. The number of mathematically possible trees (of all branching patterns) for more than a few species is enormous—for three taxa there are only four possible rooted trees, but for ten taxa there are 34 million possible rooted trees. Needless to say, such analyses are not possible without the aid of computers. Algorithms for computer-assisted tree construction began appearing in the late 1970s, and today the development of such programs comprises an entire field of research.

Phylogenetic systematists generally use either the principle of parsimony[8] or maximum likelihood to select the optimal tree from among the set of all possible trees and thus select the tree with the fewest evolutionary transformations (character state changes) or with an optimized likelihood score. The use of gene sequence

[8]Parsimony is a method of logic in which economy in reasoning is sought. The principle of parsimony, also known as Ockham's razor, has strong support in science. William of Ockham (Occam), the fourteenth-century English philosopher, stated the principle as "plurality must not be posited without necessity." A modern rendering would read, "An explanation of the facts should be no more complicated than necessary" or "Among competing hypotheses, favor the simplest one." Scientists in all disciplines follow this rule daily, and it can be viewed as a consequence of deeper principles that are supported by statistical inferences. Thus, parsimonious solutions or hypotheses are those that explain the data in the simplest way. Evolutionary biologists rely on the principle of logical parsimony for the same reason other scientific disciplines rely on it: doing so presumes the fewest ad hoc assumptions and produces the most testable (i.e., the most easily falsified) hypotheses. If evidential support favored only one hypothesis, we would have little need for parsimony as a method. The reason we must rely on parsimony in science is that there is virtually always more than one hypothesis that can explain our data. Parsimony considerations come into play most strongly when a choice must be made among equally supported hypotheses.

In phylogenetic reconstruction, any given data set can be explained by a great number of possible trees. A three-taxon data set has 3 possible dichotomous (all lines divide into just two branches) trees that explain it. A four-taxon data set has 15 possible dichotomous trees, a five-taxon data set has 105 possible dichotomous trees, and so on. Thus, the evidence alone does not sufficiently narrow the class of admissible hypotheses, and some extra-evidential criterion (parsimony) is required. Again, the virtue of choosing the shortest (i.e., most parsimonious) tree among a universe of possible trees—the one that requires the fewest character transformations—lies in its testability. William of Ockham, by the way, also denied the existence of universals except in the minds of humans and in language. This notion resulted in a charge of heresy from the Roman Catholic Church, after which he fled and, alas, died of the plague.

for more ebook/ testbank/ solution manuals requests: email 9601267346@qq.com

data has spawned a new family of model-based methods that incorporate hypotheses of nucleotide evolution (see Footnote 5). In these methods (i.e., maximum likelihood, distance methods, and Bayesian analyses), DNA nucleotide (or protein) sequences from organisms in the study group are analyzed within a framework of assumptions based on our understanding of how nucleotides (or amino acids) operate and change over time.

By identifying the precise points at which apomorphies occur, phylogenetic trees unambiguously define monophyletic lineages. Hence, these trees are **explicit phylogenetic hypotheses**. Being explicit, they can be tested (and potentially falsified) by anyone. Apomorphies are markers that identify specific places in the tree where new monophyletic taxa arise. For phylogenetic systematists, a phylogeny consists of a genealogical branching pattern expressed as a phylogenetic tree. Each split or dichotomy within the tree produces a pair of newly derived taxa called **sister taxa**, or sister groups (e.g., "sister species"). Sister groups always share an immediate common ancestor. In Figures 2.1 and 2.2, A is the sister group of B + C; D is the sister of E + F; and A + B + C is the sister group of D + E + F.

All of the trees in Figures 2.1 and 2.2 are fully dichotomous. That is, only two branches emerge from each internal node. Sometimes, trees include a **polytomy**, when more than two branches emerge from a node. Polytomies (or multifurcations) can have several different meanings. In this textbook (and most commonly in the literature) polytomies represent uncertainty about the precise evolutionary relationships among the members; it is unclear who is the exact sister group of whom. For example, we are uncertain about whether Porifera or Ctenophora is the sister group to all other animals, and in Figure 28.1 we represent this uncertainty as a polytomy at the base of the tree of Metazoa.

Like all scientific hypotheses, phylogenetic analyses and their resulting trees are tested by the discovery of new data. As new characters or new species are identified and their character states elucidated, new data matrices are developed, and new analyses are undertaken. The first molecular phylogenetic trees were based on a single gene fragment. But as techniques improved, these trees were tested with multiple gene sets and, eventually, with entire genomic data sets. Hypotheses (branches of the tree) that consistently resist refutation are said to be highly corroborated. For example, the clade called Arthropoda has been examined in thousands of analyses using a great variety of data, and it has consistently been shown to constitute a monophyletic group (i.e., it is a highly corroborated phylogenetic hypothesis).

Biological Classification

And you see that every time I made a further division, up came more boxes based on these divisions until I had a huge pyramid of boxes. Finally you see that while I was splitting the cycle up into finer and finer pieces, I was also building a structure. This structure of concepts is formally called a hierarchy and since ancient times has been a basic structure for all Western knowledge.

Robert M. Pirsig
Zen and the Art of Motorcycle Maintenance, 1974

Classifications are necessary for several reasons, not the least of which is to efficiently catalog the enormous number of species of organisms on Earth. Nearly 2 million species of prokaryotes and eukaryotes have been named and described (and a great many more remain undescribed). The insects alone comprise nearly a million named species, and over 380,000 of those are beetles! Classifications provide a detailed system for storage and retrieval of these names. The second, and most important, reason to evolutionary biologists is that classifications serve a descriptive function. This function is served not only by the descriptions that define each taxon, but also, as noted earlier, by the detailed hypotheses of evolutionary relationships among the organisms that inhabit Earth. In other words, classifications are (or should be) constructed from evolutionary relationships and capture the patterns of ancestry and descent depicted in phylogenetic trees.

The construction of a classification may at first appear straightforward. Specimens are grouped into species; related species are grouped into genera (sing., genus); related genera are grouped into families; and so forth. The grouping process creates a system of subordinated, or nested, taxa arranged in a hierarchical fashion following basic set theory (Figure 2.6). If the taxa are properly grouped, following the pattern in a phylogenetic tree (i.e., on the basis of shared derived characteristics), the hierarchy will reflect patterns of evolutionary descent. These hierarchical categories (or ranks) are commonly used for the biological classification of animals:

Kingdom
Phylum
Class
Cohort
Order
Family
Tribe
Genus
Species

Thus, the common eastern Pacific sea star *Pisaster giganteus* is classified as follows:

Category	**Taxon**
Phylum	Echinodermata
Subphylum	Asterozoa
Class	Asteroidea
Order	Forcipulatida
Family	Asteriidae
Genus	*Pisaster*
Species	*Pisaster giganteus*

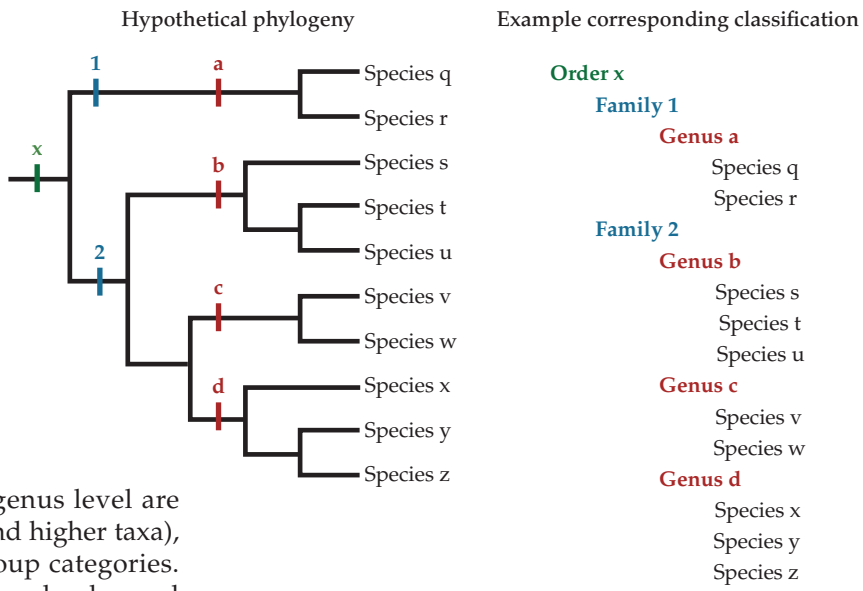

FIGURE 2.6. Phylogenies and classifications. In this phylogeny (left) ten species occur in four possible monophyletic groups (a, b, c, d), but note that b and d could be further subdivided. These four lineages, in turn, derive from two monophyletic groups (1, 2), which in turn derive from a single common ancestor (X). The classification (right) depicts one potential classification that reflects these relationships.

All categories (and taxa) above the genus level are referred to as the higher categories (and higher taxa), as distinguished from the species group categories. Taxonomic ranks may have super-, and sub-, and infracategories as well, for example, superorder, suborder, infraorder.

Converting a phylogeny into a biological classification is not always straightforward. Molecular phylogenetics, in particular, has greatly added to our understanding of animal evolution, and it is also allowing us to generate large and highly detailed phylogenetic trees, with long branching patterns depicting the history of life on Earth (e.g., Figure 2.7). Such detail creates challenges for biologists who like to produce classifications that accurately reflect phylogeny, because the traditional Linnean hierarchical ranks are too few in number to capture the great depth and detail of these trees. Many of the new multigene or genomic trees have scores of branching points, or even hundreds of branches that appear as long comblike topologies. But the standard Linnean ranks number only nine or ten, or about four times that, at best, when the prefixes super-, sub-, and infra- are also used.

There are a few solutions to this dilemma, but none of them is perfect (Figure 2.8). The most straightforward solution is to not use ranks at all in the classification, instead just indenting the subordinated groups in ways that reflect the phylogeny—an **unranked classification** (Figure 2.8, classification scheme B). Another solution is the phylogenetic sequencing convention, described previously. A third solution (and probably still the most frequently seen) is to create classifications that *do not* precisely mirror the phylogeny, referring readers to the tree if they want to understand the precise relationships of the taxa in a classification. Unranked classifications are useful when the phylogeny of a group is still quite poorly known (e.g., Chapters 15, Annelida, and 13, Mollusca). Fully ranked classifications can get cumbersome when "pushed to the limit" of available taxonomic categories (e.g., Chapter 17, Platyhelminthes). The upshot is, things are changing and the "traditional" classification schemes of the twentieth century are beginning to look rather different these days. In this book, we mostly use ranked classifications that mirror, or at least do not conflict with, the phylogeny of the groups in question. In a few instances, we have had to use fully or partly unranked classifications (e.g., annelids and molluscs).

Further confusion is added when names that have been used for many decades are difficult to discard. Some of these **legacy names** have been redefined to represent monophyletic groups, or clades, such as Protostomia and Deuterostomia. Others, however, are now known to represent nonmonophyletic groups, yet the names have not yet disappeared from textbooks and the scientific literature; for example, the gastropod group "heteropods" (which is a polyphyletic group of pelagic gastropods with laterally compressed translucent bodies and reduced or lost shells), and the arthropod group Crustacea (a paraphyletic group). In this book, as a general rule we recognize only monophyletic groups, and we point out the few instances where we make exceptions.

FIGURE 2.7 This phylogenetic tree of hexapod relationships (Misof et al. 2014) illustrates the challenges of converting large molecular-based phylogenies into classifications. The tree includes over 130 hexapod nodes. In order to erect a classification based on this tree, decisions must be made as to which nodes (clades) to name, whether or not to limit the named clades to the 30 or so traditional Linnean ranks or use unranked names, and whether to make the classification perfectly match the phylogeny. To see one way of dealing with these classification issues, see Chapter 22 (Hexapoda). Note that the seven members of Crustacea included in the analysis are shown to be a paraphyletic cluster at the base of the hexapod clade (i.e., "Crustacea" is a paraphyletic grouping; Chapter 21) and that the sister group of Hexapoda is the crustacean clade Remipedia. Note also that this is a dated phylogeny (the time scale, in millions of years, is shown at the top and bottom of the figure). (From B. Misof et al. 2014. *Science* 346: 763–767. Reprinted with permission from AAAS.)

Classification scheme A

Phylum Chordata
- Subphylum Vertebrata
  - Class Pisces (fishes)
  - Class Amphibia (amphibians)
  - Class Reptilia (turtles, crocodilians, snakes, lizards)
  - Class Aves (birds)
  - Class Mammalia (mammals)

Classification scheme B

Phylum Chordata
- Vertebrata
  - Tetrapoda
    - Lissamphibia (amphibians)
    - Amniota
      - Mammalia (mammals)
      - Sauropsida (Reptiliomorpha)
        - Anapsida (turtles)
        - Diapsida
          - Lepidosauria (snakes, lizards)
          - Archosauria
            - Crocodilia (crocodilians)
            - Aves (birds)

FIGURE 2.8. Converting a tree into a classification scheme. Vertebrates offer a well-known example of how different a phylogenetic classification may look from a traditional classification. The tree in this figure depicts a popular view of relationships among the major groups of living vertebrates. Classification scheme A depicts a traditional classification of the vertebrates, still seen in many books, in which crocodilians are classified with lizards, snakes, and turtles in the taxon Reptilia, while birds are retained as a separate taxon, Aves. In this classification, the class Reptilia is paraphyletic (because it excludes the birds). Classification scheme B strictly reflects the phylogenetic tree, mirroring the branching pattern with subordinated taxa (unranked in this case); thus, the reptiles are broken into separate taxa in recognition of their genealogical relationships—the snakes and lizards (Lepidosauria) are classified together as a separate sister group to Archosauria (crocodilians and birds).

Nomenclature

The names employed within classifications are governed by rules and recommendations that are analogous to the rules of grammar that govern European languages. The most fundamental goals of **biological nomenclature** are the creation of classifications in which (1) any single kind of organism has one and only one correct name, and (2) no two kinds of organisms bear the same name. All of the codes of nomenclature for the various groups of life address these two fundamental requirements. Nomenclature is an important tool of biologists that facilitates communication and stability.[9]

Prior to the mid-1700s, animal and plant names consisted of one to several words or often simply a descriptive phrase. In 1735, at the age of just 28, the great Swedish naturalist Carl von Linné (Carolus Linnaeus, in the Latinized form he preferred) established a system of naming organisms now referred to as **binomial nomenclature**. Linnaeus's system required that every organism have a two-part scientific name, that is, be a **binomen**. The two parts of a binomen are the generic, or genus, name and the specific name, or specific epithet. For example, the scientific name for one of the common Pacific coast sea stars is *Pisaster giganteus*. These two names together constitute the binomen; *Pisaster* is the animal's generic (genus) name, and *giganteus* is its **specific epithet**. The specific epithet is never used alone, but must be preceded by the generic name, and the animal's "species name" is thus the complete binomen. Use of the first letter of a genus name preceding the specific epithet is also acceptable once the name has appeared spelled out on the page or in a short article (e.g., *P. giganteus*).

The 1758 version of Linnaeus's system was the tenth edition of his famous *Systema Naturae*, in which he listed all animals known to him at that time and included critical guidelines for classifying organisms. Linnaeus distinguished and named over 4,400 species of animals, including *Homo sapiens*. Linnaeus's *Species Plantarum* (in which he named over 8,000 species) did the same for the plants in 1753. Linnaeus was one of the first naturalists to emphasize the use of similarities among species (or among other taxa) in constructing a classification, rather than the use of differences between them. In doing so, he unknowingly began classifying organisms by virtue of their genetic, and hence evolutionary, relatedness. Linnaeus produced

[9] We generally avoid using common, or vernacular, names in this book, simply because they are frequently misleading. Most invertebrates have no specific common name, and those that do typically have more than one name. For example, several dozen different species of sea slugs are known as "Spanish dancers." All manner of creatures are called "bugs," most of which are not true bugs (Hemiptera) at all, for example, "ladybugs," "sowbugs," "potato bugs," and so on. Recently, there has been a movement to codify common names, in an attempt to establish a single preferred vernacular for any given species. This movement is taking place mainly among vertebrate specialists, and there is, as yet, no widely accepted initiative to do this for invertebrates.

his *Systema Naturae* 100 years prior to the appearance of Darwin and Wallace's theory of evolution by means of natural selection (1859), and thus his use of similarities in classification foreshadowed the subsequent emphasis by biologists on evolutionary relationships among taxa. Linnaeus was granted nobility in 1761 (and became Carl von Linné); he died in 1778.

Binomens are Latin (or Latinized) because of the custom followed in Europe prior to the eighteenth century of publishing scientific papers in Latin, the universal language of the educated people of the time. For several decades after Linnaeus, names for animals and plants proliferated, and there were often several names for any given species (different names for the same species are called **synonyms**). The name in common use was usually the most descriptive one, or often it was simply the one used by the preeminent authority of the time. In addition, some generic names and specific epithets were composed of more than one word each. This lack of nomenclatural uniformity led, in 1842, to the adoption of a code of rules formulated under the auspices of the British Association for the Advancement of Science, called the Strickland code. In 1901 the newly formed International Commission on Zoological Nomenclature adopted a revised version of the Strickland code, called the **International Code of Zoological Nomenclature** (**ICZN**). Botanists had adopted a similar code for plants in 1813, the *Théorie Élémentaire de la Botanique*, which became in 1930 the International Code of Botanical Nomenclature (there is also a separate but complementary code for cultivated plants). Since then, it has been revised as the International Code of Nomenclature for Algae, Fungi, and Plants. There is also an International Code of Nomenclature of Bacteria.

The ICZN established January 1, 1758 (the year the tenth edition of Linnaeus's *Systema Naturae* appeared), as the starting date for modern zoological nomenclature. Any names published the same year, or in subsequent years, are regarded as having appeared after the *Systema*. The ICZN also slightly changed the description of Linnaeus's naming system, from binomial nomenclature (names of two parts) to **binominal nomenclature** (names of two names). However, one still sees the former designation in common use. This subtle change implies that the system must be truly binary; that is, both genus and species epithet names can be only one word each. Although the system is binary, it also accepts the use of subspecies names, creating a **trinomen** (three names) within which is contained the mandatory binomen. For example, the sea star *Pisaster giganteus* is known to have a distinct form occurring in the southern part of its range, which is designated as a subspecies, *Pisaster giganteus capitatus*. All codes of biological nomenclature share the following five basic principles:

1. Botanical, bacterial, and zoological codes are independent of each other. It is therefore permissible, although not recommended, for a plant genus and an animal genus to bear the same name (e.g., *Aotus* is the generic name of both golden peas and night monkeys).
2. A taxon can bear one and only one correct name.
3. No two genera within a given code can bear the same name (i.e., generic names are unique), and no two species within one genus can bear the same name (i.e., binomens are unique).
4. The correct or valid name of a taxon is based on priority of publication (first usage), with a few exceptions for very old names that have not been in use for a long period of time.
5. For the categories of superfamily in animals and order in plants, and for all categories below these, taxon names must be based on type specimens, type species, or type genera.[10]

When strict application of a code results in confusion or ambiguity, problems are referred to the appropriate commission for a "legal" decision. Rulings of the International Commission on Zoological Nomenclature are published regularly in its journal, the *Bulletin of Zoological Nomenclature*. Note that the international commissions rule only on nomenclature or "legal" matters, not on questions of scientific or biological interpretation; these latter problems are the business of systematists. Obviously, the correct name of a species (and any future changes in that name) has great importance to all fields of biology (e.g., ecology, conservation biology, physiology) and also in the field of law, where many environmental decisions are made today, because scientists (and governments) must know the correct names of their study organisms in order to communicate about them.

Names given to animals and plants are usually descriptive in some way, or perhaps indicative of the geographic area in which the species occurs. Others are named in honor of persons for one reason or another. Occasionally one runs across purely whimsical names, or even names that seem to have been formulated for seemingly diabolical reasons.[11]

The **biological species definition** (or genetic species concept), as codified by Ernst Mayr, defines species as groups of interbreeding (or potentially interbreeding)

[10]When a systematist first names and describes a new species, she or he takes a "typical" or representative individual, declares it a type specimen, and deposits it in a safe repository such as a large natural history museum. If later workers are ever uncertain about whether they are working with the same species described by the original author, they can compare their material to the type specimen. Although of substantially less value, the designation of a "typical" or type species for a genus, or a type genus for a family, serves a somewhat similar purpose in establishing, a "typical" species or genus upon which a genus or family is based.

natural populations that are reproductively isolated from other such groups. Obviously, this definition fails to accommodate nonsexual species. George Gaylord Simpson and Edward O. Wiley developed the **evolutionary species concept**, which states that a species is a single lineage of ancestor-descendant populations that maintains its identity separate from other such lineages and that has its own evolutionary tendencies and historical fate. In reality, of course, biologists rely heavily on morphological aspects of organisms and on gene sequence data as surrogates in gauging these conceptual views of species. That is, we conceive of species as genetic or evolutionary entities, but we recognize them primarily by their phenotypic or gene sequence characters. Hence, an understanding of such characters is of great importance; read on.

Higher taxa (categories and taxa above the species level) are natural groups of species (or lineages) chosen by biologists for naming in order to reflect our state of knowledge regarding their evolutionary relationships. Higher taxa, if correctly constructed, represent ancestor-descendant lineages (clades) that, like species, have an origin, a common ancestry and descent, and eventually a death (extinction of the lineage); thus they too are evolutionary units with definable boundaries. There are no rules for how many species should make up a genus—only that it be a natural group. Nor are there rules about how many genera constitute a family, or whether any group of genera should be recognized as a family, or a subfamily, or an order, or any other categorical rank. What matters is simply that the named group (the taxon) be a natural group. Hence, it is incorrect to assume that families of insects are in some way evolutionarily comparable to families of molluscs, or orders of worms comparable to orders of crustaceans. Nor are there any rules about categorical rank and geological or evolutionary age. These aspects of higher taxa are often misunderstood. Interestingly, this being said, family-level taxa often tend to be the most stable taxonomic groupings, usually recognizable even to laypersons—think, for example, of cats (Felidae), dogs (Canidae), abalone (Haliotidae), ladybird beetles (Coccinellidae), mosquitoes (Culicidae), octopuses (Octopodidae), or weevils (Curculionidae). This stability seems to be an artifact of the history of taxonomy, but it nonetheless makes families convenient higher taxa to study and discuss. However, biologists err when they compare equally ranked higher taxa from different groups in ways that presuppose them to be somehow equivalent.

---

[11] Among the many clever names given to animals are *Agra vation* (a tropical beetle that was extremely difficult for Dr. Terry Erwin to collect) and *Lightiella serendipida* (a small crustacean; the generic name honors the famous Pacific naturalist S. F. Light, 1886–1947, while the species epithet is taken from "serendipity," a word coined by Walpole in allusion to the tale of "The Three Princes of Serendip," who in their travels were always discovering, by chance or sagacity, things they did not seek—the term is said to aptly describe the circumstances of the initial discovery of this species). There are actually over 500 described species of *Agra* (those carabid beetles known as "elegant canopy beetles"), including *Agra eponine*, named after the street urchin in *Les Miserables* who, in the Broadway version of the story, personified tragic beauty ("such is the state of the tropical forests where these beetles live," according to Dr. Erwin, who also named this species). Another of Erwin's names is *Agra ichabod*, referring to the fact that the holotype is missing its head, the allusion referring to the frightened schoolteacher Ichabod Crane's phantom nemesis, the Headless Horseman, in "The Legend of Sleepy Hollow." The nineteenth-century British naturalist W. E. Leach erected numerous genera of isopod crustaceans whose spellings were anagrams of the name Caroline. Exactly who Caroline was (and the nature of her relationship with Professor Leach) is still being debated, but the prevailing theory implicates Caroline of Brunswick, who was in the public eye at this time in history. It is said that Caroline was badly treated by her husband (the Prince Regent, later George IV) and that she was herself a lady of questionable fidelity. Leach, from Devon, may have taken the side of support for Caroline by honoring her with a long series of generic names, including *Cirolana*, *Lanocira*, *Rocinela*, *Nerocila*, *Anilocra*, *Conilera*, *Olincera*, and others.

A light-hearted attitude toward naming organisms has not always been without Freudian overtones, as there also exist *Thetys vagina* (a large, hollow, tubular pelagic salp), *Succinea vaginacontorta* (a hermaphroditic snail whose vagina twists in corkscrew fashion), *Phallus impudicus* (a slime-covered mushroom), and *Amanita phalloides* and *Amanita vaginata* (two species of highly toxic mushrooms around which numerous Indigenous ceremonies and legends exist). *Humbert humberti* is a wasp named after Vladimir Nabokov's Humbert Humbert, the narrator in the great novel *Lolita* who was obsessed with his 12-year old, soon-to-be stepdaughter. *Crepidula fornicata* is a hermaphroditic slipper shell (gastropod) that forms stacks of alternating male- and female-functioning individuals (males on top turn into females as they grow). Injecting a lyrical dose of sexual innuendo into taxonomy is not new. Linnaeus himself incorporated a few good zingers into his writings and, in fact, drew parallels between plant sexuality and human love. In 1729 he wrote of flower petals, "[These] serve as bridal beds which the Creator has so gloriously arranged, adorned with such noble bed curtains, and perfumed with so many soft scents, that the bridegroom with his bride might there celebrate their nuptials with so much the greater solemnity." Such sexually explicit writing (in the early eighteenth century) did not go uncriticized, and Linnaeus had his detractors. The German botanist Johann Siegesbeck (a Demonstrator at the Botanical Garden at St. Petersburg) called it "loathsome harlotry" and commented, "Who would have thought that bluebells, lilies, and onions could be up to such immorality?" Linnaeus had his revenge, however, when he named a small, ugly, foul-smelling, mud-inhabiting European weed (St. Paul's wort) *Siegesbeckia*.

Other fun names include *Upupa epops*, euphoniously named for the call of the hoopoe (a bird), and the fish *Zappa confluentus*, which was named by a fan of Frank Zappa. The Grateful Dead have a fly named in their honor (*Dicrotendipes thanatogratus*). And there is the vampire squid *Vampyroteuthis infernalis* (the "vampire squid from hell"), a bivalve named *Abra cadabra*, a blood-sucking spider *Draculoides bramstokeri*, and a wasp *Aha ha*. Even Linnaeus created a curious name for a common ameba, *Chaos chaos*. And, in a stroke of whimsy, the entomologist G. W. Kirkaldy created the bug genera *Polychisme* ("Polly kiss me"), *Peggichisme*, *Marichisme*, *Dolychisme*, and *Florichisme*. There are fish genera named *Zeus*, *Satan*, *Zen*, *Batman*, and *Sayonara*. There are insect genera named *Cinderella*, *Aloha*, *Oops*, and *Euphoria*; the siboglinid genus *Bobmarleya*; and a lucinid clam with a periostracum looking like dreadlocks named *Rasta*. The spider genus *Orsonwelles* contains such species as *O. macbeth* and *O. othello*. Some other clever binomens include *Leonardo davincii* (a moth), *Phthiria relativitae* (a fly), and *Ba humbugi* (a snail). A few biologists have gone overboard in erecting names for new animals, and many binomens exceed 30 letters in length, including *Strongylocentrotus droebachiensis* (32 letters), for the common North Pacific sea urchin, and *Lagenivaginopseudobenedenia*, a 27-letter genus name for a group of monogenean flukes.

Chapter Summary

In this chapter we have introduced you to the field of systematics, the oldest and most foundational field among the biological sciences. The main goal of systematists is to describe and organize the many forms of life in evolutionarily meaningful ways, whether those genetic linkages are depicted as a branching diagram (or phylogenetic tree) or a nested list (classification). This task would be straightforward if we knew how all species were related to one another. But since we do not know for certain what Darwin's "great Tree of Life" looks like, we must infer the shape of the tree through phylogenetic inference. In recent years, the field of molecular phylogenetics has revealed a great deal about how species are related to one another, but much more remains to be accomplished.

CHAPTER 3

Introduction to the Animal Kingdom

Animal Architecture and Body Plans

Animal bodies are marvelous things—so complex, yet so consistent and true to form within a species. All the parts seem to work together in perfect harmony, like the architecture of a beautiful building, which is how it should be after millions of years of evolutionary fine-tuning. This chapter is about the architecture of animals. The German language includes a wonderful word that expresses the essence of animal architecture—*bauplan* (pl. *baupläne*). The word means, literally, "a structural plan or design," but a direct translation is not entirely adequate. The concept of a *bauplan* captures in a single word the essence of structural range and architectural limits, as well as the functional aspects of a design. The term "body plan" is a close English equivalent. If an organism is to "work," all of its body components must be both structurally and functionally compatible. The entire organism encompasses a definable body plan, and the specific organ systems themselves also encompass structural plans; in both cases the structural and functional components of the particular plan establish both capabilities and limits.

The diversity of form in the biological world is dazzling, yet there are real limits to what may be successfully molded by evolutionary processes. All animals must accomplish certain basic tasks in order to survive and reproduce. They must acquire, digest, and metabolize food and distribute its usable products throughout their bodies. They must obtain oxygen for cellular respiration, while at the same time ridding themselves of metabolic wastes and undigested materials. The strategies employed by animals to maintain life are extremely varied, but they rest upon relatively few biological, physical, and chemical principles, regardless of what body plan they have. Within the constraints imposed by particular body plans, animals have a limited number of options available to accomplish life's tasks. For this reason, a few recurring fundamental themes are apparent. This chapter is a general review of these themes: the structural/functional aspects of invertebrate body plans and the basic survival strategies employed within each. It is a description of how invertebrates are put together and how they manage to survive and reproduce. Each subject discussed here reflects fundamental principles of animal mechanics, physiology, and adaptation. We realize that much of this chapter presents material that students learn in introductory biology courses, but here we provide specific viewpoints that set the stage for topics covered in more detail in each "animal" chapter of this book.

Keep in mind that even though this chapter is organized on the basis of what might be called the "components" of animal structure, whole animals are integrated functional combinations of these components. Furthermore, there is a strong element of predictability in the concepts discussed in this chapter.

For example, given a particular type of symmetry, one can make reasonable guesses about other aspects of an animal's structure that should be compatible with that symmetry—some combinations work, others do not. Herein are explained many of the concepts and terms used throughout this book, and we encourage you to become familiar with this material now as a basis for understanding the remainder of the text.

Body Symmetry

A fundamental aspect of an animal's body plan is its overall shape or geometry. In order to discuss invertebrate architecture and function, we must first acquaint ourselves with a basic aspect of body form: symmetry. Symmetry refers to the regular arrangement of body structures relative to a particular axis of the body. Animals that can be bisected or split along at least one plane, so that the resulting halves are similar to one another, are said to be symmetrical. For example, a shrimp can be bisected vertically through its midline, head to tail, to produce right and left halves that are mirror images of one another. Some animals have no body axis and no plane of symmetry; these are said to be **asymmetrical**. Many sponges, for example, have an irregular growth form and lack any clear plane of symmetry. Similarly, placozoans, which may depict ameboid forms, are asymmetrical (Figure 3.1).

One form of symmetry is **spherical symmetry**. It is seen in creatures whose bodies lack an axis and have the form more or less of a sphere, with the body parts arranged concentrically around, or radiating from, a central point (Figure 3.2). A sphere has an infinite number of planes of symmetry that pass through its center to divide it into like halves. Spherical symmetry is rare in nature; in the strictest sense, it is found only in certain protists and a few sponges. Organisms with spherical symmetry share an important functional attribute with asymmetrical organisms, in that both groups lack polarity. That is, there exists no clear differentiation along an axis. In all other forms of symmetry, some level of polarity has been achieved; and with polarity comes specialization of body regions and structures.

A body displaying **radial symmetry** has the general form of a cylinder, with one or more main axes around which the various body parts are arranged (Figure 3.3). In a body displaying perfect radial symmetry, the body parts are arranged equally around the axis, and any plane of sectioning that passes along that axis results in similar halves. That is to say, both halves of an animal divided down the middle, along a plane of symmetry, have the same exact structures in the same exact relationship to one another (rather like a cake being divided and subdivided into equal halves and quarters). Nearly perfect radial symmetry is rare in nature but occurs in some sponges and perhaps in some cnidarian polyps

(Figure 3.3A,B). But most radially symmetrical animals have evolved modifications on this theme. **Biradial symmetry**, for example, occurs where portions of the body are specialized and only two planes of sectioning

(B) The barrel-like sponge *Xestospongia*. (C) The sea anemone *Epiactis*, whose mouth alignment and internal organization produce biradial symmetry. (D) The hydromedusa *Scrippsia*, with quadriradial symmetry. (E) The starfish *Patiria*, with pentaradial symmetry. (F) The sea biscuit *Clypeaster*, with pentaradial symmetry. (G) In this view of a stylized ctenophore, multiple planes of symmetry can be seen to divide the animal into nearly equal halves, making it multiradial. Some of these are the stomodeal plane, the anal pore plane, and the tentacular plane. Ctenophores also have rotational symmetry, which is defined as a shape that looks precisely the same after some rotation of 180° or less (in this case, a full 180° is required to accomplish this). (G after M. Q. Martindale and J. Q. Henry. 1998. *Amer Zool* 38: 672–684.)

can divide the animal into perfectly similar halves. Common examples of biradial organisms are many sea anemones (Figure 3.3C). Ctenophores have various forms of biradial symmetry, but they can also show a type of rotational symmetry (Figure 3.3G). Rotational symmetry is defined as a shape that looks precisely the same after some rotation of 180° or less. In the case of the generalized ctenophore shown in Figure 3.3G, the animal would be precisely the same after a 180° rotation, giving it rotational symmetry. But other planes of radial symmetry, such as through the gut (stomodeal plane), tentacles (tentacular plane), or anal pores, divide the animal into two halves that have the same exact structures, in the same exact relationship to one another.

Further specializations of a basic radial body plan can produce nearly any combination of multiradiality. For example, many jellyfishes possess **quadriradial symmetry** (Figure 3.3D). Most echinoderms have **pentaradial symmetry** (Figure 3.3E,F), although given the location of the madreporite, this is imperfect, and thus starfish actually possess a form of pentaradial bilaterality. But this is splitting hairs. And many multiarmed starfish are also known.

A radially symmetrical animal has no front or back end; rather it is organized about an axis that passes through the center of its body, like an axle through a wheel. When a gut is present, this axis passes through the mouth-bearing (oral) surface to the opposite (aboral) surface. Radial symmetry is most common in sessile and sedentary animals (e.g., sponges, starfish, and sea anemones) and drifting pelagic species living in three-dimensional environments (e.g., jellyfishes). Given these lifestyles, it is clearly advantageous to be able to confront the environment equally from a variety of directions. In such creatures the feeding structures (tentacles) and sensory receptors are distributed at equal intervals around the periphery of the organism so that they contact the environment more or less equally in all directions. Furthermore, many bilaterally symmetrical animals have become functionally radial in certain ways associated with sessile lifestyles. For example, their feeding structures may be in the form of a whorl of radially arranged tentacles, an arrangement allowing more efficient interactions with the immediate environment.

The body parts of **bilaterally symmetrical** animals are oriented about an axis that passes from the front (anterior) to the rear (posterior) end. A single plane of symmetry—the **midsagittal plane** (or median sagittal plane)—passes along the axis of the body to separate right and left sides. Any longitudinal plane passing perpendicular to the midsagittal plane and separating the upper (dorsal) from the lower (ventral) side is called a **frontal plane** (Figure 3.4). Any plane that cuts across the body perpendicular to the main body

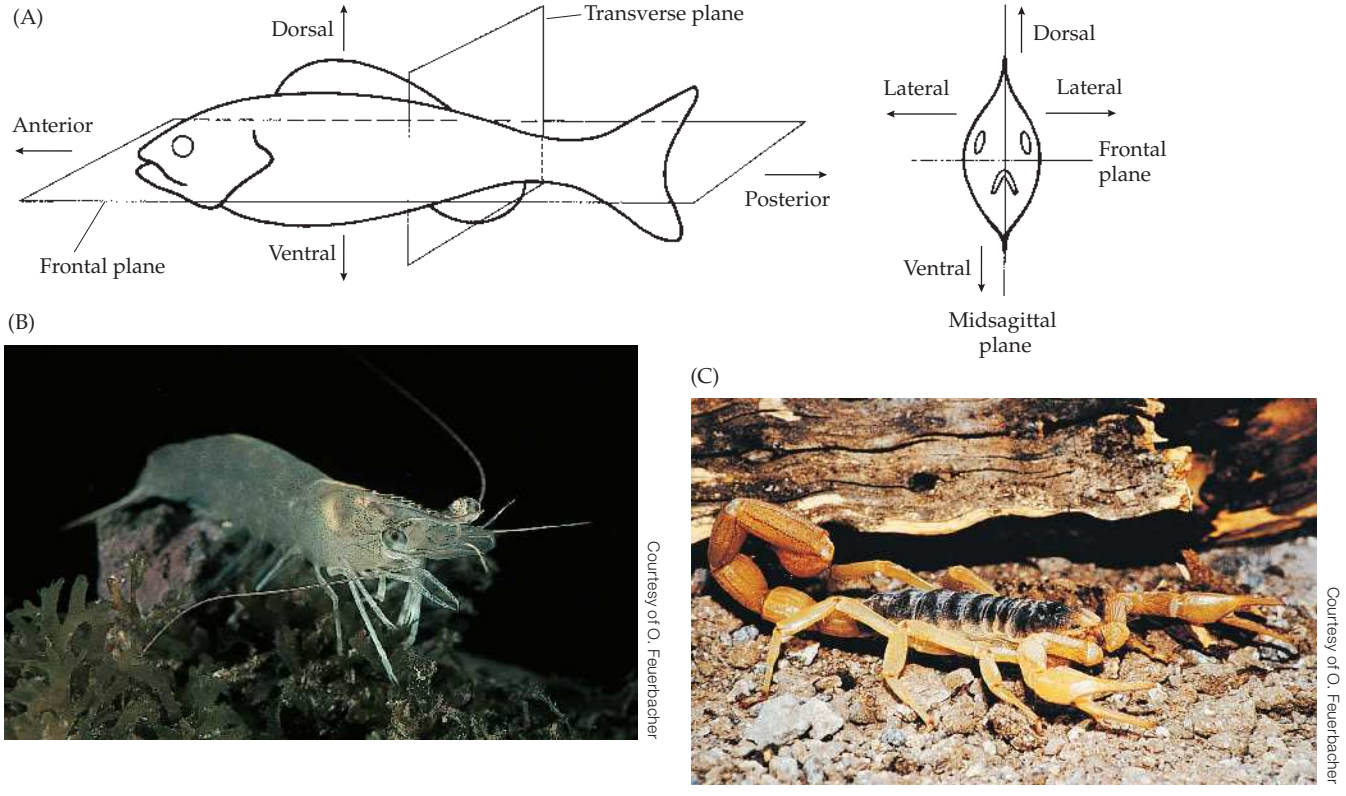

FIGURE 3.4 Bilateral symmetry in animals; a single plane—the midsagittal plane—divides the body into equal halves. (A) Diagrammatic illustration of bilateral symmetry, with terms of orientation and planes of sectioning. A shrimp (B) and a scorpion (C) show obvious bilateral symmetry.

for more ebook/ testbank/ solution manuals Request: Kingdom email:960126734@qq.com

axis and the midsagittal plane is called a **transverse plane** (or, simply, a cross section). In bilaterally symmetrical animals the term "lateral" refers to the sides of the body, or to structures away from (to the right and left of) the midsagittal plane. The term "medial" refers to the midline of the body, or to structures on, near, or toward the midsagittal plane.

Whereas radial and rotational symmetry are typically associated with sessile or drifting animals, bilaterality is generally found in animals with highly directional mobility. In these animals, the anterior end of the body confronts the environment first. Associated with bilateral symmetry and unidirectional movement is a concentration of feeding and sensory structures at the anterior end of the body. The evolution of a specialized "head," containing those structures and the nervous tissues that innervate them, is called **cephalization** (from the Greek *kephalos*, "head"). Furthermore, the surfaces of the animal differentiate as dorsal and ventral regions, the latter becoming locomotory and the former being specialized for protection. A variety of secondary asymmetrical modifications of bilateral (and radial) symmetry have occurred, for example, the spiral coiling of snails and hermit crabs. Furthermore, many radial animals have become secondarily bilateral, at least for their main body organization, as is the case of sea cucumbers or some irregular sea urchins.

Cellularity, Body Size, Germ Layers, and Body Cavities

One of the main characteristics used to define grades of animal complexity is the presence or absence of true tissues. Tissues are aggregations of morphologically and physiologically similar cells that perform a specific function. Protists do not possess tissues, but occur only as single cells or as simple colonies of cells. In a sense, they are all at a unicellular grade of construction. But beyond protists is the vast array of multicelled animals, the Metazoa. The Metazoa are often divided into two major groups—the non-Bilateria and the Bilateria, as described below. These names may be used to group the Metazoa by their level of overall structural complexity. The nonbilaterians comprise a nonmonophyletic grouping of "primitive" metazoans; bilaterians are almost certainly a monophyletic group, or clade. The non-Bilateria include Porifera, Placozoa, Cnidaria, and Ctenophora. In the last two phyla, embryogenesis produces two distinct germ layers—ectoderm and endoderm—and thus they are referred to as being diploblastic. Among the bilaterians a third embryonic germ layer forms, the mesoderm, and thus the Bilateria are said to be triploblastic. These concepts are elaborated below.

Each of these two grades of body complexity is associated with inherent constraints and capabilities, and within each grade there are obvious limits to size. As the Scottish biologist D'Arcy Thompson wrote, "Everything has its proper size ...men and trees, birds and fishes, stars and star-systems, have... more or less narrow ranges of absolute magnitudes." As a cell (or an organism) increases in size, its volume increases at a rate faster than the rate of increase of its surface area (surface area increases as the square of linear dimensions; volume increases as the cube of linear dimensions). Because a cell ultimately relies on transport of material across its plasma membrane for survival, this disparity quickly reaches a point at which the cytoplasm can no longer be adequately serviced by simple cellular diffusion. Some unicellular protists develop complexly folded surfaces or are flattened or threadlike in shape. Such creatures can be quite large, but eventually a limit is reached; thus we have no meter-long amebas.

To increase in size, ultimately the only way around the **surface-to-volume dilemma** is to increase the number of cells constituting a single organism; hence the Metazoa. But size increase in the Metazoa is also limited. Those Metazoa lacking complex specializations of tissues and organs must rely on diffusion into and out of the body, and this is inadequate to sustain life unless a majority of the body's cells are near or in contact with the external environment. In fact, diffusion is an effective method of oxygenation only when the diffusion path is less than about 1.0 mm. So here, too, there are limits. An animal simply cannot increase indefinitely in volume when most of its cells must lie close to the body surface. Some animals solve this problem to some degree by arranging their cellular material so that diffusion distances from cell to environment are comfortably short. One method of accomplishing this is to pack the internal bulk of the body with nonliving (or largely nonliving) material, such as the jellylike mesoglea of medusae and ctenophores. Another is to assume a body geometry that maximizes the surface area. Increase in one dimension leads to a vermiform body plan, like that of cestid ctenophores (Ctenophora; Figure 6.2E) or ribbon worms (Nemertea). Increase in two dimensions results in a flat, sheetlike body like that of flatworms (Platyhelminthes). In these cases the diffusion distances are kept short. Sponges effectively increase their surface area by a process of complex branching and folding of the body, both internally and externally. This folding keeps most of the body cells close to the environment.

If these were the only solutions to the surface-to-volume dilemma, the natural world would be filled with tiny, thin, flat animals and convoluted, spongelike creatures. However, many organisms increase in size by one to several orders of magnitude during their ontogeny, and life-forms on Earth span about 19 orders of magnitude (in mass). Thus, another solution arose, probably multiple times, during the course of animal evolution that allowed for increases in body size. This solution was to bring the "environment" functionally closer to each cell in the body by the use of internal transport

and exchange systems with large surface areas. A significant three-dimensional increase in body size thus necessitated the development of sophisticated internal transport mechanisms (e.g., circulatory systems) for nutrients, oxygen, waste products, and so on. These evolving transport structures became the organs and organ systems of higher animals. For example, the body volume of humans is so large that we require a highly branched network of gas exchange surfaces (our lungs) to provide an adequate surface area for gas diffusion. This network has about 1,000 square feet of surface—as much area as half a tennis court! The same constraints apply to food absorption surfaces; hence the evolution of very long, highly folded, or branched guts.

The embryonic tissue layers of metazoans are called **germ layers** (from the Latin *germen*, "a sprout, bud, or embryonic primordium"), and it is from these germ layers that all adult structures develop. Chapter 4 provides an overview of germ layer formation and other aspects of metazoan developmental patterns. But here we need to point out that the germ layers initially form as outer and inner sheets or coherent masses of embryonic cells, termed **ectoderm** and **endoderm** (or entoderm), respectively. In the embryogeny of the phyla Cnidaria and Ctenophora, only these two germ layers develop (or if a middle layer does develop, it is produced by the ectoderm, is largely noncellular, and is not considered a true germ layer). These animals are regarded as **diploblastic** (Greek *diplo*, "two"; *blast*, "bud" or "sprout"). In the embryogeny of most animals, however, a third cellular germ layer, the **mesoderm**, arises between the ectoderm and the endoderm; these metazoans are said to be **triploblastic**. All Bilateria are triploblastic. The long-standing term "diploblastic" may at first seem a bit misleading, as many cnidarians and ctenophores do have a "middle body layer"; but, importantly, it is not derived embryologically from a distinct middle germ layer as in the Bilateria. In this book, we use the terms "diploblastic" and "triploblastic" in this embryological germ-layer sense.

The evolution of a mesoderm greatly expanded the evolutionary potential for animal complexity. As we shall see, the triploblastic phyla have achieved many more highly sophisticated body plans than are possible within the confines of a diploblastic body plan. Simply put, a developing triploblastic embryo has more building material to work with than does a diploblastic embryo.

One of the major trends in the evolution of the triploblastic Metazoa has been the development of a fluid-filled cavity between the outer body wall and the digestive tube, that is, between the adult derivatives of the ectoderm and the endoderm. The evolution of this space created a radically new architecture, a tube-within-a-tube design in which the inner tube (the gut and its associated organs) was largely freed from the constraint of being attached to the outer tube (the body wall). The fluid-filled cavity not only served as a mechanical buffer between these two largely independent tubes, but also allowed for the development and expansion of new structures within the body, served as a storage chamber for various body products (e.g., gametes), provided a medium for circulation, and was in itself an incipient hydrostatic skeleton. The nature of this cavity (or the absence of it) is associated with the formation and subsequent development of the mesoderm, as discussed in detail in Chapter 4.

Three grades of construction occur in triploblastic Metazoa: **acoelomate**, **blastocoelomate**, and **coelomate**. The acoelomate grade (Greek *a*, "without"; *coel*, "hollow, cavity") occurs in numerous triploblastic phyla: Xenacoelomorpha, Platyhelminthes, Entoprocta, Cycliophora, Gnathostomulida, Micrognathozoa, Nematomorpha, Gastrotricha, some Loricifera and some Nematoda. In these animals, the mesoderm forms a more or less solid mass of tissue, sometimes with small open spaces (lacunae), between the gut and body wall (Figure 3.5A). In nearly all other triploblastic animals, an actual space develops as a fluid-filled cavity between the body wall and the gut. In many phyla (e.g., annelids and

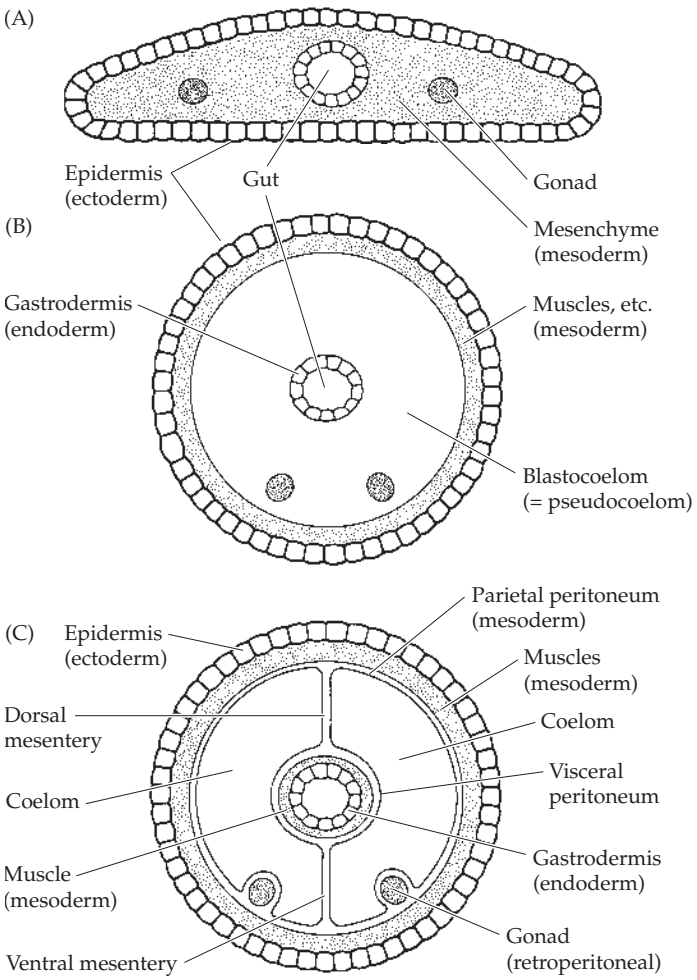

FIGURE 3.5 Principal body plans of triploblastic Metazoa (diagrammatic cross sections). (A) The acoelomate body plan. (B) The blastocoelomate body plan. (C) The coelomate (= eucoelomate) body plan.

for more ebook/ testbank/ solution manuals Request: United Kingdom email:960126734@qq.com

echinoderms), this cavity arises within the mesoderm itself and is completely enclosed within a thin lining called the **peritoneum**, which is derived from the mesoderm. Such a cavity is called a true **coelom (eucoelom)**. Notice that the organs of the body are not actually free within the coelomic space itself, but separated from it by the peritoneum (Figure 3.5C). The peritoneum is usually a squamous epithelial layer, at least that portion of it covering the gut and internal organs.

Several groups of triploblastic Metazoa (e.g., Rotifera, some Nematoda, some Loricifera, most Priapula, Tardigrada, and some Kinorhyncha) possess small or large body cavities that are neither formed from the mesoderm nor fully lined by peritoneum or any other form of mesodermally derived tissue. Such a cavity used to be called a "pseudocoelom" (Greek *pseudo*, "false"; *coel*, "hollow, cavity") (Figure 3.5B). The organs of these animals actually lie free within the body cavity and are bathed directly in its fluid. In most cases the space represents persistent remnants of the embryonic blastocoel, and since there is nothing "false" about it, we use the more descriptive term **blastocoelom** in this text. Although originally used to organize animals by their evolutionary complexity, the organization of the body cavity shows only a loose correlation to phylogeny.

Within the constraints inherent in each of the basic body organizations discussed above, animals have evolved a multitude of variations on these themes. Throughout the remainder of this chapter, we describe the fundamental organizational plans of major body systems as they have evolved within these basic body plans. In subsequent chapters, we describe how members of the various phyla have modified these basic plans through their own particular evolutionary program or direction.

Locomotion and Support

As eukaryotic life progressed from the single-celled stage to multicellularity, body size increased dramatically. And this increase in body size, coupled with directed movement, was accompanied by the evolution of a variety of support structures and locomotor mechanisms. Because these two body systems evolved mutually and usually work in a complementary fashion, they are conveniently discussed together. And of course, there was a rapid evolutionary boost in body size and support in the Cambrian, approximately 540 to 515 million years ago—an event known as the Cambrian Explosion, or Cambrian Radiation. The reasons for this rapid radiation of larger animals are still being debated (Chapter 1).

There are four fundamental locomotor patterns in Metazoa: ameboid movement (of certain body cells, and perhaps of placozoans), ciliary and flagellar movement, hydrostatic propulsion, and locomotor limb movement. There are three basic kinds of support systems: structural endoskeletons, structural exoskeletons, and hydrostatic skeletons. In this section we briefly describe the basic architecture and mechanics of the various combinations of these systems. We begin with a review of an important concept to describe movement in fluids, Reynolds number.

Reynolds Number

Most invertebrate lineages inhabit water, and aquatic environments present obstacles and advantages to support and locomotion that are quite different from those of terrestrial environments. Just staying in one place in the face of swiftly moving water, without being damaged or dislodged, can require both support and flexibility. Animals moving through water (or moving water over their bodies—the effect is much the same) face problems of fluid dynamics created by the interaction between a solid body and a surrounding liquid. What happens during this interaction is tied to the concept of Reynolds number, a unitless value based on the experiments of Osborne Reynolds (1842–1912). Reynolds number represents a ratio of inertial force to viscous force. At higher Reynolds numbers, inertial force predominates and determines the behavior of water flow around an object. At lower Reynolds numbers, viscous force predominates and determines the behavior of the water flow. The importance of this concept is being increasingly applied to biological systems. Some interesting generalizations can be made about aquatic locomotion and suspension feeding in light of Reynolds numbers. Reynolds number is expressed by the following equation:

$$R_e = plU/v$$

where p equals the density of fluid, l is some measurement of the size of the solid body, U equals the relative velocity of the fluid over the body surface, and v is the viscosity of the fluid. The formula was derived by Reynolds to describe the behavior of cylinders in water. Of course, since animal bodies are not perfect cylinders, the size variable (l) is difficult to standardize. Nonetheless, meaningful relative (comparative) values can be derived and applied to living creatures in water.

Without belaboring this issue beyond its importance here, we can see that the challenges of a large animal swimming through water are very different from those of a small animal. Large animals such as fishes, whales, or even humans, by virtue of their size or high velocity or both, move in a world of high Reynolds numbers. With increased body size, fluid viscosity becomes less and less significant as far as the animal's energy output during locomotion is concerned. At the same time, however, inertia becomes more and more important. A large animal must expend more energy than a small animal does to put its body in motion. But, by the same token, inertia works in favor of the moving large animal by

carrying it forward when the animal stops swimming. When large animals move at high Reynolds numbers, the effect of inertia also imparts motion to the water around the animal's body. Thus, as the Reynolds number increases, a point is reached at which the flow of water changes from laminar to turbulent, decreasing swimming efficiency.

Small organisms generally move in a world of low Reynolds numbers. For example, a larva 1 mm in diameter, moving at a speed of 1 mm/sec, has a Reynolds number of about 1.0. Inertia and turbulence are virtually nonexistent, but viscosity becomes important—increasingly so as body size and velocity decrease (i.e., as the Reynolds number decreases). Small organisms swimming through water have been likened to a human swimming through liquid tar or thick molasses, but this isn't quite accurate. In animals swimming in a world of low Reynolds numbers, as water moves over the surface of the animal, some of the fluid sticks to and moves with the surface of the animal's body. The effect of this situation is that tiny creatures, such as many small metazoans, start and stop instantaneously, and the motion of the water set up by their swimming also ceases immediately if the animal stops moving. Thus, small creatures neither pay the price nor reap the benefits of the effects of inertia. The organism only moves forward when it is expending energy to swim; as soon as it stops moving its cilia or flagella or appendages, it stops—and so does the fluid surrounding it. Each seta on a tiny crustacean's appendage, for example, will carry a layer of water with it as it is moved. Closely spaced setae will carry so much water that an appendage acts like a paddle; more widely spaced setae allow water to flow between them and thus can act as a sieve. Tiny organisms swimming at low Reynolds numbers (i.e., < 1.5) must expend an incredible amount of energy to propel themselves through their "viscous" surroundings.

Ameboid Locomotion

Ameboid movement is used principally by certain protists and by numerous kinds of ameboid cells that occur within the bodies of most Metazoa. Ameboid cells possess a gel-like **ectoplasm**, which surrounds a more fluid **endoplasm** (Figure 3.6). Movement is facilitated by changes in the states of these regions of the cell. At one or several points on the cell surface, **pseudopods** (or pseudopodia) develop; and as endoplasm flows into a growing pseudopod (or pseudopodium), the cell creeps in that direction. This seemingly simple process actually involves complex changes in cell fine structure, chemistry, and behavior. The innermost endoplasm moves "forward" while the outermost endoplasm takes on a granular appearance and remains fairly stable. The advancing portion of endoplasm pushes forward and then becomes semirigid ectoplasm at the tip of the advancing pseudopodium. Concurrently, endoplasm is recruited from the trailing end of the cell, from where it streams forward to join in the "growing" pseudopod. Many protists, and certain cells of eukaryotes, have wide, blunt-tipped pseudopods called **lobopods** (or lobopodia)—not to be confused with the walking appendages of some panarthropods.

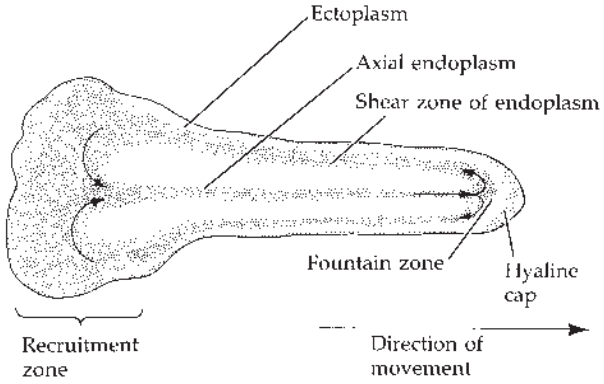

FIGURE 3.6 Ameboid locomotion. Pseudopod formation in a single cell (such as certain cells in the blood or hemolymph of metazoans) enables ameboid movement.

Cilia and Flagella

Cilia or flagella, or both, occur in virtually every animal phylum, with the qualified exception of the Arthropoda, where only flagella occur, and only in the sperm cells of some species. Structurally, cilia and flagella are nearly identical (and clearly homologous), but the former are shorter and tend to occur in relatively larger numbers (in patches or tracts), whereas the latter are long and generally occur singly or in pairs. During cell development, each new flagellum or cilium arises from an organelle called the **kinetosome** (sometimes called a basal body or a blepharoplast), to which it remains anchored.

The movement of cilia and flagella creates a propulsive force that either moves the organism through a liquid medium or, if the animal (or cell) is anchored, creates a movement of fluid over it. Such action always occurs at very low Reynolds numbers. When the animal is large, the viscosity may be increased by secretion of mucus, which lowers the Reynolds number. The general structure of a flagellum or cilium consists of a long, flexible rod, the outer covering of which is an extension of the plasma membrane of the cell (Figure 3.7A). Inside is the **axoneme**—a circle of nine paired microtubules (often called doublets) that runs the length of the flagellum or cilium. One microtubule of each doublet bears two rows of projections, the **dynein arms**, directed toward the adjacent doublet. Flagella and cilia move as the microtubules slide up or down against one another, bending the flagellum or cilium in one direction or another. Microtubule

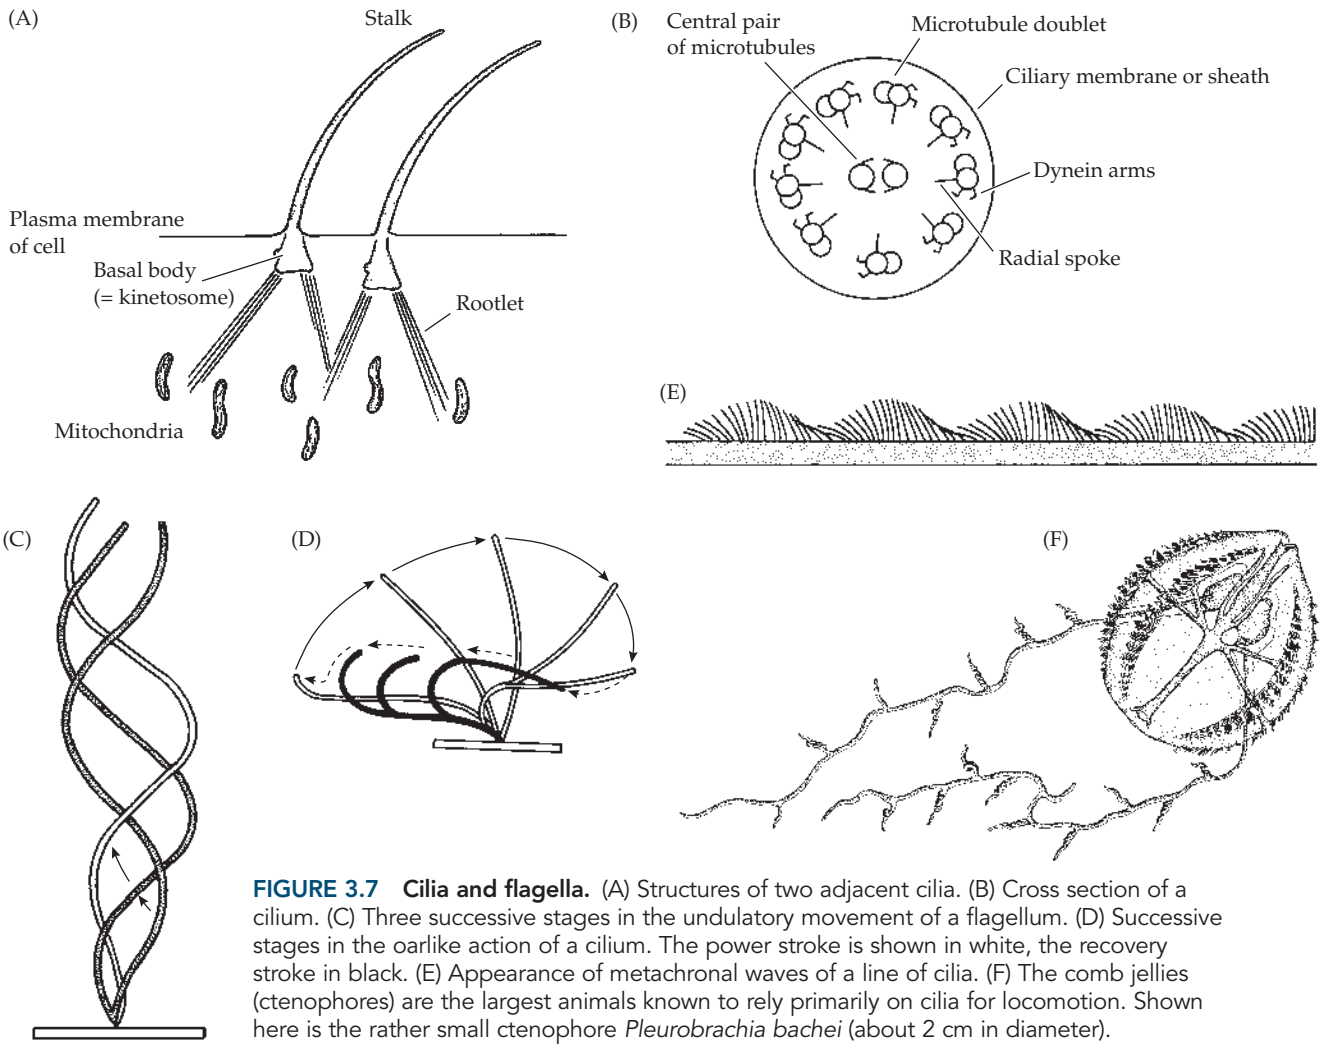

FIGURE 3.7 Cilia and flagella. (A) Structures of two adjacent cilia. (B) Cross section of a cilium. (C) Three successive stages in the undulatory movement of a flagellum. (D) Successive stages in the oarlike action of a cilium. The power stroke is shown in white, the recovery stroke in black. (E) Appearance of metachronal waves of a line of cilia. (F) The comb jellies (ctenophores) are the largest animals known to rely primarily on cilia for locomotion. Shown here is the rather small ctenophore *Pleurobrachia bachei* (about 2 cm in diameter).

sliding is driven by the dynein arms, particularly by protein complexes called **radial spokes** that arise from the arms. The radial spokes attach to each doublet microtubule immediately adjacent to the inner row of dynein arms and project centrally. Down the center of the doublet circle is an additional pair of **microtubules**. This familiar 9+2 pattern is characteristic of nearly all flagella and cilia (Figure 3.7B).[1] Flagellar/ciliary microtubules are modified hollow tubules similar to those present in the matrix of most cells. The principal function of these cellular tubules appears to be support, so the cytoplasmic microtubules act as a sort of simple "endoskeleton" that helps cells retain their shape. Microtubules are also components of the mitotic spindle and help distribute the chromosomes during cell division.

In addition to the locomotor function for which small metazoans use cilia or flagella, they have an enormous variety of functions in many other animals. For example, they create feeding and gas exchange currents, they line digestive tracts and facilitate food movement, and they propel sex cells and larvae. They also form sensory structures of many kinds. Here we focus on their use as locomotor structures.

Analysis by high-speed photography reveals that the movement of these structures is complex and differs among taxa and even among different locations on the same organism. Some flagella beat back and forth, while others beat in a helical rotary pattern that drives some sperm and other flagellated cells something like the propeller of an outboard motor (Figure 3.7C). Depending on whether the undulation moves from base to tip or from tip to base, the effect will be, respectively, to push or pull the cell along.

Some flagella possess tiny, hairlike side branches called **mastigonemes** that increase the effective surface area and thus improve the propulsive capability. The beat of a cilium is generally simpler, consisting of a power stroke and a relaxed recovery stroke (Figure 3.7D). When many cilia are present on a cell, they often occur in distinct tracts, and their action is integrated, with beats usually moving in metachronal waves over the cell surface (Figure 3.7E,F). Since

[1]Dyneins are a family of adenosine triphosphatases that cause microtubule sliding in ciliary and flagellar axonemes.

at any one time some cilia are always performing a power stroke, metachronal coordination ensures a uniform and continuous propulsive force.

It was once suggested that ciliary tracts on individual cells were coordinated by a primitive sort of cellular "nervous system," but this hypothesis was never confirmed. Current thinking suggests that the coordinated beating of cilia is probably due to hydrodynamic constraints imposed on them by the interference effects of the surrounding water layers and by the simple mechanical stimulation of moving, adjacent cilia. Nevertheless, some ciliary responses in animals are clearly under neural control, for example, reversal of power stroke direction. Cilia are used for locomotion by members of several metazoan phyla (including Placozoa, Rhombozoa, Ctenophora, Platyhelminthes, Rotifera, some gastropod molluscs, and others) and by the larval stages of a great many taxa.

Muscles and Skeletons

Almost all animals have some sort of a skeleton, the major functions of which are to maintain body shape, provide support, serve as attachments for muscles, transmit the forces of muscle contraction to perform work, and extend relaxed muscles. These functions may be attained by either hard tissues or secreted skeletons, or even by the turgidity of body fluids or tissues under pressure. Muscles, skeletons, and body form are closely integrated, both developmentally and functionally. When rigid skeletal elements are present, they can serve as fixed points for muscle attachment. For example, the rigid and jointed exoskeleton of arthropods allows for a complex system of levers that results in very precise and restricted limb movements. Many invertebrates lack hard skeletons and can change their body shape by alternate contraction and relaxation of various muscle groups attached to tough connective tissues or to the inside of the body wall. These "soft-bodied" invertebrates usually have a hydrostatic skeleton.

The hydrostatic skeleton The performance of a hydrostatic skeleton is based on two fundamental properties of liquids: their incompressibility and their ability to assume any shape. Because of these features, body fluids transmit pressure changes rapidly and equally in all directions. It is important to realize a basic physical limitation concerning the action of muscles—they can only perform work by getting shorter (contracting).[2] In hydrostatic skeletons, a body region is extended (or protruded) by the contractile force of a muscle being imparted to a fluid-filled body compartment, creating a hydrostatic pressure that displaces the wall of the compartment. Such indirect muscle actions can be compared to squeezing a rubber glove filled with water, thereby extending and stiffening the fingers. The enclosure of a fluid-filled chamber (e.g., a coelom) within sets of opposing muscle layers establishes a system in which muscles in one part of the body can contract, forcing body fluids into another region of the body, where the muscles relax; the body is thus extended or otherwise changed in shape (Figure 3.8).

In the most common plan, two muscle layers surround a fluid-filled body cavity, and the fibers of the layers run in different directions (e.g., a circular muscle layer and a longitudinal muscle layer). A soft-bodied invertebrate can move forward by using its hydrostatic skeleton in the following way: The circular muscles at the posterior end of the animal contract, and thus the

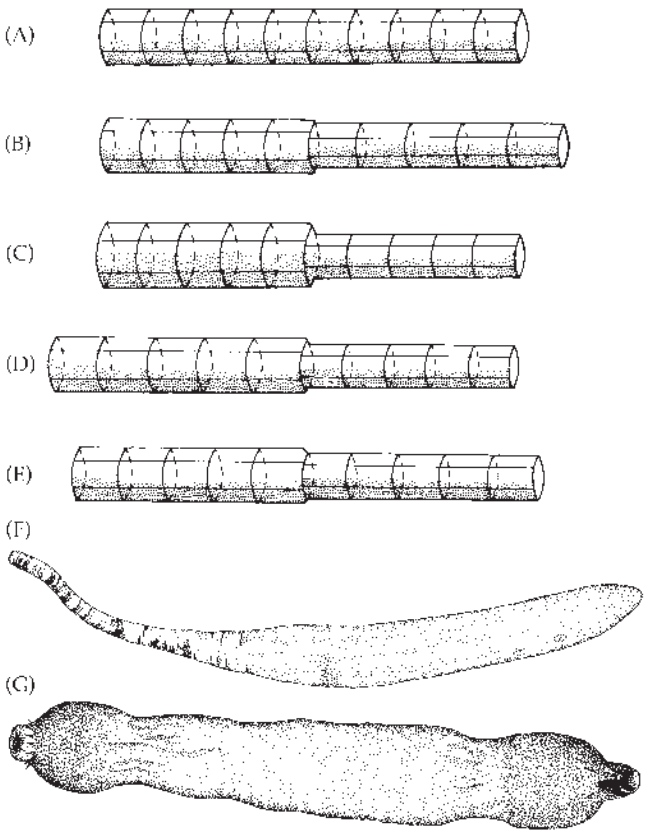

FIGURE 3.8 The hydrostatic skeleton. (A–E) The initial state and the four possible results of contraction of the circular muscles at one end of a cylindrical animal with a hydrostatic skeleton. (A) The muscles are all relaxed. (B) The circular muscles of the right-hand end have contracted and this end has elongated; the left-hand end has remained unaltered. (C) The length of the right-hand end has remained the same but the diameter of the left-hand end has increased. (D) The length of the right-hand end and the diameter of the left-hand end have remained the same, but the length of the left-hand end has increased. (E) The lengths of both ends have increased, but their respective diameters have remained the same. (F,G) Two animals that rely on hydrostatic skeletons for support and locomotion. [2]Bear in mind that muscles can contract isometrically and do no work.

for more ebook/ testbank/ solution manuals Request Kingdom email 960126734@qq.com

hydrostatic pressure generated pushes anteriorly to extend the relaxed longitudinal muscles of the front of the body. Then contraction of the posterior longitudinal muscles pulls the rear end of the body forward. This sequence of muscle contractions results in a directed and controlled movement forward. Such movement requires that the posterior end be anchored when the anterior end is extended, and that the anterior end be anchored when the posterior end is pulled forward. This system is commonly used for locomotion by many worms that generate posterior-to-anterior metachronal waves of muscle action, resulting in what is called peristalsis. A similar hydrostatic system can be used to temporarily or intermittently extend selected parts of the body, such as the feeding proboscis of worms, tube feet of echinoderms, and siphons of clams.

Reliance on only circular and longitudinal muscles could result in twists and kinks when a hydrostatic system engaged itself against the resistance of the substratum. Hence, most animals that rely on hydrostatic movement also have helically wound, diagonal muscle fibers—a left- and right-handed set, intersecting at an angle between 0 and 180 degrees. The diagonal muscles allow extension and contraction, even at a constant volume, without stretching and while preventing kinking and twisting. A good analogy is the children's finger toy—the helically woven straw cylinder into which one youngster convinces another to insert his two index fingers; pushing your fingers together increases the diameter of the cylinder (and decreases the length), and pulling your fingers apart decreases the diameter (and increases the length). All of this is accomplished without an appreciable stretching or compression of the straw fibers (or the diagonal muscles of an invertebrate). When a cylinder is extended, the fiber angle decreases; when it is compressed, the angle increases.

The volume of the working fluid in a hydrostatic skeleton should remain constant, thus any leakage should not be greater than the rate at which the fluid can be replaced. Body fluids must be retained despite "holes" in the body wall, such as the excretory pores of many coelomate animals, the mouth openings of cnidarians, etc. Such openings are often encircled by sphincter muscles that can close and control the loss of body fluids.

One way in which movement by a hydrostatic skeleton can be made more precise is to divide an animal up into a series of separate compartments. For example, in many annelid worms, partitioning of the coelom and body muscles into segments with separate neural control enables body expansions and contractions to be confined to a few segments at a time. By manipulating particular sets of segmental muscles, most annelids not only can move forward and backward but can turn and twist in complex maneuvers.

The rigid skeleton In "hard-bodied" invertebrates, a fixed or rigid skeleton prevents the gross changes in body form seen in soft-bodied invertebrates. This reduction in flexibility is a trade-off that gives hard-bodied animals several advantages: the capacity to grow larger (an advantage that is especially useful in terrestrial habitats, which lack the buoyancy provided by aquatic environments), more precise or controlled body movements, better defense against predators, and often greater speed of movement.

Hard skeletons can be broadly classed as either endoskeletons or exoskeletons. Among Bilateria, endoskeletons are generally derived from mesoderm, whereas exoskeletons are derived from ectoderm; both usually have organic and inorganic components. It has been hypothesized that rigid skeletons may have originated by chance, as byproducts of certain metabolic pathways. By sheer accident (preadaptation or exaptation), for example, the accumulation of nitrogenous wastes and their incorporation into complex organic molecules might have resulted in the evolution of the chitinous exoskeleton so common among invertebrates. Similar speculation suggests that a metabolic system that originally functioned to eliminate excess calcium from the body might have produced the first calcareous shell of molluscs. In any event, marine invertebrates are capable of forming, through their various biological activities, a vast array of minerals, some of which cannot be formed inorganically in the biosphere. Indeed, the ever-increasing amounts of these biominerals have radically altered the character of the biosphere since the origin of hard skeletons in the earliest Cambrian. Most common among these biominerals are various carbonates, phosphates, halides, sulfates, and iron oxides.

Invertebrate skeletons may be of the articulating type (e.g., the exoskeletons of arthropods, clams, and brachiopods and the endoskeleton of some echinoderms), or they may be of the nonarticulating type, as seen in the simple one-piece exoskeletons of snails and in the rigid endoskeletons composed of interlocking fused plates of sea urchins and sand dollars. Animal endoskeletons may be as simple as the microscopic calcareous or siliceous spicules embedded in the body of a sponge, cnidarian, or sea cucumber, or they may be as complex as the bony skeleton of vertebrates (Figure 3.9) or the jaws of micrognathozoans (Figure 11.16). Hard skeletons of calcium carbonate have evolved in many animal (and some algal) phyla, but the use of silica in a mineralized skeleton occurs only in sponges (Porifera). Vertebrate skeletal tissues include a calcium phosphate–collagen matrix. In invertebrates, collagen often forms a substratum upon which calcareous spicules or other skeletal structures form, but with a single exception (certain gorgonians) collagen is never incorporated directly into the calcareous skeletal material.[3]

[3]Collagen, of course, also is the primary component of basement membrane that underlies epithelia in all Metazoa, providing structural integrity to tissues.

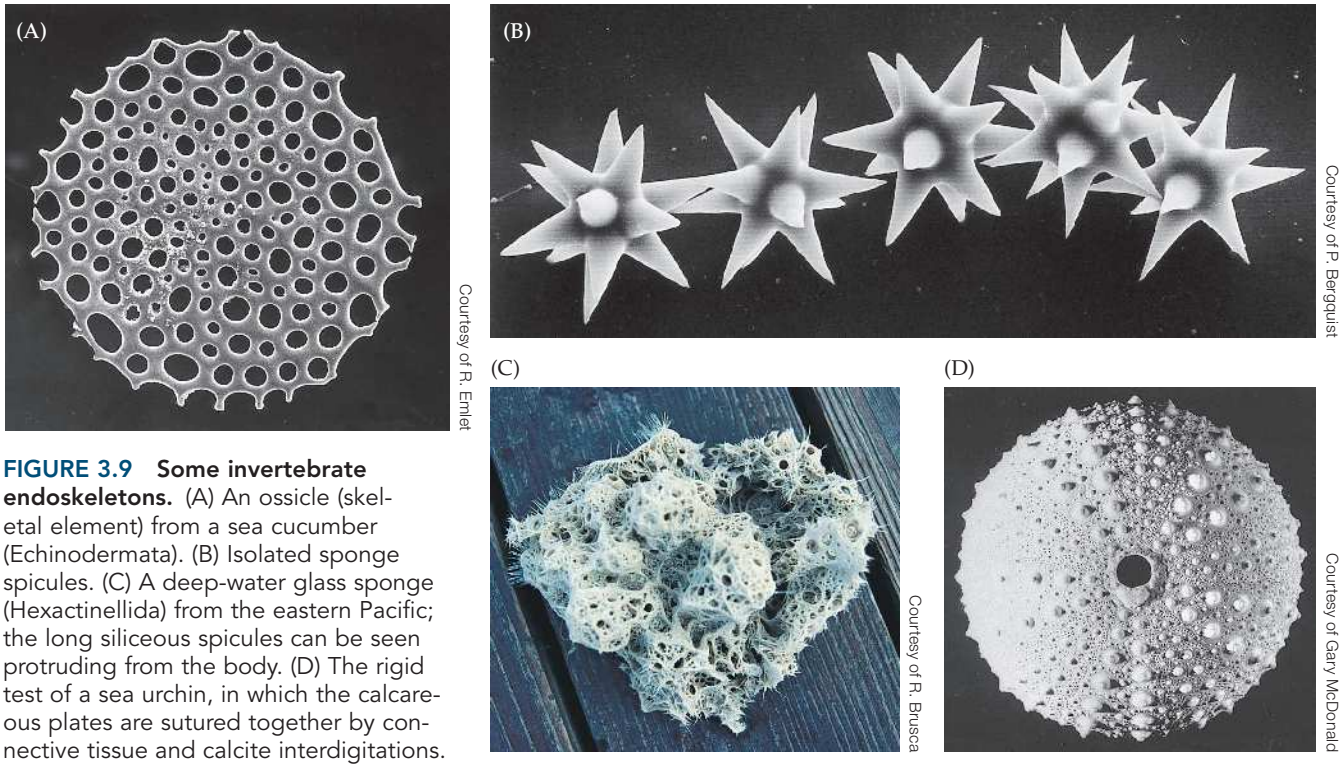

FIGURE 3.9 Some invertebrate endoskeletons. (A) An ossicle (skeletal element) from a sea cucumber (Echinodermata). (B) Isolated sponge spicules. (C) A deep-water glass sponge (Hexactinellida) from the eastern Pacific; the long siliceous spicules can be seen protruding from the body. (D) The rigid test of a sea urchin, in which the calcareous plates are sutured together by connective tissue and calcite interdigitations.

From their epidermis, many Metazoa secrete a nonliving external layer called the cuticle, which serves as an exoskeleton. A cuticle is an extracellular matrix secreted by and covering the epidermis. It may be composed of various different organic materials, such as a glycocalyx matrix, collagen, keratin, chitin, and cellulose. It may also be mineralized to form spicules or shells. The cuticle varies in thickness and complexity, but it often has several layers of differing structure and composition. In the arthropods, for example, the cuticle is a complex combination of the polysaccharide chitin and various proteins.[4] This skeleton may be strengthened by the formation of internal cross-linkages (a process called **tanning**) and by the addition of calcium and pigments. The chitinous layer of most invertebrates is the first line of defense against infective microbes and desiccation. In most insects, the outermost layer is impregnated with wax, which decreases its permeability to water. The cuticle is often ornamented with spines, tubercles, scales, or striations; frequently it is divided into rings or segments, a feature lending flexibility to the body (Figure 3.10).

Most skeletons act as body elements against which muscles operate and by which muscle action is converted to body movement. Because muscles cannot elongate by themselves, they must be stretched by antagonistic forces—usually other muscles, hydrostatic forces, or elastic structures. In animals possessing rigid but articulated skeletons, antagonistic muscles often appear in pairs, for example, flexors and extensors. These muscles extend across a joint and are used to move a limb or other body part (Figure 3.11). Most muscles have a discrete origin, where the muscle is anchored, and an insertion, which is the point of major body or limb movement. A classic vertebrate example of this system is the biceps muscle of the human arm, in which the origin is on the scapula and the insertion is on the radius bone of the forearm; contraction of the biceps causes flexion of the arm by decreasing the angle between the upper arm and the forearm. Movement of a limb toward the body is brought about by **flexor muscles**, of which the biceps is an example (Figure 3.11A,B). The muscle antagonistic to the biceps is the triceps, an **extensor muscle** whose contraction extends the forearm away from the body. Other common sets of antagonistic muscles and actions are **protractors** and **retractors**, which respectively cause anterior and posterior movement of entire limbs at their place of juncture with the body; and **adductors** and **abductors**, which move a body part toward or away from a particular point of reference. Although vertebrates have

[4]The term "chitin" refers to a family of closely related chemical compounds, which, in various forms, are produced by and incorporated into the cuticles of many invertebrates. Certain types of chitin are also produced by some fungi and diatoms. Chitins are high-molecular-weight, nitrogenous polysaccharide polymers that are tough yet flexible (Figure 3.10C). In addition to its supportive and protective functions in the formation of exoskeletons, chitin is also a major component of the teeth, jaws, and grasping and grinding structures of a wide variety of invertebrates. That chitin is one of the most abundant macromolecules on Earth is evidenced by the estimated 1,011 tons produced annually in the biosphere—most of it in the ocean.

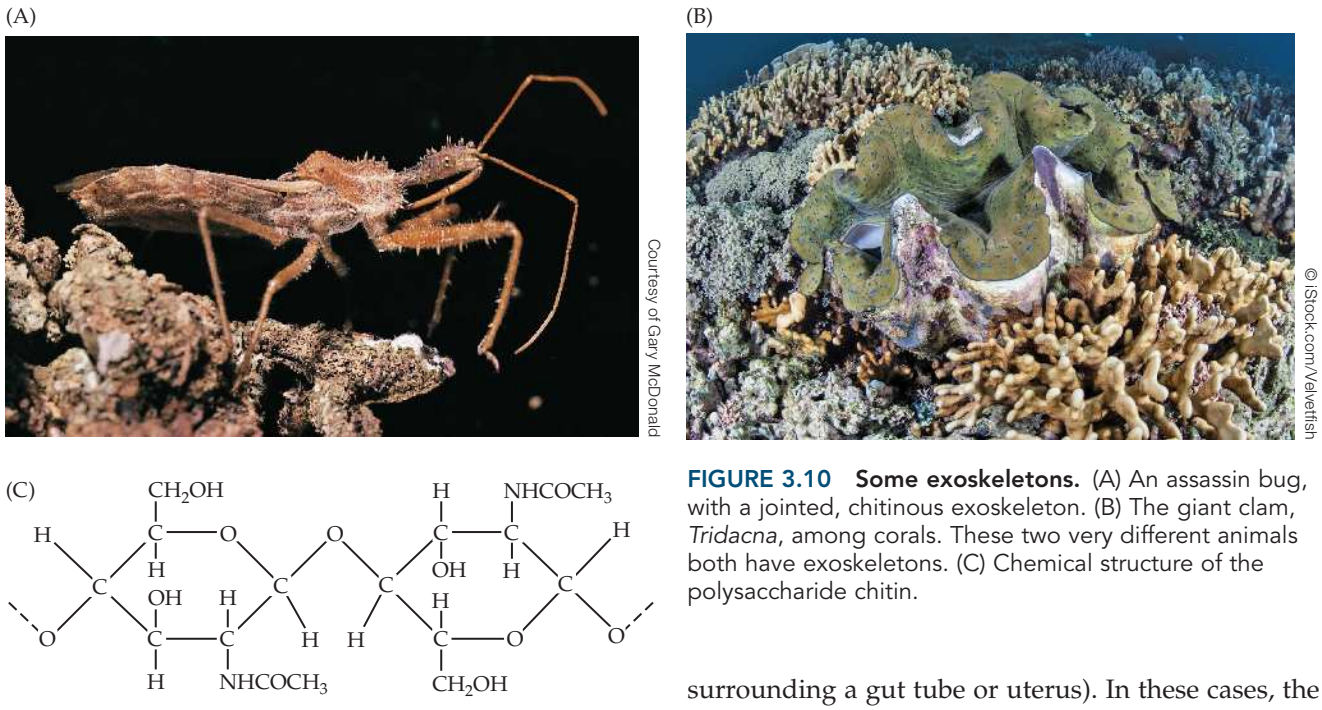

FIGURE 3.10 Some exoskeletons. (A) An assassin bug, with a jointed, chitinous exoskeleton. (B) The giant clam, *Tridacna*, among corals. These two very different animals both have exoskeletons. (C) Chemical structure of the polysaccharide chitin.

endoskeletons and arthropods have exoskeletons, most muscles of arthropods are arranged in antagonistic sets similar to those seen in vertebrates (Figure 3.11C). The muscles of arthropods attach to the inside of the skeletal parts, whereas those of vertebrates attach to the outside, but they both operate systems of levers.

Not all muscles attach to rigid endo- or exoskeletons. Some form masses of interlacing muscle fibers, like those in the body wall of a worm, the foot of a snail, or the muscle layers in the walls of "hollow" organs (like those surrounding a gut tube or uterus). In these cases, the muscles have no definite origin and insertion but act on each other and the surrounding tissues and body fluids to affect changes in the shape of the body or body parts.

The basic physiology and biochemistry of muscle contraction is the same in vertebrates and invertebrates, although a variety of specialized variations on the basic model have evolved. For example, the adductor muscle of most clams (the muscle that holds the shell closed) is divided into two parts. One part is heavily striated and used for rapid shell closure (the phasic, or "quick," muscle); the other is smooth, or tonic, and is used to hold the shell closed for hours or

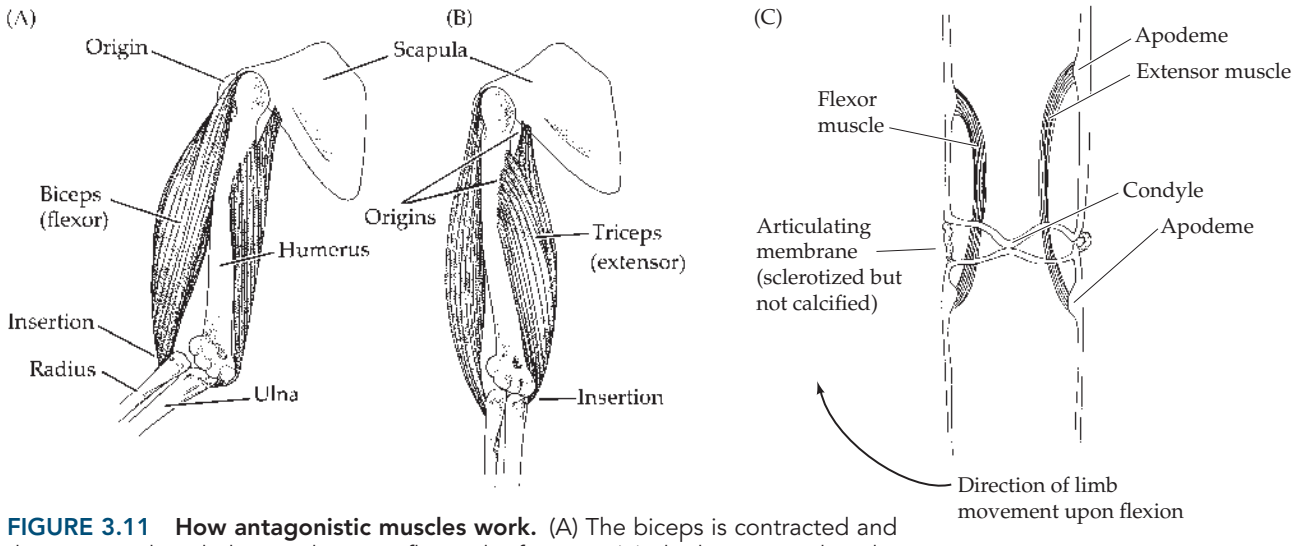

FIGURE 3.11 How antagonistic muscles work. (A) The biceps is contracted and the triceps relaxed; this combination flexes the forearm. (C) A diagrammatic representation of an arthropod joint, illustrating a similar relationship between flexor and extensor. In arthropods, however, the muscles attach to the inside of the skeleton.

even days at a time (the "catch" muscle). Brachiopods have a similar adductor muscle specialization—a good example of convergent evolution. Other specializations are found in crustacean muscle innervation, which differs from that typically seen in other invertebrates, and in certain insect flight muscles that are capable of contracting at frequencies far higher than can be induced by nerve impulses alone.

Feeding and Digestion

Intracellular and Extracellular Digestion

Virtually all Metazoa must locate, select, capture, ingest, and finally digest and assimilate food. Although the physiology of digestion is similar at the biochemical level, considerable variation exists in the mechanisms of capture and digestion as a result of constraints placed on organisms by their overall body plans.

Digestion is the process of breaking down food by hydrolysis into units suitable to the nutrition of cells. When this breakdown occurs outside the body, it is called **extracorporeal digestion**; when it occurs in a gut chamber of some sort, it is referred to as **extracellular digestion**; and when the process occurs within a cell, it is called **intracellular digestion**. Regardless of the site of digestion, all organisms are ultimately faced with the fundamental challenge of cellular capture of nutritional products (food, digested or not). This cellular challenge is met by the process of **phagocytosis** (literally, "eating by cells") and **pinocytosis** ("drinking by cells"). These processes, collectively called **endocytosis**, are mechanically simple and involve the engulfment of food "particles" at the cell surface.

In 1892 the great comparative anatomist Elie Metchnikoff made a discovery that led to his receiving a Nobel Prize 16 years later. Metchnikoff discovered the process by which certain ameboid cells in the coelomic fluid of starfish engulf and destroy foreign matter such as bacteria. He named this process phagocytosis. In phagocytosis, extensions of a cell's plasma membrane encircle the particle to be captured (whether it be food or a foreign microbe), form an inpocketing on the cell surface, and then pinch off the pocket inside the cell (Figure 3.12A). The resultant intracellular membrane-bounded structure is called a food vacuole. The plasma membrane surrounding the food vacuole is, of course, no longer part of the cell's outer membrane, and in this sense it and whatever is in the vacuole are now "inside" the cell, and the subsequent digestive processes that take place are considered intracellular, not extracellular. However, food inside the food vacuole is not actually incorporated into the cell's cytoplasm until it is digested and the resultant molecules are released.

Sponges largely rely on phagocytosis as a feeding mechanism, and the digestive cells of metazoan guts take up food particles in the same fashion. Once a cell has phagocytosed a food particle and intracellular digestion has been completed, any remaining waste particles may be carried back to the cell surface by what remains of the old food vacuole, which fuses with the plasma membrane to discharge its wastes in a sort of reverse phagocytosis, called **exocytosis**.

Pinocytosis can be thought of as a highly specialized form of phagocytosis, in which molecule-sized particles are taken up by the cell. Such molecules are always dissolved in some fluid (e.g., a body fluid or sea water). During pinocytosis, minute invaginations (pinocytotic channels) form on the cell surface, fill with liquid from the surrounding medium (which includes the dissolved nutritional molecules), and then pinch off to enter the cytoplasm as pinocytotic vesicles (Figure 3.12B). Pinocytosis generally occurs in cells lining some body cavity

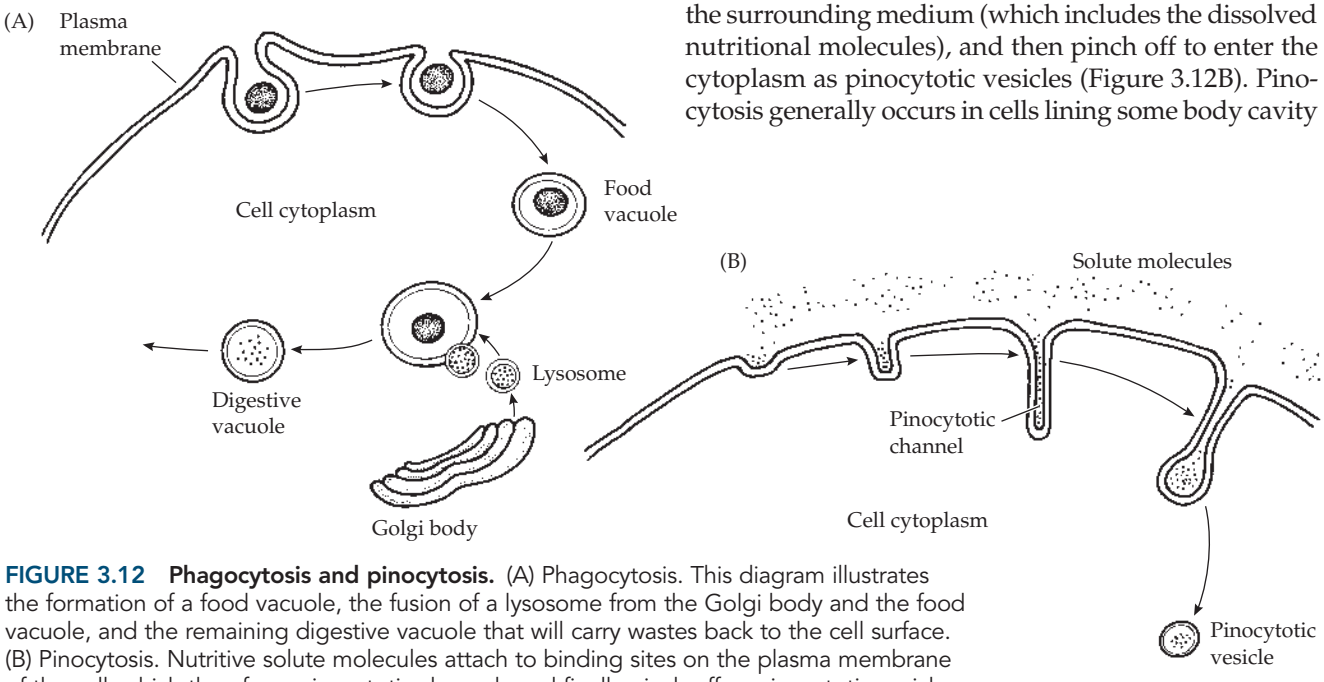

FIGURE 3.12 Phagocytosis and pinocytosis. (A) Phagocytosis. This diagram illustrates the formation of a food vacuole, the fusion of a lysosome from the Golgi body and the food vacuole, and the remaining digestive vacuole that will carry wastes back to the cell surface. (B) Pinocytosis. Nutritive solute molecules attach to binding sites on the plasma membrane of the cell, which then form pinocytotic channels and finally pinch off as pinocytotic vesicles.

for more ebook/ testbank/ solution manuals Request Kingdom email 960126734@qq.com

(e.g., the gut) in which considerable extracellular digestion has already taken place and nutritive molecules have been released from the original food source. In some cases, however, nutritional molecules may be taken up directly from seawater, and there is growing evidence that many invertebrates rely substantially on the direct uptake of dissolved organic matter (DOM) from their environment, including many sponge cells, and this is the main way of feeding of placozoans.

Some animals have no true digestive tract (e.g., Porifera, Placozoa, tapeworms, acanthocephalans), but most metazoans possess some sort of dedicated, internal chamber into which food is moved for processing. In some (e.g., Cnidaria, Xenacoelomorpha, Platyhelminthes) there is only one opening through which food is ingested and undigested materials are eliminated. These animals are said to have an **incomplete gut** (or blind gut). Most other Metazoa have both mouth and anus (a **complete gut**, or **through gut**), an arrangement that allows the one-way flow of food and the specialization of different gut regions for functions such as grinding, secretion, storage, digestion, and absorption. As the noted biologist Libbie Hyman so aptly put it, "The advantages of an anus are obvious," and ctenophores have two, although it seems that only one might be functional, though which one is functional is not necessarily the same in different individuals even of the same species!

The overall anatomy and physiology of an animal's gut are closely tied to the type and quality of food consumed. In general, the guts of herbivores are long and often have specialized chambers for storage, grinding, and so on because vegetable matter is difficult to digest and requires long residence times in the digestive system. Carnivores tend to have shorter, simpler guts, and the animal foods they consume are easier to digest.

Feeding Strategies

Just as body architecture influences and limits the digestive modes of invertebrates, it is also intimately associated with the processes of food location, selection, and ingestion. Animals are generally defined as **heterotrophic** organisms (as opposed to autotrophs and saprophytes); they ingest organic material in the form of other organisms or parts thereof. In addition, many invertebrate groups have developed intimate symbiotic relationships with single-celled algae, especially with certain species of dinoflagellates. These invertebrates use photosynthetic byproducts as an accessory (or occasionally as the primary) food source. Notable in this regard are reef-building corals, giant clams (*Tridacna*) (Figure 3.10B), and certain flatworms, acoels, sea slugs, hydroids, ascidians, sea anemones, and even some freshwater sponges. However, the overwhelming majority of invertebrates lead strictly heterotrophic lives.

Biologists classify heterotrophic feeding strategies in a number of ways. For example, organisms can be considered herbivores, carnivores, or omnivores; or they can be classed as grazers, predators, or scavengers. Organisms can also be classified as microphagous or macrophagous by the comparative size of their food or prey, or they can be classified by the environmental source of their food as suspension feeders, deposit feeders, or detritivores. In the remainder of this section, we define some important feeding-strategy terms and explain some common themes of feeding.

Few invertebrates are strictly herbivores or carnivores, even though most show a clear preference for either a vegetable or a meat diet. For example, the Atlantic purple sea urchin *Arbacia punctulata* usually feeds on micro- and macroalgae. However, in certain portions of its range, where algae may become seasonally scarce, epifaunal animals constitute the bulk of this urchin's diet. Omnivores, of course, must have the anatomical and physiological capability to capture, handle, and digest both plant and animal material. Among invertebrates, there are two large categories of feeding strategies in which omnivory prevails: suspension feeding and deposit feeding.

Suspension feeding **Suspension feeding** is the removal of suspended food particles from the surrounding medium by some sort of capture, trapping, or filtration mechanism. Lest you think suspension feeding is a sideline strategy in the animal kingdom, let us remind you that the largest living animals utilize it—baleen whales and several lineages of sharks and rays. This mode of feeding has three basic steps: transport of water past the feeding structures, removal of particles from the water, and transport of the captured particles to the mouth. It is a major mode of feeding in sponges, ascidians, appendicularians, brachiopods, bryozoans, entoprocts, phoronids, most bivalves, and many crustaceans, polychaetes, echinoderms, hemichordates, and gastropods. The main food selection criterion is particle size, and the size limits of food are determined by the nature of the particle-capturing device. In some cases potential food particles may also be sorted on the basis of their specific gravity, or even their perceived nutritional quality.

Suspension-feeding invertebrates generally consume bacteria, phytoplankton, zooplankton, and some detritus. All suspension feeders probably have optimal ranges of particle size; but some are capable, experimentally, of preferentially selecting "enriched" artificial food capsules over nonenriched (nonfood) capsules, an observation suggesting that chemosensory selectivity may occur in situ as well. To capture food particles from their environment, suspension feeders must move part or all of their body through the water, or else water must be moved over their feeding structures. As with locomotion in water, the relative motion between a solid and liquid during suspension feeding creates a system that behaves according to the concept of Reynolds numbers. Virtually all suspension-feeding invertebrates capture

particles from the water at low Reynolds numbers. The flow rates in such systems are very low and the feeding structures are small (e.g., cilia, flagella, setae).

Recall that at low Reynolds numbers viscous forces dominate, and water flow over small feeding structures is laminar and nonturbulent and ceases instantaneously when energy input stops. Thus, in the absence of inertial influence, suspension feeders that generate their own feeding currents expend a great deal of energy. Some suspension feeders conserve energy by depending to various degrees on prevailing ambient water movements to continually replenish their food supplies (e.g., barnacles on wave-swept shores and mole crabs in the wash zone on sandy beaches). Others take advantage of water currents created by other animals, as is typical in many brittle stars and other invertebrates that sit on top of sponges to get their food. For most organisms, however, the effort expended for feeding is a major part of their energy budget.

Only a relatively few suspension feeders are true filterers. Because of the principles outlined above, it is energetically extremely costly to drive water through a fine-meshed filtering device. For small animals, this is somewhat analogous to moving a fine-mesh filter through thick syrup. Such actual sieving does occur, most notably in many bivalve molluscs, many tunicates, some larger crustaceans, and some worms that produce mucous nets. However, most suspension feeders employ a less expensive method of capturing particles from the water, one that does not involve continuous filtration. Many invertebrates simply expose a sticky surface, such as a coating of mucus, to flowing water. Suspended particles contact and adhere to the surface and then are moved to the mouth by ciliary tracts (as in crinoids), setal brushes (as in certain crustaceans), or some other means of transport. Other "contact suspension feeders" living in still water may simply expose a sticky surface to the rain of particulate material settling downward from the water above, thus letting gravity do much of the work of acquiring food. Some oysters are suspected of this feeding strategy, at least on a part-time basis. Several other contact methods of suspension feeding may occur, but all eliminate the costly activity of actual sieving in the highly viscous world of low Reynolds numbers.

Another nonfiltering suspension-feeding method is called "scan and trap." The general strategy here is to move water over part or all of the body, detect suspended food particles, isolate the particles in a small parcel of water, and process only that parcel by some method of particle extraction. The animal thus avoids the energetic expense of continuously driving water over the feeding surface at low Reynolds numbers. The precise methods of particle detection, isolation, and capture vary among invertebrates that use the scan-and-trap technique, and this basic strategy is probably employed by certain crustaceans (e.g., planktonic copepods), many bryozoans, and a variety of larval forms.

Among some crustaceans, certain limbs are equipped with rows of featherlike setae adapted for removing particles from the water (Figure 3.13). The size of the particles captured is often directly proportional to the "mesh" size of the interlaced setae on the food-capture structure. In sessile crustaceans such as barnacles, the feeding appendages are swept through the water or held taut against moving water. In either case, sessile animals are dependent upon local currents to continually replenish their food supply. Motile setal-net feeders, like many larger planktonic crustaceans and certain benthic crustaceans (e.g., porcelain crabs), may have modified appendages that generate a current across the feeding appendages that bear the capture setae. Sometimes these same appendages serve simultaneously for locomotion. In cephalocarid and many branchiopod crustaceans, for example, complex coordinated movements of the highly setose thoracic legs propel the animal forward and also produce a constant current of water (Figure 3.13D). These appendages simultaneously capture food particles from the water and collect them in a median ventral food groove at the leg bases, from which they are passed forward to the mouth region.

Another suspension-feeding device is the mucous net, or mucous trap, wherein a sheet or patches of mucus are used to capture suspended food particles. Most mucous-net feeders consume their net along with the food and then recycle the chemicals used to produce it. Again, sessile and sedentary species often rely largely on local currents to keep a fresh supply of food coming their way. Some, however, especially benthic burrowers, actively pump water through their burrow or tube, where it passes across or through the mucous sheet. A classic example of mucous-net feeding is seen in the annelid worm *Chaetopterus* (Figure 3.14A). This animal lives in a U-shaped tube in the sediment and pumps water through the tube and through a mucous net. As the net fills with trapped food particles, it is periodically manipulated and rolled into a ball, which is then passed to the mouth and swallowed. An example of mucous-trap feeding is seen in the tube-building gastropods (family Vermetidae). These wormlike snails construct colonies of meandering calcareous tubes in the intertidal zone. Each animal secretes a mucous trap that is deployed just outside the opening of the tube, until nearly the entire colony surface is covered with mucus. Suspended particulate matter settles and becomes trapped in the mucus. At periodic intervals, each animal withdraws its mucous sheet and swallows it, whereupon a new sheet is immediately constructed.

Still another type of suspension feeding is the ciliary-mucous mechanism, in which rows of cilia carry a mucous sheet across some structure while water is passed through or across it. Ascidians (sea squirts; Figure 3.14B) move a more or less continuous

mucous sheet across their sievelike pharynx, while at the same time pumping water through it. Fresh mucus is secreted at one side of the pharynx while the food-laden mucus at the other side is moved into the gut for digestion. Several hemichordate and polychaete groups also make use of the ciliary-mucous feeding technique (Figure 3.14C). For example, some species of tube-dwelling fan worms feed with a crown of tentacles that are covered with cilia and mucus and bear ciliated grooves that slowly move captured food particles to the mouth. Many sand dollars capture suspended particles, especially diatoms, on their mucus-covered spines; food and mucus are transported by the tube feet and ciliary currents to food tracts, and then to the mouth.

And another kind of suspension feeding is tentacle or tube feet suspension feeding. In this strategy, some sort of tentacle-like structure captures larger food particles, with or without the aid of mucus. Food particles captured by this mechanism are generally larger than those captured by setal or mucous traps or sieves. Examples of tentacle or tube feet suspension feeding are most commonly encountered in the echinoderms (e.g., many brittle stars and crinoids as well as dendrochirotid sea cucumbers) and cnidarians (e.g., certain sea anemones, gorgonians, and corals) (Figure 3.15).

Much research has been done on suspension feeding, and we now know what size range of particles many animals feed on and what kinds of capture rates they have. In general, feeding rates increase with food particle concentration to a plateau, above which the rate levels off. At still higher particle concentrations, entrapment mechanisms may become overtaxed or clogged and feeding may be inhibited or simply cease. In sessile and sedentary suspension feeders, for example, pumping rates decrease quickly as the amount of suspended inorganic sediment (mud, silt, and sand) increases beyond a given concentration. For this reason, the amount of sediment in coastal waters limits the distribution and abundance of certain invertebrates such as clams, corals, sponges, and ascidians. Many tropical coral reefs are dying as a result of increased coastal sediment loads generated by runoff from land areas subjected to deforestation or urban development.

Deposit feeding The **deposit feeders** make up another major group of omnivores. These animals obtain nutrients from the sediments of soft-bottom habitats (muds and sands) or terrestrial soils, but their techniques for feeding are diverse. Direct deposit feeders simply swallow large quantities of

The worm's head is seen sweeping around the radial spokes to retrieve the mucous web and its trapped food particles.

sediment—mud, sand, soil, organic matter, everything. In some cases, they may consume hundreds of times their body weight daily. The usable organics are digested and the unusable materials passed out the anus. The resultant fecal material is essentially "cleaned dirt." This kind of deposit feeding is seen in many polychaete annelids (Figure 3.16A), some snails, some sea urchins, and most earthworms and sea cucumbers. Some deposit feeders utilize tentacle-like structures to consume sediment; these include some sea cucumbers, most sipunculans, certain bivalves, and several types of polychaetes (Figure 3.16B,C). Tentacle-utilizing deposit feeders preferentially remove only the uppermost deposits from the sediment surface and thus consume a far greater percentage of living organisms (especially bacteria, diatoms, and protists) and detrital organic material that accumulates there than do the burrowing deposit feeders. These tentacle-utilizing animals are generally called **selective deposit feeders**. Aquatic deposit feeders may also rely to a significant extent on fecal material that accumulates on the bottom, and many will actively consume their own fecal pellets (**coprophagy**), which may contain some undigested or incompletely digested organic material as well as microorganisms. Studies have shown that only about half

of the bacteria ingested by marine deposit feeders is digested during passage through the gut. In all cases, deposit feeders are microphagous.

The ecological role of deposit feeding in sediment turnover is a critical one. When burrowing deposit feeders are removed from an area, organic debris accumulates, subsurface oxygen is depleted by bacterial decomposition, and anaerobic sulfur bacteria eventually bloom. On land, earthworms and other burrowers are important in maintaining the health of agricultural and garden soils.

Herbivory The following discussion deals with macroherbivory, or the consumption of macroscopic plants and algae. **Herbivory** is common throughout the animal kingdom.[5] It is most dramatically illustrated when certain invertebrate herbivores undergo a temporary population explosion. Famous examples are outbreaks of locusts, which can destroy virtually all plant material in their path of movement. In a similar fashion, herbivory by extremely high numbers of the Pacific sea urchin *Strongylocentrotus purpuratus* results in the wholesale destruction of kelp beds. Unlike suspension- and deposit-feeding herbivory, in which mostly single-celled and microscopic plant matter is consumed, macroherbivory requires the ability to "bite and chew" large pieces of vegetable matter. Although the evolution of biting and chewing mechanisms has taken place within the architectural framework of a number of different invertebrate lineages, it is always characterized by the development of hard (usually calcified or chitinous) "teeth," which are manipulated by powerful muscles. Members of a number of major invertebrate taxa have evolved macroherbivorous lifestyles, including molluscs, polychaetes, arthropods, and sea urchins.

Most molluscs have a unique structure called a **radula**, which is a muscularized, beltlike rasp armed with chitinous teeth that can be hardened with iron oxides. Herbivorous molluscs use the radula to scrape algae off rocks or to tear pieces of algal fronds or the leaves of terrestrial plants. The radula acts like a curved file that is drawn across the feeding surface (Figure 3.17C,D). Some polychaetes, such as nereids (family Nereidae), have sets of large chitinous teeth on an eversible pharynx or proboscis. The proboscis is protracted by hydrostatic pressure, exposing the teeth, which by muscular action tear or scrape off pieces of algae that are swallowed when the proboscis is retracted. As might be expected, the toothed pharynx of polychaetes is also suited for carnivory, and many primarily herbivorous polychaetes can switch to meat eating when algae are scarce. Sap-sucking sea slugs (Gastropoda: Sacoglossa) feed by piercing algal cells and sucking out the cellular contents. In some species of sacoglossans, the slugs sequester and use the living chloroplasts from the algae they feed on as a "solar energy source"—a unique behavior among metazoans.

Macroherbivory in arthropods is best illustrated by certain insects and crustaceans. Both of these large groups have powerful mandibles capable of biting off pieces of plant material and subsequently grinding or chewing them before ingestion. Some macroherbivorous

[5] Although in the broad sense, herbivory is a form of predation (on plants), for clarity of discussion we restrict the use of "herbivory" to vegetable eating and the use of "predation" to animal eating.

arthropods are able to temporarily switch to carnivory when necessary. This switching is rarely seen in the terrestrial herbivores because it is almost never necessary; terrestrial plant matter can almost always be found. In marine environments, however, algal supplies may at times be very limited. Some invertebrates have become specialized to feed on dead cellulose through their relationship with endosymbiotic bacteria, such as the sea daisies (Echinodermata: Asteroidea) and shipworms. Shipworms (highly specialized bivalve molluscs in the family Teredinidae) feed on floating logs, pier pilings, and ship bottoms in the sea (Figure 3.18).

Carnivory and scavenging The most sophisticated methods of feeding are those that require the active capture of live animals, or predation. Most carnivorous predators will, however, consume dead or dying animal matter when live food is scarce. Only a few generalizations about the many kinds of predation are presented here; detailed discussions of various taxa are presented in their appropriate chapters.

Active predation often involves five recognizable steps: prey location (predator orientation), pursuit (usually), capture, handling, and finally ingestion. Prey location usually requires a certain level of nervous system sophistication in which specialized sense organs are present (discussed later in this chapter). Many carnivorous invertebrates rely primarily on chemosensory location of prey, although many also use visual orientation, touch, and vibration detection. Chemoreceptors tend to be equally distributed around the bodies of radially symmetrical carnivores (e.g., jellyfish) but, coincidentally with cephalization, most invertebrates have their gustatory and olfactory receptors ("tasters" and "smellers") concentrated in the anterior region of their body or even in the head, if this anterior region is differentiated. A number of insects, including fruit flies, mosquitoes, and moths, rely on CO_2 sensing to locate their food source, but the sensing mechanisms are not yet fully characterized.

Predators may be classified by how they capture their prey—as motile stalkers, lurking predators (ambushers), sessile opportunists, or grazers (Figure 3.19). Stalkers actively pursue their prey; they include

The walls of the burrow are lined with a smooth, calcareous, shell-like material.

members of such disparate groups as polyclads, nemerteans, polychaete worms, gastropods, octopuses and squids, crabs, starfish, and many terrestrial arthropods. In all these groups, chemosensation is highly important in locating potential prey, although some cephalopods are known to be the most highly visual of all the invertebrate predators.

Lurking predators are those that sit and wait for their prey to come within capture distance, whereupon they quickly seize the victim. Many lurking predators, such as certain species of mantis shrimps (stomatopods), crabs, snapping shrimp (Alpheidae), spiders, and polychaetes, live in burrows or crevices from which they emerge to capture passing prey. There are even ambushing planarian flatworms, which produce mucous patches that form sticky traps for their prey. The cost of building traps is significant. Ant lions, for example, may increase their energy consumption as much as eightfold when building their sand capture pits, and energy lost in mucus secretion by planarians may account for 20% of the worm's energy. Predatory invertebrates, especially lurking predators, are frequently more or less territorial.

Sessile opportunists operate in much the same fashion as lurking predators do, but they lack the mobility of the latter. The same may be said for drifting opportunists, such as most jellyfishes. Many sessile predators, such as barnacles and cnidarians, are actually suspension feeders with a strong preference for live prey. A unique kind of carnivorous scavenging is seen in bone-eating annelid worms (*Osedax* spp.) that employ bacterial endosymbionts to facilitate their consumption of marine vertebrate bones that fall to the seafloor.

Grazing carnivores move about the substratum picking at the epifauna. Grazers may be indiscriminate, consuming whatever happens to be present, or they may be fairly choosy about what they eat. In either case, their diet consists largely of sessile and slow-moving animals, such as sponges, bryozoans, tunicates, snails, small crustaceans, and worms. Most grazers are omnivorous to some degree, consuming plant material along with their animal prey. Many crabs and shrimps are excellent grazers, continuously moving across the bottom and picking through the epifauna for tasty morsels. Sea spiders (pycnogonids) and some carnivorous sea slugs can also be classed as grazers on hydroids, bryozoans, sponges, tunicates, and other sessile epifauna. Ovulid snails (family Ovulidae) inhabit, and usually mimic, the gorgonians and corals upon which they slowly crawl about, nipping off polyps as they go.

One special category of carnivory is cannibalism, or intraspecific predation. Gary Polis (1981) examined over 900 published reports describing cannibalism in about 1,300 different species of animals. In general, he found that species of large animals (and also larger individuals in any given species) are the most likely to be cannibals. By far, the majority of the victims are juveniles. However, in a number of invertebrate groups, the tables turn and cannibalism occurs when smaller individuals band together to attack and consume a larger individual. Furthermore, females tend generally to be more cannibalistic than males, and males tend to be eaten far more often than females. In many species, filial cannibalism is common, in which a parent eats its dying, deformed, weak, or sick offspring. Polis concluded that cannibalism is a major factor in the biology of many species and may influence population structure, life history, behavior, and competition for mates and resources. He went so far as to point out that *Homo sapiens* may be "the only species capable of worrying whether its food is intra- or extraspecific."

Dissolved organic matter The total living biomass of the world's oceans is estimated to be about 2×10^9 tons of organic carbon (roughly 500 times the amount of organic carbon in the terrestrial environment). Furthermore, an additional 20×10^9 tons of particulate organic matter is estimated to occur in the seas, and another 200×10^9 tons of organic carbon (C) may occur in the seas as **dissolved organic matter (DOM)**.

(H) The Atlantic dog whelk (*Nucella lapillus*), a predatory gastropod feeding on small barnacles.

Thus, at any moment in time, only a small fraction of the organic carbon in the world's seas actually exists in living organisms. Amino acids and carbohydrates may be the most common dissolved organics. Typical oceanic values of DOM range from 0.4 to 1.0 mg C/liter, but they may reach 8.0 mg C/liter near shore. Pelagic and benthic algae release copious amounts of DOM into the environment, as do certain invertebrates. Coral mucus, for example, is an important fraction of suspended and dissolved organic material over reefs, and it contains significant amounts of energy-rich compounds, including mono- and polysaccharides and amino acids. Other sources of DOM include decomposing tissue, detritus, fecal material, and metabolic byproducts discharged into the environment.

The idea that DOM may contribute significantly to the nutrition of marine invertebrates has been around for over 100 years. Marine microorganisms are known to use DOM, but its relative role in the nutrition of aquatic Metazoa is uncertain. Available data strongly suggest that members of all marine taxa (except perhaps arthropods and vertebrates) are capable of absorbing DOM to some extent, and in the case of ciliary-mucous suspension feeders, marine larvae, and many echinoderms and mussels, the ability to rapidly take up dissolved free amino acids from a dilute external medium is well established. But because of the complex chemical nature of dissolved organics, and the difficulty of measuring their rates of influx and loss, we still lack strong evidence of the actual use, or relative nutritional importance, of DOM to invertebrates.

Evidence from numerous studies indicates that absorption of DOM occurs directly across the body wall of invertebrates, as well as via the gills. Also, inorganic particles of colloidal dimensions provide a surface on which small organic molecules are concentrated by adsorption, to be captured and utilized by suspension-feeding invertebrates. Interestingly, most freshwater organisms seem incapable of removing small organic molecules from solution at anything like the rates characteristic of marine invertebrates. In fresh water, the uptake of DOM is probably retarded by the processes of osmoregulation.

Chemoautotrophy A special form of autotrophy that occurs in certain bacteria relies not on sunlight and photosynthesis as a source of energy to make organic molecules from inorganic raw materials (**photoautotrophy**), but rather on the oxidation of certain inorganic substances. This is called **chemoautotrophy**. Chemoautotrophs use CO_2 as their carbon source, obtaining energy by oxidizing hydrogen sulfide (H_2S), ammonia (NH_3), methane (CH_4), ferrous ions (Fe^{2+}), or some other chemical, depending on the species. These prokaryotes are not uncommon in aerated soils, and certain species live as symbionts in the tissues of a few marine invertebrates.

Some of the most interesting of these chemoautotrophic organisms derive their energy from the oxidation of hydrogen sulfide released at hydrothermal vents on the deep-sea floor—where, in fact, they are the sole primary producers in the ecosystem. In this environment, chemoautotrophic bacteria inhabit the tissues of certain mussels, clams, and vestimentiferan tube worms, where they produce organic compounds that are utilized by their hosts. Similar invertebrate-bacteria relationships have been discovered in shallow cold-water petroleum and salt (brine) seeps, where the chemoautotrophic microorganisms live off the methane- and hydrogen sulfide–rich waters associated with such seafloor environments. In all these cases, the bacteria actually live within the cells of their hosts. In bivalves, the bacteria inhabit the gill cells and extract methane or other chemicals from the water that flows over those structures. In the case of the tube worms, the hosts must transport the H_2S to their bacterial partners, which live in tissues deep within the animals' bodies. The worms have a unique type of hemoglobin that transports not only oxygen (for the worm's metabolism) but sulfide as well.

Excretion and Osmoregulation

Excretion is the elimination from the body of metabolic waste products, including carbon dioxide and water (produced primarily by cellular respiration) and excess nitrogen (produced as ammonia from deamination of amino acids). The excretion of respiratory CO_2 is generally accomplished by structures that are separate from those associated with other waste products and is discussed in the Circulation and Gas Exchange section.

The excretion of nitrogenous wastes is usually intimately associated with osmoregulation—the regulation of water and ion balance within the body fluids—so these processes are considered together here. Excretion, osmoregulation, and ion regulation serve not only to rid the body of potentially toxic wastes, but also to maintain concentrations of the various components of body fluids at levels appropriate for metabolic activities. As we shall see, these processes are structurally and functionally tied to the overall level of body complexity and construction, the nature of other physiological systems, and the environment in which an animal lives. We again emphasize the necessity of

looking at whole animals, the integration of all aspects of their biology and ecology, and the possible evolutionary histories that could have produced compatible and successful combinations of functional systems.

Nitrogenous Wastes and Water Conservation

The source of most of the nitrogen in an animal's system is amino acids produced from the digestion of proteins. Once absorbed, these amino acids may be used to build new proteins, or they may be deaminated and the residues used to form other compounds (Figure 3.20). The excess nitrogen released during deamination is typically liberated from the amino acid in the form of ammonia (NH_3), a highly soluble but quite toxic substance that must be either diluted and eliminated quickly or converted to a less toxic form. Typically, one nitrogenous waste form tends to predominate in a given species, and the nature of that chemical is generally related to the availability of environmental water.

The major excretory product in most marine and freshwater invertebrates is ammonia, since their environment provides an abundance of water as a medium for rapid dilution of this toxic substance. Such animals are said to be **ammonotelic**. Being highly soluble, ammonia diffuses easily through fluids and tissues, and much of it is lost straight across the body walls of some ammonotelic animals. Animals that do not possess discrete excretory organs (e.g., sponges, cnidarians, xenacoelomorphs, and echinoderms) are more or less limited to the production of ammonia and thus are restricted to aquatic habitats.

Terrestrial invertebrates (indeed, all land animals) have water conservation challenges. They simply cannot afford to lose much body water in the process of diluting their wastes. These animals convert their nitrogenous wastes to more complex but far less toxic substances. These compounds are energetically expensive to produce, but they often require relatively little or no dilution by water, and they can be stored within the body prior to excretion.

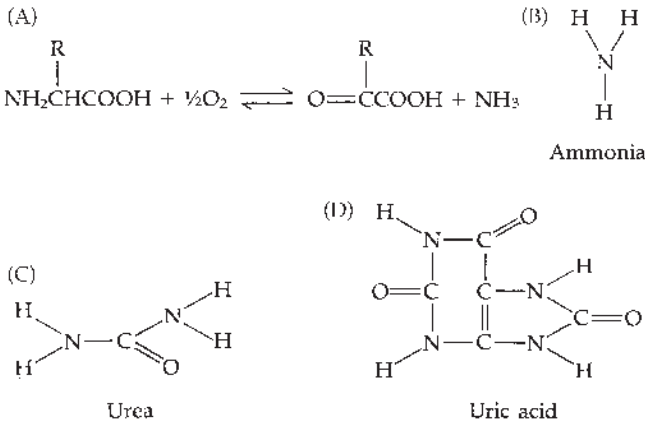

FIGURE 3.20 Nitrogenous waste products. (A) The general reaction for deamination of an amino acid producing a keto acid and ammonia. (B–D) The structures of three common excretory compounds. (B) Ammonia. (C) Urea. (D) Uric acid.

There are two major metabolic pathways for the detoxification of ammonia: the urea pathway and the uric acid pathway. The products of these pathways, **urea** and **uric acid**, are illustrated in Figure 3.20, along with ammonia for comparison. **Ureotelic animals** include amphibians, mammals, and cartilaginous fishes (sharks and rays); urea is a relatively rare and insignificant excretory compound among invertebrates. On the other hand, the ability to produce uric acid is critically associated with the success of certain invertebrates on land. **Uricotelic animals** have capitalized on the relative insolubility (and very low toxicity) of uric acid, which is generally precipitated and excreted in a solid or semisolid form with little water loss. Most land-dwelling arthropods and snails have evolved structural and physiological mechanisms for the incorporation of excess nitrogen into molecules of uric acid. We emphasize that various combinations of these and other forms of nitrogen excretion are found in most animals. In some cases, individual animals can actually vary the proportion of these compounds they produce, depending on short-term environmental changes affecting water loss.

Osmoregulation and Habitat

In addition to its relationship to excretion, osmoregulation is directly associated with environmental conditions. The composition of seawater is very similar to that of the body fluids of most invertebrates, in terms of *total* concentration *and* the concentrations of many particular ions. Thus, the body fluids of many marine invertebrates and their habitats are close to being isotonic. We hasten to add, however, that probably no animal has body fluids that are exactly isotonic with seawater, and therefore all are faced with the need for some degree of ionic and osmoregulation. Nonetheless, marine invertebrates certainly do not face the extreme osmoregulatory problems encountered by land and freshwater forms.

As shown in Figure 3.21, the body fluids of freshwater animals are strongly hypertonic with respect to their environment, and thus they face serious problems of water influx as well as the potential loss of precious body salts. Terrestrial animals are exposed to air and thus to problems of water loss. The evolutionary invasion of land and fresh water was accompanied by the development of mechanisms that solved these problems, and only a relatively small number of invertebrate groups have managed to do this. Animals inhabiting freshwater and terrestrial habitats generally have excretory structures that are responsible for eliminating or retaining water as needed, and they often possess modifications of the body wall to reduce overall

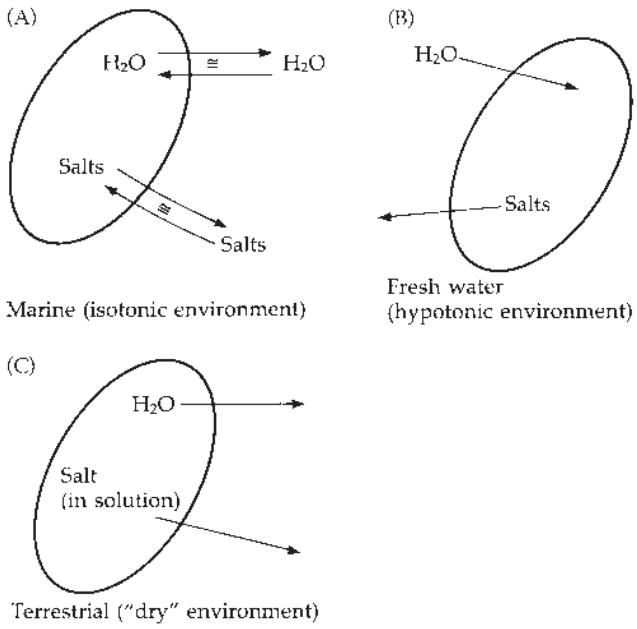

FIGURE 3.21 Relative osmotic and ionic conditions existing in marine, freshwater, and terrestrial invertebrates and their environments. The arrows indicate the directions in which water and salts move passively in response to concentration gradients. Remember that in each of these cases, movement occurs in both directions, but it is the potential net movement along the gradient that is important and is what the freshwater and terrestrial animals must constantly battle against. For marine invertebrates, the body fluids and the environment are nearly isotonic, so there is little net movement in either direction. (A) The organism and its environment are isotonic. (B) The organism is hypertonic. (C) The organism is hypotonic.

permeability. The most successful invertebrate body plans on land, and in some ways of all environments, are those of the arthropods and gastropods. Their effective excretory structures and/or thickened exoskeletons provide them with physiological osmoregulatory capabilities plus a barrier against desiccation.

Osmoregulatory problems of aquatic animals are, of course, determined by the salinity of the environmental water relative to the body fluids (Figure 3.21). Organisms respond physiologically to changes in environmental salinities in one of two basic ways. Some, such as most freshwater forms (certain crustaceans and clitellate annelids), maintain their internal body fluid concentrations regardless of external conditions and are thus called **osmoregulators**. Others, including a number of intertidal and estuarine forms (mussels and some other bivalves, and a variety of soft-bodied animals), allow their body fluids to vary with changes in environmental salinities; they are appropriately called **osmoconformers**. Again, even the body fluids of marine, so-called osmoconformers are not exactly isotonic with respect to their surroundings; thus, these animals must osmoregulate slightly. Neither of these strategies is without limits, and tolerance to various environmental salinities varies among different species. Those that are restricted to a very narrow range of salinities are said to be **stenohaline**, while those that tolerate relatively extensive variations, such as many estuarine animals, are **euryhaline**.

Although the preceding discussion may seem clear-cut, it is an oversimplification. Experimental data from whole animals tell only part of the story of osmoregulation. When a whole marine animal is placed in a hypotonic medium, it tends to swell (if it is an osmoconformer) or to maintain its normal body volume (if it is an osmoregulator). Even at this gross level, most invertebrates usually show evidence of both conforming and regulating. For instance, an osmoconformer generally swells for a period of time in a lowered-salinity environment and then begins to regulate. Its swollen volume will decrease, although probably not to its original size. The same is true of most osmoregulators when faced with a decrease in environmental salinity, but the degree of original swelling is much reduced. In both cases, the swelling of the body is a result of an influx of environmental water into the extracellular body fluids (blood, coelomic fluids, and intercellular fluids). Within limits, this excess water is handled by excretory organs and various surface epithelia of the gut and body wall. However, a second part of the osmoregulatory phenomenon takes place at the cellular level.

As the tonicity (relative concentrations) of the body fluids drops with the entrance of water, the cells in contact with those fluids are placed in conditions of stress—they are now in hypotonic environments. These stressed cells swell to some degree because of the diffusion of water into their cytoplasm, but not to the degree one might expect, given the magnitude of the osmotic gradient to which they are subjected. Cellular-level osmoregulation is accomplished by a loss of dissolved materials from the cell into the surrounding intercellular fluids. The solutes released from these cells include both inorganic ions and free amino acids. Thus, osmoconformers are not passive animals that inactively tolerate extremes of salinities. Nor are marine invertebrates free from osmotic problems, even though we read statements that they are "98% water" or other such comments.

Excretory and Osmoregulatory Structures

Water expulsion vesicles The form and function of organs or systems associated with excretion and osmoregulation are related not only to environmental conditions, but also to body size (especially the surface-to-volume ratio) and other basic features of an organism's body plan. In very small creatures, most metabolic wastes diffuse easily across the body covering because these organisms have sufficient body surface (environmental contact) relative to their volume. However, this high surface-area-to-volume ratio presents a distinct

osmoregulatory problem, particularly for freshwater forms. Freshwater protists and freshwater sponges typically possess specialized organelles called **contractile vacuoles** or **water expulsion vesicles** (WEVs), which actively excrete excess water. These structures accumulate cytoplasmic water and expel it from the cell. Both of these activities apparently require energy, as suggested in part by the large numbers of mitochondria typically associated with WEVs. The idea that WEVs are primarily osmoregulatory in function is supported by a good deal of evidence. Most convincing is the fact that their rates of filling and emptying change dramatically when the cell is exposed to different salinities.

Nephridia Although certain invertebrates possess no known excretory structures, most nephrozoans have some sort of ectodermally derived nephridia that serve for excretion or osmoregulation, or both. The simplest type of nephridium to appear in the evolution of animals was the **protonephridium** (Figure 3.22A). Protonephridial systems are characterized by a tubular arrangement opening to the outside of the body via one or more nephridiopores and terminating internally in closed unicellular units. These units are the cap cells (or terminal cells) and may occur singly or in clusters. Each cell is folded into a cup shape, creating a concavity leading to an excretory duct (nephridioduct) and eventually to the nephridiopore. Two generally recognized types of protonephridia are **flame bulbs**, bearing a tuft of numerous cilia within the cavity, and **solenocytes**, usually with only one or two flagella. There is some evidence that several different types of flame bulb protonephridia have been independently derived from solenocyte precursors, but the details of nephridial evolution are still controversial.

The cilia or flagella drive fluids down the nephridioduct, thereby creating a lowered pressure within the tubule lumen. This lowered pressure draws body fluids, carrying wastes, across the thin cell membranes and into the duct. Selectivity is based primarily on molecular size. Protonephridia are common in acoelomates, many blastocoelomates, and some annelids but are rare among most adult coelomates (although they occur frequently in various larval types). Protonephridia are

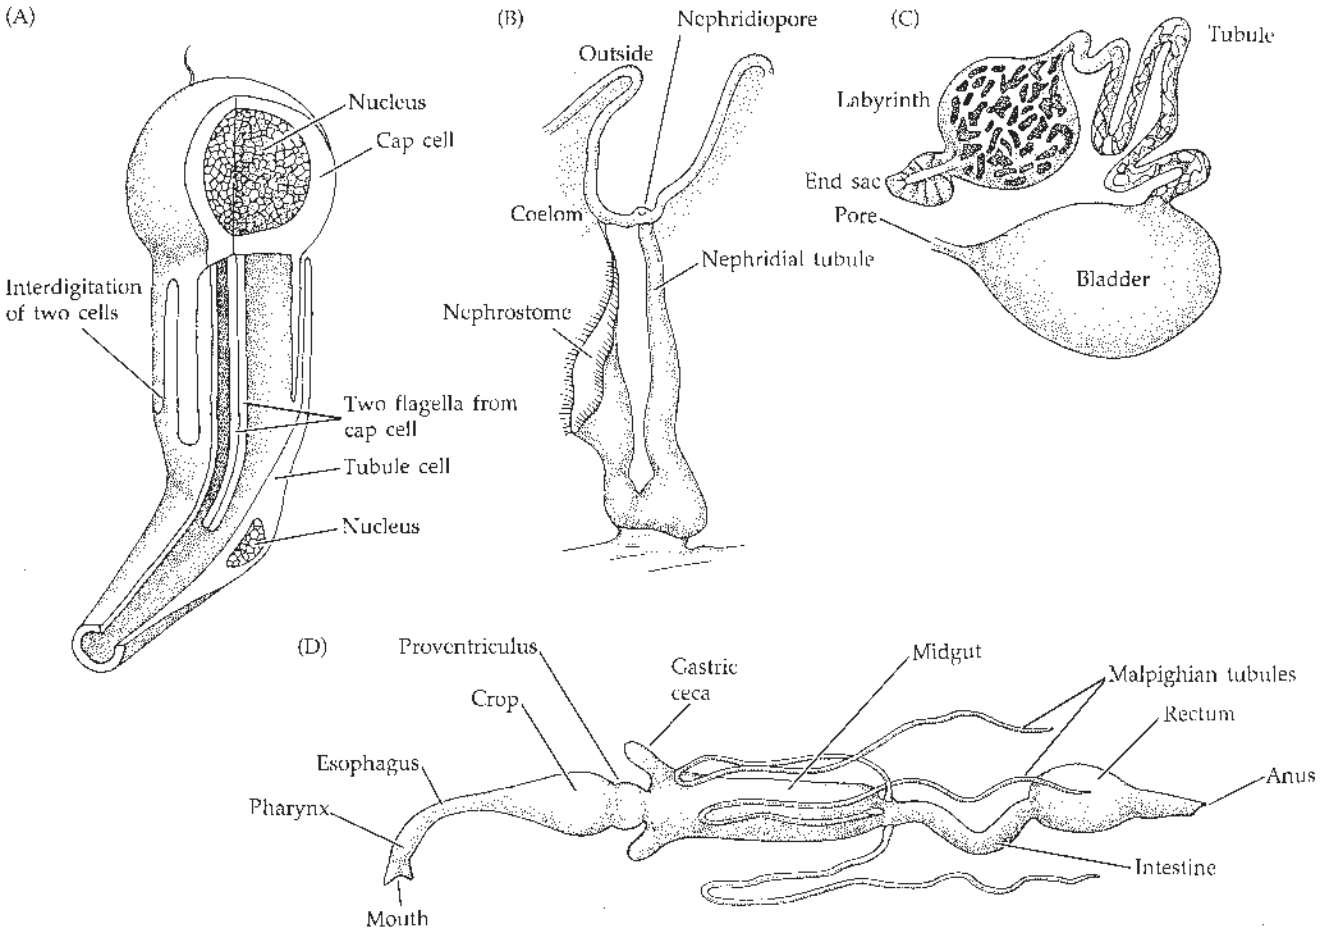

FIGURE 3.22 Some invertebrate excretory structures. (A) A single protonephridium, with the cap cell and tubule cell (cutaway view). (B) A simple metanephridium from a marine annelid. (D) An insect's digestive tract; excretory Malpighian tubules extract wastes from the hemocoel and empty them into the gut.

for more ebook/ testbank/ solution manuals Request: Kingdom email:9012673 4@qq.com

probably more important in osmoregulation than in excretion, and in taxa with both marine and freshwater species (e.g., Entoprocta) they are typically more abundant in the latter group. In most of these animals, nitrogenous wastes are expelled primarily by diffusion across the general body surface.

A second and more complex type of excretory structure among invertebrates is the **metanephridium** (Figure 3.22B). There is a critical structural difference between protonephridia and metanephridia: both are open to the outside, but metanephridia are open internally to the body fluids as well, although arthropods have closed metanephridia. Metanephridia are also multicellular. The inner end typically bears a ciliated funnel (nephrostome), and the duct is often elongated and convoluted and may include a bladderlike storage region. Metanephridia function by taking in large amounts of body fluid through the open nephrostome and then selectively absorbing most of the reclaimable components back into the body fluids through the walls of the bladder or the excretory duct.

In very general terms, we can relate the structural and functional differences between proto- and metanephridia to the body plans with which they are commonly associated. Whereas protonephridia can adequately serve animals that have solid bodies (acoelomates), body cavities of small volume (blastocoelomates), or very small bodies (e.g., larvae), metanephridia cannot. Open funnels would be ineffective in acoelomates and would quickly drain small blastocoelomates of their limited body fluids. Conversely, protonephridia are generally not capable of handling the relatively large body and fluid volumes typical of coelomate invertebrates. Thus, in many large coelomate animals (e.g., annelids, molluscs, onychophorans) one or more pairs of metanephridia are typically found.

We have very broadly interpreted the terms "protonephridia" and "metanephridia" in the above discussion, and we use them as explained above throughout this text unless specified otherwise. However, there are more complications than our simple usage suggests. For example, there is a frequent association of nephridia, especially metanephridia, with structures called coelomoducts. **Coelomoducts** are tubular connections arising from the coelomic lining and extending to the outside via special pores in the body wall. Their inner ends are frequently funnellike and ciliated, resembling the nephrostomes of metanephridia. Coelomoducts may have arisen evolutionarily as a means of allowing the escape of gametes to the outside; they are, in fact, considered homologous with the reproductive ducts of many invertebrates. Primitively, the coelomoducts and nephridia were separate units; however, through evolution they have in many cases fused in various fashions to become what are called **nephromixia**.

Generally speaking, there are three types of nephromixia. When a coelomoduct is joined with a protonephridium and they share a common duct, the structure is called a **protonephromixium**. When a coelomoduct is united with a metanephridium, the result is either a **metanephromixium** or **mixonephridium**, depending on the structural nature of the union. Whereas coelomoducts originate from the coelomic lining, the nephridial components arise from the outer body wall, so nephromixia are a combination of mesodermally and ectodermally derived parts. Obviously there is some confusion at times about which term applies to a particular "nephridial" type if the precise developmental origin is not clear. We do not wish to belabor this point, so we leave it here to be resurrected periodically in later chapters.

Other organs of excretion Not all Nephrozoa possess excretory organs that are clearly proto- or metanephridia. In some taxa (e.g., echinoderms, chaetognaths), no definite excretory structures are known. In such cases wastes are eliminated across the surface of the skin or gut lining, perhaps with the aid of ameboid phagocytic cells that collect and transport these products. Other groups possess excretory organs that may represent highly modified nephridia or secondarily derived ("new") structures. For example, the antennal and maxillary glands of crustaceans appear to be derived from metanephridia, whereas the Malpighian tubules of tardigrades, insects, and spiders arose independently (Figure 3.22C,D). Nematodes have a series of different excretory organs not found in other animal phyla. The details of these structures are discussed in appropriate later chapters.

Circulation and Gas Exchange

Internal Transport

The transport of materials from one place to another within an organism's body depends on the movement and diffusion of substances in body fluids. Nutrients, gases, and metabolic waste products are generally carried in solution or bound to other soluble compounds within the body fluid itself or sometimes in loose cells (such as blood cells) suspended in fluid. Any system of moving fluids that reduces the functional diffusion distance that these products must traverse may be referred to as a circulatory system, regardless of its embryological origin or its ultimate design. The nature of the circulatory system is directly related to the size, complexity, and lifestyle of the organism in question. Usually the circulatory fluid is an internal, extracellular, aqueous medium produced by the animal. There are, however, a few instances in which circulatory functions are accomplished at least partly by other means. For instance, sponges and most cnidarians utilize water from the environment as a circulatory fluid, sponges by passing the water through a series of channels in their bodies, and cnidarians by circulating water through the gut (Figure 3.23A,B).

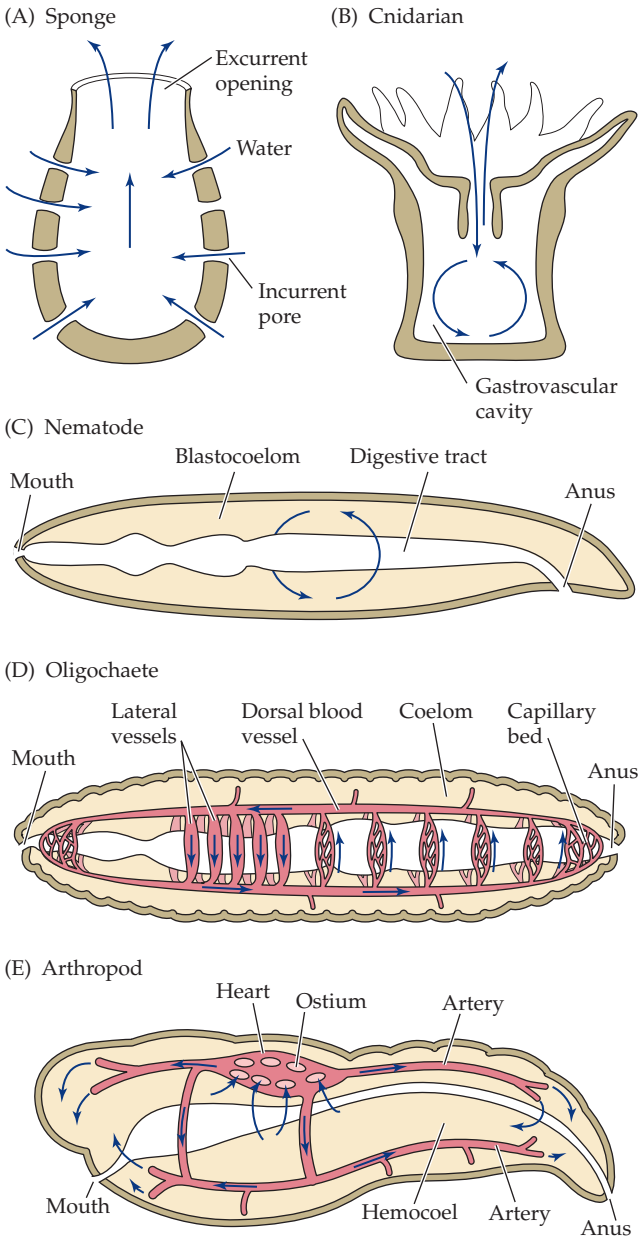

FIGURE 3.23 Invertebrate circulatory systems. Sponges (A) and cnidarians (B) utilize environmental water as their circulatory fluid. (C) Blastocoelomates (e.g., rotifers and nematodes) use their body cavity fluid for internal transport. (D) The closed circulatory system of an earthworm contains blood that is kept separate from the coelomic fluid. (E) Arthropods are characterized by an open circulatory system, in which the blood and body cavity (hemocoelic) fluid are one and the same.

In all Metazoa, the intercellular fluids play a critical role as a transport medium. Even where complicated circulatory plumbing exists, tissue fluids are still necessary to bring dissolved materials in contact with cells, a vital process for life support. In some animals (e.g., flatworms), there are no special chambers or vessels for body fluids other than the gut and intercellular spaces through which materials diffuse on a cell-to-cell level. This condition limits these animals to relatively small sizes or to shapes that maintain low diffusion distances. Most animals, however, have some specialized structure to facilitate the transport of various body fluids and their contents. This structure may include the body cavities themselves or actual circulatory systems of vessels, chambers, sinuses, and pumping organs. Actually, many animals employ both their body cavity and a circulatory system for internal transport.

Blastocoelomate invertebrates use the fluids of the body cavity for circulation (Figure 3.23C). Most of these animals (e.g., rotifers and many nematodes) are quite small, or are long and thin, and adequate circulation is accomplished by the movements of the body against the body fluids, which are in direct contact with internal tissues and organs. Several types of cells are generally present in the body fluids of blastocoelomates. These cells may serve in activities such as transport and waste accumulation, but their functions have not been well studied. A few coelomate invertebrates (e.g., some annelid groups like sipunculans, and most echinoderms) also depend largely on the body cavity as a circulatory chamber.

Circulatory Systems

Beyond the relatively rudimentary circulatory mechanisms discussed above, there are two principal designs or structural plans for accomplishing internal transport (exceptions and variations are discussed under specific taxa). These two organizational plans are closed and open circulatory systems, both of which contain a circulatory fluid, or blood. In **closed circulatory systems** the blood stays in distinct vessels and perhaps in lined chambers; exchange of circulated material with parts of the body occurs in special areas of the system such as capillary beds (Figure 3.23D). Since the blood itself is physically separated from the intercellular fluids, the exchange sites must offer minimal resistance to diffusion; thus one finds capillaries typically have membranous walls that are only a single cell layer thick. Closed circulatory systems are common in animals with well-developed or spacious coelomic compartments (e.g., annelids, nemerteans, phoronids, vertebrates). Such arrangements facilitate the transport of materials that might otherwise be isolated by the mesenteries or peritoneum of the body cavity. In such situations the blood and coelomic fluid may be quite different from one another, both in composition and in function from one body area to another. For example, blood may transport nutrients and gases, while coelomic fluid may accumulate metabolic wastes for removal by nephridia and also serve as a hydrostatic skeleton.

It takes power to keep a fluid moving through a plumbing system. Many invertebrates with closed systems rely on body movements and the exertion of coelomic pressure on vessels (often containing one-way valves) to move their blood. These activities are

for more ebook/ testbank/ solution manuals Request: Kingdom email:960126734@qq.com

frequently supplemented by muscles of the blood vessel walls that contract in peristaltic waves. In addition, there may be special heavily muscled pumping areas along certain vessels. These regions are sometimes referred to as hearts, but most are perhaps more appropriately called contractile vessels or pulsatile organs.

Open circulatory systems are associated with a reduction of the adult coelom, including a secondary loss of most of the peritoneal lining around the organs and inner surface of the body wall. The circulatory system itself usually includes a distinct heart, as the primary pumping organ, and various vessels, chambers, or ill-defined sinuses (Figure 3.23E). The degree of elaboration of such systems depends primarily on the size, complexity, and to some extent the activity level of the animal. This kind of system, however, is "open" in that the blood, often called the **hemolymph**, empties from vessels into the body cavity and directly bathes the organs. The body cavity is called a **hemocoel**. Open circulatory systems are typical of arthropods and noncephalopod molluscs, and such animals are sometimes referred to as being hemocoelomate.

Just because the open circulatory system seems a bit sloppy in its organization, it should not be viewed as poorly "designed" or inefficient. In fact, in many groups this type of system has assumed a variety of functions beyond circulation. For example, in bivalves and gastropods, the hemocoel functions as a hydrostatic skeleton for locomotion and certain types of burrowing activities. In most spiders, the limbs are extended by forcing hemolymph into the appendages. In aquatic arthropods, it also serves a hydrostatic function when the animal molts and temporarily loses its exoskeletal support. In large terrestrial insects, the transport of respiratory gases has been largely assumed by the tracheal system, and one of the primary responsibilities taken on by the open circulatory system appears to be thermal regulation.

Hearts and Other Pumping Mechanisms

Circulatory systems—open or closed—generally have structural mechanisms for pumping the blood and maintaining adequate blood pressure. Beyond the influence of general body movements, most of these structures fall into the following categories: contractile vessels (as in annelids), ostiate hearts (as in arthropods), and chambered hearts (as in molluscs and vertebrates). The method of initiating contraction of these different pumps (the pacemaker mechanism) may be intrinsic (originating within the musculature of the structure itself) or extrinsic (originating from motor nerves arising outside the structure). The first case describes the myogenic hearts of molluscs and vertebrates; the second describes the neurogenic hearts of most arthropods and, at least in part, the contractile vessels of annelids.

Blood pressure and flow velocities are intimately associated not only with the activity of the pumping mechanism, but also with vessel diameters. Energetically, it costs a good deal more to maintain flow through a narrow pipe than through a wide pipe. This cost is minimized in animals with closed circulatory systems by keeping the narrow vessels short and using them only at sites of exchange (i.e., capillary beds) and by using the larger vessels for long-distance transport from one exchange site to another. In the human circulatory system, for example, arteries have an average radius of 2.0 mm, veins 2.5 mm, and capillaries 0.006 mm. But reducing the diameter of a single vessel increases flow velocity, which poses problems at an exchange site. This problem is solved by the presence of large numbers of small vessels, the total cross-sectional area of which exceeds that of the larger vessel from which they arise. The result is that blood pressure and total flow velocity actually decrease at capillary exchange sites. A drop in blood pressure and a relative rise in blood osmotic pressure along the capillary bed facilitate exchanges between the blood and surrounding tissue fluids. In open systems, both pressure and velocity drop once the blood leaves the heart and vessels and enters the spacious hemocoel.

Gas Exchange and Transport

One of the principal functions of most circulatory fluids is to carry oxygen and carbon dioxide through the body and exchange these gases with the environment. With few exceptions, oxygen is necessary for catabolic cellular respiration. Although a number of invertebrates can survive periods of environmental oxygen depletion—either by dramatically reducing their metabolic rate or by switching to anaerobic respiration—most cannot; they depend upon a relatively constant oxygen supply.

All animals can take in oxygen from their surroundings while at the same time releasing carbon dioxide, a metabolic waste product of respiration. We define the uptake of oxygen and the loss of carbon dioxide at the surface of the organism as gas exchange, reserving the term "respiration" for the energy-producing metabolic activities within cells. Some authors distinguish these two processes with the terms "external respiration" and "cellular (internal) respiration."

Gas exchange in nearly all animals operates according to certain common principles regardless of any structural modifications that serve to enhance the process under different conditions. The basic strategy is to bring the environmental medium (water or air) close to the appropriate body fluid (blood or body cavity fluid) so that the two are separated only by a wet membrane across which the gases can diffuse. The system must be moist because the gases must be in solution in order to diffuse across the membrane. The diffusion process

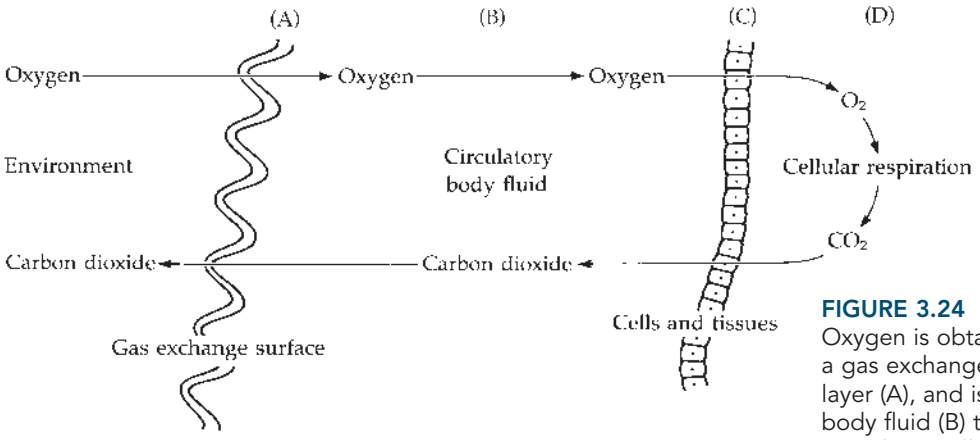

FIGURE 3.24 Gas exchange in animals. Oxygen is obtained from the environment at a gas exchange surface, such as an epithelial layer (A), and is transported by a circulatory body fluid (B) to the body's cells and tissues (C), where cellular respiration occurs (D). Carbon dioxide follows the reverse path. See text for details.

depends on the concentration gradients of the gases at the exchange site; these gradients are maintained by the circulation of internal fluids to and away from these areas (Figure 3.24).

Gas exchange structures Many invertebrates lack special gas exchange structures. In such animals gas exchange is typically integumentary or cutaneous, and it occurs over much of the body surface. Such is the case in many tiny animals with very high surface-to-volume ratios and in some larger soft-bodied forms (e.g., cnidarians and flatworms). Most animals with integumentary gas exchange are restricted to aquatic or damp terrestrial environments where the body surface is kept moist. Integumentary gas exchange also supplements other methods in many animals, even certain vertebrates (e.g., amphibians).

Many marine and many freshwater invertebrates possess gills (Figure 3.25A–C,G), which are external organs or restricted areas of the body surface specialized for gas exchange. Basically, gills are thin-walled processes, well supplied with blood or other body fluids, which promote diffusion between this fluid and the environment. Gills are frequently highly folded or digitate, increasing the diffusive surface area. A great number of nonhomologous structures have evolved as gills in different taxa, and they often serve other functions in addition to gas exchange (e.g., sensory input and feeding). By their very nature, gills are permeable surfaces that must be protected during times of osmotic stress, such as occur in estuaries and intertidal environments. In these instances, the gills may be housed within chambers or be retractable.

A few marine invertebrates employ the lining of the gut as the gas exchange surface. Water is pumped in and out of the hindgut, or a special evagination thereof, in a process called **hindgut irrigation**. Many sea cucumbers and thalassimatid worms use this method of gas exchange (Figure 3.25F).

As you can imagine, protruding gills would not work on dry land. Here, the gas exchange surfaces must be internalized to keep them moist and protected and to prevent body water loss through the wet surfaces. The lungs of terrestrial vertebrates are the most familiar example of such an arrangement. Among the invertebrates, the arthropods have managed to solve the problems of "air breathing" in two basic ways. Scorpions, spiders and their kin possess book lungs, and many other arachnids, most insects, and all centipedes and millipedes possess tracheae (Figure 3.25D,E). **Book lungs** are blind inpocketings with highly folded inner linings across which gases diffuse between the hemolymph and the air. **Tracheae**, however, are branched, usually anastomosed invaginations of the outer body wall and are open both internally and externally.

The tracheae of most insects allow diffusion of oxygen from air directly to the tissues of the body; the blood plays little or no role in gas transport. Rather, intercellular fluid extends partway into the tracheal tubes as a solvent for gases. Atmospheric pressure tends to prevent these fluids from being drawn too close to the external body surface, where evaporation is a potential problem. In addition, the outside openings (**spiracles**) of the tracheae are often equipped with some mechanism of closure. In many insects,

especially large ones, special muscles ventilate the tracheae by actively pumping air in and out. Terrestrial isopod crustaceans (e.g., sowbugs and pillbugs) have invaginated gas exchange structures on some of their abdominal appendages. These inpocketings are called **pseudotracheae** but are probably not homologous with the tracheae or the book lungs of insects and spiders.

The only other major group of terrestrial invertebrates whose members have evolved distinct air-breathing structures are the land snails and slugs (Figure 3.25H). The gas exchange structure here is a lung that opens to the outside via a pore called the **pneumostome**. This lung is derived from a feature common to molluscs in general, the mantle cavity, which in other molluscs houses the gills and other organs.

Gas transport Metabolism in animals requires oxidation of organic molecules and catabolic respiration requires available oxygen. Thus, natural selection has favored special molecules, or **respiratory pigments**, that can reversibly bind and transport oxygen, notably hemoglobins, hemocyanins, chlorocruorins, and hemerythrins (see below). As illustrated in Figure 3.24, oxygen must be transported from the sites of environmental gas exchange to the cells of the body, and carbon dioxide must get from the cells where it is produced to the gas exchange surface for release. Generally, groups displaying marked cephalization circulate freshly oxygenated blood through the "head" region first, and secondarily to the rest of the body.

Invertebrates vary considerably in their oxygen requirements. In general, active animals consume more oxygen than sedentary ones. In slow-moving and sedentary invertebrates, oxygen consumption and utilization are quite low. For example, no more than 20% oxygen withdrawal from the gas exchange water current has ever been demonstrated in sessile sponges, bivalves, or tunicates. The amount of oxygen available to an organism varies greatly in different environments. The concentration of oxygen in dry air at sea level is about 210 ml/liter, whereas in water it ranges from near zero to about 10 ml/liter. The variation in aquatic environments is due to such factors as depth, surface turbulence, photosynthetic activity, temperature, and salinity (oxygen concentrations drop as temperature and salinity increase). With the exception of certain areas prone to oxygen depletion (e.g., muds rich in organic detritus), most habitats provide adequate sources of oxygen to sustain animal life. Also, the relatively low capacity of body fluids to carry oxygen in solution is greatly increased by binding oxygen with complex organic compounds called respiratory pigments.

Respiratory pigments differ in molecular architecture and in their affinity for oxygen but all have a metal ion with which the oxygen combines (iron in hemoglobins, hemerythrins, and chlorocruorins; copper in hemocyanins). In most invertebrates, these pigments occur in solution within the blood or other body fluids, but in some invertebrates (and virtually all vertebrates), they may be in specific blood cells. In general, the pigments respond to high oxygen concentrations by "loading" (combining with oxygen) and respond to low oxygen concentrations by "unloading," or dissociating from oxygen (releasing oxygen). The loading and unloading qualities are different for various pigments, in terms of their relative saturations at different levels of oxygen in their immediate surroundings, and are generally expressed in the form of dissociation curves. Respiratory pigments load at the site of gas exchange, where environmental oxygen levels are high relative to the body fluid, and unload at the cells and tissues, where surrounding oxygen levels are low relative to the body fluid. In addition to simply carrying oxygen from the loading to the unloading sites, some pigments may carry reserves of oxygen that are released only when tissue levels are unusually low. Other factors, such as temperature and carbon dioxide concentration, also influence the oxygen-carrying capacities of respiratory pigments.

Hemoglobins are among the most common respiratory pigments in animals. There are a number of different hemoglobins. Some function primarily for transport, whereas others store oxygen and then release it during times of low environmental oxygen availability. Hemoglobins are reddish pigments containing iron as the oxygen-binding metal. They are found in a variety of invertebrates and, with the exception of a few fishes, in all vertebrates. Among the major groups of invertebrates, hemoglobin occurs in many annelids, some crustaceans, some insects, and a few molluscs and echinoderms. Interestingly, hemoglobin is not restricted to the Metazoa; it is also produced by some protists, certain fungi, and in the root nodules of leguminous plants. Among animals, hemoglobin may be carried within red blood cells (erythrocytes) or in coelomic cells (called hemocytes) in a few echinoderms, or it may simply be dissolved in the blood or coelomic fluid.

Two other types of iron-based respiratory pigments occur in certain invertebrates—**hemerythrins** and **chlorocruorins**. The former are violet to pink when oxygenated; the latter are green in dilute concentrations but red in high concentrations. Chlorocruorins generally function as efficient oxygen carriers when environmental levels are relatively high; hemerythrins function more in oxygen storage. Chlorocruorin is found in many annelids, freely floating in body fluids. Hemerythrin is known from some annelids (including sipunculans) and some priapulans and brachiopods.

Hemocyanins are the most commonly occurring respiratory pigments found in the hemolymph of molluscs and arthropods, although they have been identified from at least 11 nephrozoan phyla, in both

for more ebook/ testbank/ solution manuals Request: Kingdom email:960126734@qq.com

protostomes and deuterostomes. Among arthropods, hemocyanin occurs in chelicerates, a few myriapods, and many crustaceans. There is indirect evidence that it also occurred in trilobites. Hemocyanin has been found in most classes of molluscs. Although hemocyanins, like hemoglobins, are proteins, they display significant structural differences, contain copper rather than iron, and tend to have a bluish color when oxygenated. Unlike most hemoglobins, hemocyanins tend to release oxygen easily and provide a ready source of oxygen to the tissues as long as there is a relatively high concentration of available environmental oxygen. Hemocyanins are always found in solution, never in cells, a characteristic probably related to the necessity for rapid oxygen unloading. Hemocyanins often give a bluish tint to the hemolymph of arthropods, although the presence of carotenoid pigments (beta-carotene and related molecules) commonly imparts a brown or orange coloration.

The widespread detection of hemerythrins, across three domains of life (Archaea, Bacteria, Eukaryota), suggests there are other activities of these proteins, aside from oxygen binding, but we know little about this possibility. In any case, it is apparent that hemerythrins have a long and complex evolutionary history that likely included gene loss and duplication, and possibly even lateral gene transfer.

Table 3.1 gives some of the basic properties of oxygen-carrying pigments. There seems to be no obvious phylogenetic rhyme or reason to the occurrence of these pigments among the various taxa. Respiratory pigments are rare among insects, although hemoglobin has been found in chironomid midges, some notonectids, and certain parasitic flies of the genus *Gastrophilus*. The absence of respiratory pigments among the insects reflects the fact that most of them do not use the blood as a medium for gas transport, but employ extensive tracheal systems to carry gases directly to the tissues. In those insects without well-developed tracheae, oxygen is simply carried in solution in the hemolymph.

Respiratory pigments raise the oxygen-carrying capacity of body fluids far above what would be achieved by transport in simple solution. Similarly, carbon dioxide levels in body fluids (and in sea water) are much higher than would be expected strictly on the basis of its solubility. The enzyme carbonic anhydrase greatly accelerates the reaction between carbon dioxide and water, forming carbonic acid:

$$CO_2 + H_2O \leftrightharpoons H_2CO_3$$

Furthermore, carbonic acid ionizes to hydrogen and bicarbonate ions, so a series of reversible reactions takes place:

$$CO_2 + H_2O \leftrightharpoons H_2CO_3 \leftrightharpoons H^+ + HCO_3^-$$

Because carbon is "tied up" in other forms, the concentration of CO_2 in solution is lowered, thus raising the overall CO_2-carrying capacity of the blood. This set of reactions responds to changes in pH, and in the presence of appropriate cations (e.g., Ca^{2+} and Na^+) it shifts back and forth, serving as a buffering mechanism by regulating hydrogen ion concentration.

Nervous Systems and Sense Organs

All living cells respond to some stimuli and conduct some sort of "information," at least for short distances. Thus, even when no real nervous system is present—the condition found in sponges and placozoans—coordination and reaction to external stimulation do occur. The integration and coordination of bodily activities in Metazoa are in large part due to the processing of information by a true nervous system. The functional units of nervous systems are **neurons**: cells that are specialized for high-velocity impulse conduction. Dense networks of interwoven nerve fibers and their branches and synapses, usually with glial filaments (e.g., brains), are called **neuropils**. A network of cells forming a nerve center in the nervous system is called a **ganglion**.

The generation of an impulse within a true nervous system usually results from a stimulus imposed on the nervous elements. The source of stimulation may be external or internal. A typical pathway of events occurring in a nervous system is shown in Figure 3.26. A stimulus received by some receptor (e.g., a sense organ) generates an impulse that is conducted along a **sensory nerve** (**afferent nerve**) via a series of adjacent neurons to some coordinating center or region of the system. The information is processed and an appropriate response is "selected." A **motor nerve** (**efferent nerve**) then conducts an impulse from the central processing center to an effector (e.g., a muscle), where the response occurs. Once an impulse is initiated within the system,

TABLE 3.1 Properties of oxygen-carrying respiratory pigments

Pigment	Molecular Weight	Metal	Ratio of Metal to O_2	Metal Associate
Hemoglobin	65,000	Fe	1:1	Porphyrin
Hemerythrin	40,000–108,000	Fe	2:1	Protein chains
Hemocyanin	40,000–9,000,000	Cu	2:1	Protein chains
Chlorocruorin	3,000,000	Fe	1:1	Porphyrin

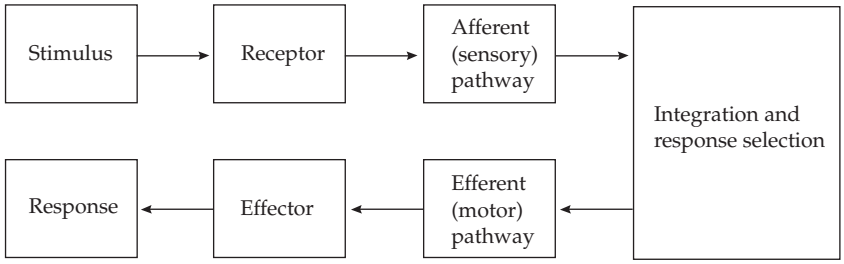

FIGURE 3.26 A generalized pathway within the nervous system. A stimulus initiates an impulse within some sensory structure (the receptor); the impulse is then transferred to some integrative portion of the nervous system via sensory nerves. Following response selection, an impulse is generated and transferred along motor nerves to an effector (e.g., muscle), where the appropriate response is elicited.

the mechanism of conduction is essentially the same in all neurons, regardless of the stimulus. The wave of depolarization along the length of each neuron and the chemical neurotransmitters crossing the synaptic gaps between neurons are common to virtually all nervous conduction. How then is the information interpreted within the system for response selection? The answer to this question involves three basic considerations.

First is the occurrence of a point called a threshold, which corresponds to the minimum intensity of stimulation necessary to generate an impulse. Receptor sites consist of specialized neurons whose thresholds for various kinds of stimuli are drastically different from one another because of structural or physiological qualities. For example, a sense organ whose threshold for light stimulation is very low (compared with other potential stimuli) functions as a light sensor, or photoreceptor. In any such specialized sensory receptor, the condition of differential thresholds essentially screens incoming stimuli so that an impulse normally is generated by only one kind of information (e.g., light, sound, heat, or pressure). Second is the nature of the receptor itself. Receptor units (e.g., sense organs) are generally constructed in ways that permit only certain stimuli to reach the impulse-generating cells. For example, the light-sensitive cells of the human eye are located beneath the eye surface, where stimuli other than light would not normally reach them.

And third, the overall "wiring" or circuitry of the entire nervous system is such that impulses received by the integrative (response-selecting) areas of the system from any particular nerve will be interpreted according to the kind of stimulus for which that sensory pathway is specialized. For example, all impulses coming from a photoreceptor are understood as being light induced. Threshold and circuitry can be demonstrated by introducing false information into the system by stimulating a specialized sense organ in an inappropriate manner: if photoreceptors in the eye are stimulated by electricity or pressure, the nervous system will interpret this input as light. Remember that an impulse can be generated in any receptor by nearly any form of stimulation if the stimulus is intense enough to exceed the relevant threshold. A blow to the eye often results in "seeing stars," or flashes of light, even when the eye is closed. In such a situation, the photoreceptor's threshold to mechanical stimulation has been reached. By the same token, the application of extreme cold to a heat receptor may feel hot.

Nervous systems in general operate on the principles outlined above. However, this description applies largely to nervous systems that have structural centralized regions. Following a discussion below of the basic types of sense organs (receptor units), we discuss centralized and noncentralized nervous systems and their relationships to general body architecture.

Sense Organs

Invertebrates possess an impressive array of receptor structures through which they receive information about their internal and external environments. An animal's behavior is in large part a function of its responses to that information. These responses often take the form of some sort of movement relative to the source of a particular stimulus. A response of this nature is called a **taxis** and may be positive or negative depending on the reaction of the animal to the stimulus. With respect to light or phototaxis, many animals tend to move away from bright light and are thus said to be negatively phototactic.

The activities of receptor units represent the initial step in the usual functioning of the nervous system; they are a critical link between the organism and its surroundings. Consequently, the kinds of sense organs present and their placement on the body are intimately related to the overall complexity, mode of life, and general body plan of any animal. The following general review provides some concepts and terminology that serve as a basis for more detailed coverage in later chapters. The first five categories of sense organs may all be viewed as mechanoreceptors, in that they respond to mechanical stimuli (e.g., touch, vibrations, and pressure). The last three are sensitive to nonmechanical input (e.g., chemicals, light, and temperature). In addition, a few invertebrates have been shown to possess a magnetic compass. For example, during their migrations between North America and central Mexico, monarch butterflies probably navigate using a combination of the sun and the inclination angle component of the Earth's magnetic field to guide their flights, as has been shown for most vertebrate migrators.

FIGURE 3.27 Some invertebrate tactile receptors. (A) Tactile organ of *Sagitta bipunctata* (an arrow worm, phylum Chaetognatha). (B) A sensory epithelial cell of a nemertean worm. (C) Long, touch-sensitive setae (and stout grasping setae) on the leg of an isopod, *Politolana* (SEM).

Tactile receptors Touch or tactile receptors are generally derived from modified epithelial cells associated with sensory neurons. The nature of the epithelial modifications depends a great deal on the structure of the body wall. For instance, the form of a touch receptor in an arthropod with a rigid exoskeleton must be different from that in a soft-bodied cnidarian. Most such receptors, however, involve projections from the body surface, such as bristles, spines, setae, and tubercles (Figure 3.27). Objects in the environment with which the animal makes contact move these receptors, thereby creating mechanical deformations that are imposed upon the underlying sensory neurons to initiate an impulse.

Virtually all animals are touch sensitive, but their responses are varied and often integrated with other sorts of sensory input. For example, the gregarious nature of many animals may involve a positive response to touch (positive thigmotaxis) combined with the chemical recognition of members of the same species. Some touch receptors are highly sensitive to mechanically induced vibrations propagated in water, in loose sediments, through solid substrata, or in other materials. Such vibration sensors are common in certain tube-dwelling polychaetes that retract quickly into their tubes in response to movements in their surroundings. Some crustacean ambush-predators are able to detect the vibrations induced by nearby potential prey animals, and web-building spiders quickly and accurately sense prey in their webs through vibrations of the threads. Some spiders have highly sensitive tactile setae on their appendages, called **trichobothria**, that sense airborne vibrations of prey, such as wing beats and perhaps even some sound frequencies.

Georeceptors Georeceptors respond to the pull of gravity, giving animals information about their orientation relative to "up and down." Most georeceptors are structures called **statocysts** (Figure 3.28). Statocysts usually consist of a fluid-filled chamber containing a solid granule or pellet called a **statolith**. The inner lining of the chamber includes a touch-sensitive epithelium from which project bristles or "hairs" associated with underlying sensory neurons. In aquatic invertebrates, some statocysts are open to the environment and thus are filled with water. In some of these the statolith is a sand grain obtained from the animal's surroundings. Most statoliths, however, are secreted within closed cellular capsules by the organisms themselves.

Because of the resting inertia of the statolith within the fluid, any movement of the animal results in a change in the pattern or intensity of stimulation of the sensory epithelium by the statolith. Additionally, when the animal is stationary, the position of the statolith

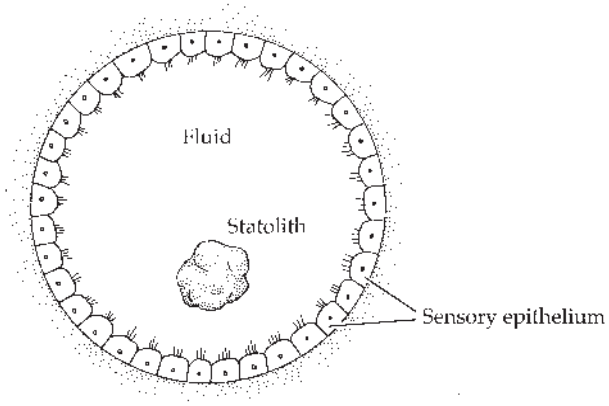

FIGURE 3.28 A generalized statocyst, or georeceptor (section).

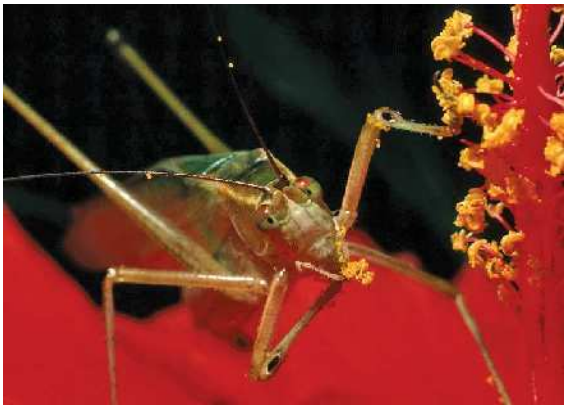
within the chamber provides information about the organism's orientation to gravity. The fluid within statocysts of at least some invertebrates (especially certain crustaceans) also acts something like the fluid of the semicircular canals in vertebrates. When the animal moves, the fluid tends to remain stationary—the relative "flow" of the fluid over the sensory epithelium provides the animal with information about its linear and rotational acceleration relative to its environment.

Whether stationary or in motion, animals utilize the input from georeceptors in different ways, depending on their habitat and lifestyle. The information from these statocysts is especially important under conditions where other sensory reception is inadequate. For example, burrowing invertebrates cannot rely on photoreceptors for orientation when moving through the substratum, and some employ statocysts for that purpose. Similarly, planktonic animals face orientation problems in their three-dimensional aqueous environment, especially in deep water and at night; many such creatures possess statocysts.

There are a few exceptions to the standard statocyst arrangements described above. For example, a number of aquatic insects detect gravity by using air bubbles trapped in certain passageways (e.g., tracheal tubes). The bubbles move according to their orientation to the vertical, much like the air bubble in a carpenter's level, and stimulate sensory bristles lining the tube in which they are located.

Proprioceptors Internal sensory organs that respond to mechanically induced changes caused by stretching, compression, bending, and tension are called **proprioceptors**, or simply stretch receptors. These receptors give the animal information about the movement of its body parts and their positions relative to one another. Proprioceptors have been most thoroughly studied in vertebrates and arthropods, where they are associated with appendage joints and certain body extensor muscles. The sensory neurons involved in proprioception are associated with and attached to parts of the body that are stretched or otherwise mechanically affected by movement or muscle tension. These parts may be specialized muscle cells, elastic connective tissue fibers, or membranes that span joints. As these structures are stretched, relaxed, and compressed, the sensory endings of the attached neurons are distorted accordingly and thus stimulated. Some of these receptor arrangements can detect changes not only in position but also in static tension.

Phonoreceptors General sensitivity to sound—phonoreception—has been demonstrated in a number of invertebrates (certain annelid worms and a variety of arthropods), but true auditory receptors are known only in a few groups of insects and perhaps some arachnids and centipedes. Crickets, grasshoppers, and cicadas possess phonoreceptors called **tympanic organs** (Figure 3.29). A rather tough but flexible tympanum covers an internal air sac that allows the tympanum to vibrate when struck by sound waves. Sensory neurons attached to the tympanum are stimulated directly by the vibrations. Most arachnids possess structures called **slit sense organs**, which, although poorly studied, are suspected to perform auditory functions; at least they appear to be capable of sensing sound-induced vibrations. Certain myriapods bear so-called **organs of Tömösváry**, which some workers believe may be sensitive to sound.



© Larry Jon Friesen

FIGURE 3.29 An arthropod phonoreceptor, or auditory organ, of the fork-tailed katydid, *Scudderia furcata*. Note the position of the right-side tympanum on the tibia of the first walking leg (arrow).

Baroreceptors The sensitivity of invertebrates to pressure changes—baroception—is not well understood, and no structures for this purpose have been positively identified. However, behavioral responses to pressure changes have been demonstrated in several pelagic invertebrates, including medusae, ctenophores, cephalopods, and copepod crustaceans, as well as in some planktonic larvae. Aquatic insects also sense changes in pressure and may use a variety of methods to do so. Some intertidal crustaceans coordinate daily migratory activities with tidal movements, perhaps partly in response to pressure as water depth changes.

Chemoreceptors Many animals have a general chemical sensitivity, which is not a function of any definable sensory structure but is due to the general irritability of protoplasm itself. When they occur in sufficiently high concentrations, noxious or irritating chemicals can induce responses via this general chemical sensitivity. In addition, most animals have specific chemoreceptors.

Chemoreception is a rather direct sense in that the molecules stimulate sensory neurons by contact, usually after diffusing in solution across a thin epithelial covering. The chemoreceptors of many aquatic invertebrates are located in pits or depressions, through which

for more ebook/ testbank/ solution manuals Request: United Kingdom email:960126734@qq.com

water may be circulated by ciliary action. In arthropods, the chemoreceptors are usually in the form of hollow setae or other projections, within which are chemosensory neurons. While chemosensitivity is a universal phenomenon among invertebrates, a wide range of specificities and capabilities exists.

The types of chemicals to which particular animals respond are closely associated with their lifestyles. Chemoreceptors may be specialized for tasks such as general water analysis, humidity detection, sensitivity to pH, prey tracking, mate location, substratum analysis, and food recognition. Probably all aquatic organisms leak small amounts of amino acids into their environment through the skin and gills as well as in their urine and feces. These released amino acids form an organism's "body odor," which can create a chemical picture of the animal that others detect to identify such characteristics as species, sex, stress level, distance and direction, and perhaps size and individuality. Amino acids are widely distributed in the aquatic environment, where they provide general indicators of biological activity. Many aquatic animals can detect amino acids with much greater sensitivity than our most sophisticated laboratory equipment.

Photoreceptors Nearly all animals are sensitive to light, and most have some kind of identifiable photoreceptors. Although members of only a few of the metazoan phyla appear to have evolved eyes capable of image formation (Cnidaria, Mollusca, Annelida, Arthropoda, and Chordata), virtually all animal photoreceptors share structurally similar light receptor molecules that probably predate the origin of discrete structural eyes. Thus, the structural photoreceptors of animals share the common quality of possessing light-sensitive pigments. These pigment molecules are capable of absorbing light energy in the form of photons, a process necessary for the initiation of any light-induced, or photic, reaction. The energy thus absorbed is ultimately responsible for stimulating the sensory neurons of the photoreceptor unit.

Some animal eyes see only black and white; others perceive the full rainbow and beyond. Some can't gauge the direction of incoming light, while others can spot running prey miles away. The smallest animal eyes may be those on the heads of fairy wasps, the size of a large ameba, while the biggest are the dinner-plate-sized eyes of giant squids. Many animals have two eyes, or four, or eight. Some chitons have hundreds of eyes situated on their shell plates, each with its own lens, retina, and pigment layer. Box jellies typically have 24 eyes, grouped into four clusters on their rhopalia. Four of the six eyes in each rhopalium are simple light-sensing slits and pores. But the other two have light-focusing lenses and can see images. Mantis shrimps can have 12 color receptors (compared with the human 3) and can see infrared and ultraviolet light. Yet with all this diversity, only 2 or 3 types of photoreceptor protein groups have been discovered in metazoans: opsins, cryptochromes, and possibly the taste receptor homolog LITE-1 (a UV light receptor recently identified from nematode worms).

Beyond this basic commonality, however, there is an incredible range of variation in complexity and capability of light-sensitive structures. Arthropods, molluscs, and some polychaete annelids possess eyes with extreme sensitivity, good spatial resolution, and, in some cases, multiple spectral channels. Most classifications of photoreceptors are based upon grades of complexity, and the same categorical term may be applied to a variety of nonhomologous structures, from simple pigmented spots to extremely complicated lensed eyes. Functionally, the capabilities of these receptors range from simply perceiving light intensity and direction to forming images with a high degree of visual discrimination and resolution.

The simplest metazoan photoreceptors are unicellular structures scattered over the epidermis or concentrated in some area of the body. These are usually called **eyespots**. Multicellular photoreceptors may be classified into three general types, with some subdivisions. These types include **ocelli** (sometimes also called simple eyes or eyespots), **compound eyes** (found in most arthropods), and **complex eyes** (the "camera" eyes of cephalopod molluscs and vertebrates). In multicellular ocelli, the light-sensitive (retinular) cells may face outward; these ocelli are then said to be direct. Or the light-sensitive cells may be inverted. The inverted type is common among flatworms and nemerteans and is made up of a cup of reflective pigment and retinular cells (Figure 3.30A). The light-sensitive ends of these neurons face into the cup. Light entering the opening of the pigment cup is reflected back onto the retinular cells. Because light can enter only through the cup opening, this sort of ocellus gives the animal a good deal of information about light direction as well as variations in intensity.

Compound eyes are composed of a few to many distinct units called **ommatidia** (Figure 3.30B) and are described in more detail in Chapter 20. Although eyes of multiple units occur in certain annelid worms, they are best developed and best understood among the arthropods. Each ommatidium is supplied with its own nerve tract leading to a large optic nerve, and apparently each has its own discrete field of vision. The visual fields of neighboring ommatidia overlap to some degree, with the result that a shift in position of an object within the total visual field causes changes in the impulses reaching several ommatidial units; based in part on this phenomenon, compound eyes are especially suitable for detecting movement. Compound eyes nearly identical to those of living arthropods have been found in trilobite fossils and in numerous Cambrian stem-group arthropods. In fact, evidence

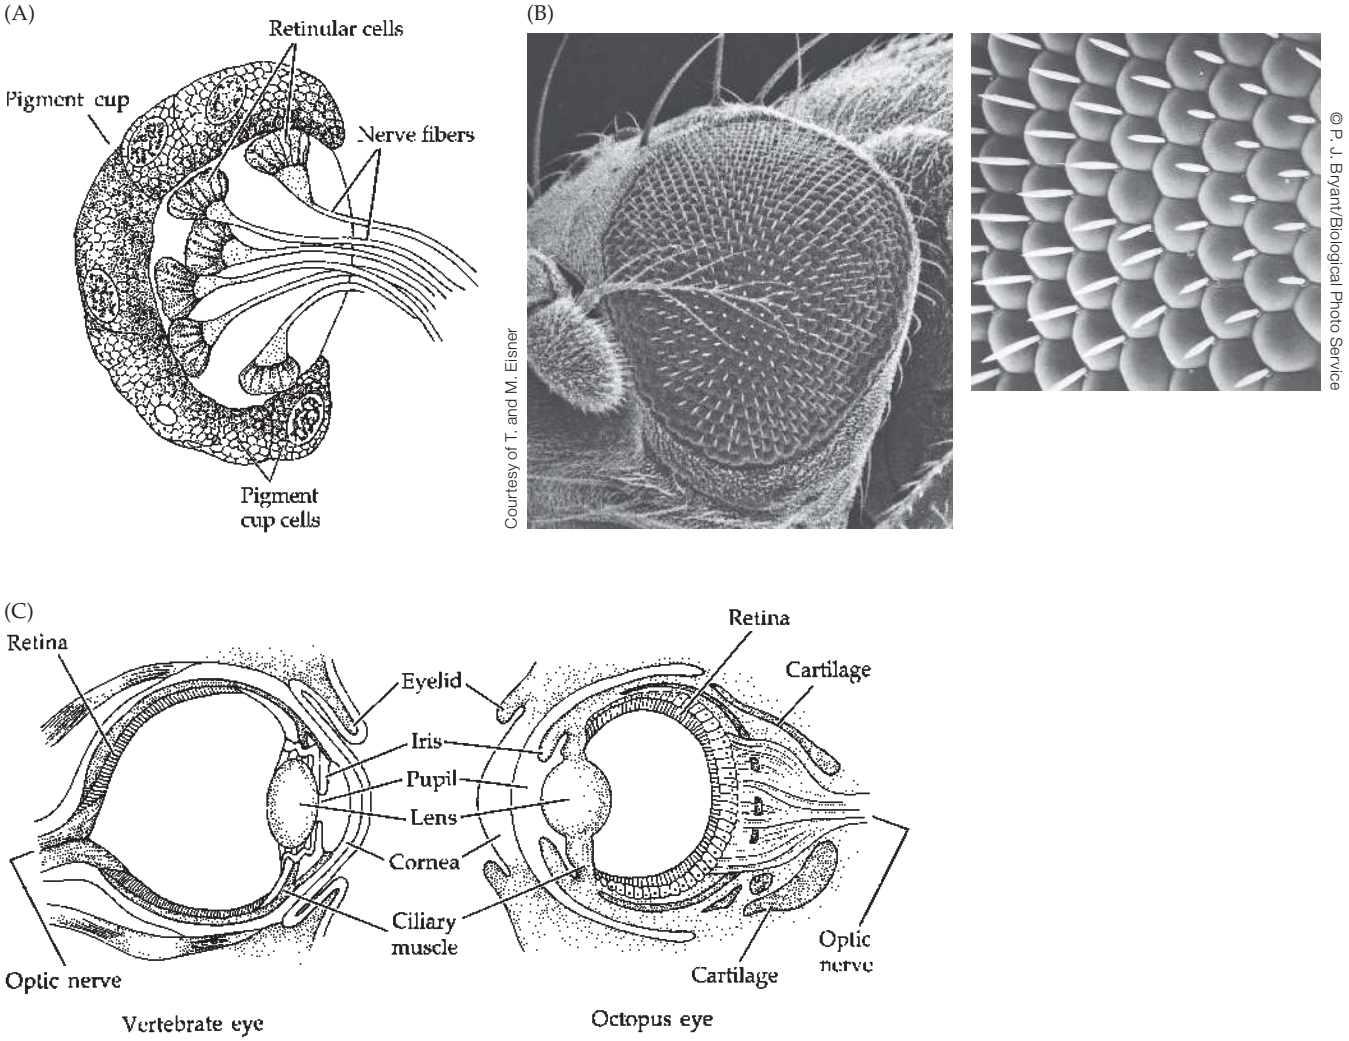


FIGURE 3.30 Some photoreceptors. (A) An inverted pigment-cup ocellus of a flatworm (section). (B) An insect's compound eye and a blown-up section of the eye. A single unit is called an ommatidium. (C) A vertebrate eye (left) and a cephalopod eye (right) (vertical cross-sections). Although many structural similarities are shared between vertebrate and cephalopod eyes (e.g., cornea, pupil, iris, ciliary muscle, lens, retina, optic nerve, etc.), their development differs. The cephalopod eye forms from an epidermal placode through a series of successive infoldings, whereas the vertebrate eye forms from the neural plate and induces the overlying epidermis to form the lens.

suggests that all of the arthropod eye types evolved out of an early arthropod compound eye architecture, even noncompound eyes such as the naupliar eyes of crustaceans and the ocelli of insects.

The complex eyes of squids and octopuses (Figure 3.30C) are probably the best image-forming eyes among the invertebrates. Cephalopod eyes are frequently compared with those of vertebrates, but they differ in many respects. The eye is covered by a transparent protective cornea. The amount of light that enters the eye is controlled by the iris, which regulates the size of the slitlike pupil. The lens is held by a ring of ciliary muscles and focuses light on the retina, a layer of densely packed photosensitive cells from which the neurons arise. The receptor sites of the retinal layer face in the direction of the light entering the eye. This direct eye arrangement is quite different from the indirect eye condition in vertebrates, where the retinal layer is inverted. Another difference is that in many vertebrates, focusing is accomplished by the action of muscles that change the shape of the lens, whereas in cephalopods it is achieved by moving the lens back and forth with the ciliary muscles and by compressing the eyeball.

A good deal of work suggests that metazoan photoreceptors evolved primarily along two lines. On one hand are photoreceptor units derived from or closely associated with cilia (e.g., in cnidarians, echinoderms, and chordates). These types of eyes are called **ciliary eyes**. On the other hand are photoreceptors derived from microvilli or microtubules and referred to as **rhabdomeric eyes** (e.g., in flatworms, annelids, arthropods, and molluscs). All animal photoreceptors may share a deep developmental homology with the *Pax-6* gene, which is known to initiate eye development (even in structurally nonhomologous eyes) in numerous distantly related phyla of both Protostomia and Deuterostomia.

for more ebook/ testbank/ solution manuals Request: Kingdom email:960126734@qq.com

The evolution of blindness has occurred in many different phyla, although we still know very little about it. In situations like dark caves and the deep sea, there is an apparent selective advantage to eye loss, given that eyes are energetically expensive organs. However, studies have shown that in many, perhaps most, cases eyes that are dramatically degraded or reduced still retain remnants of the visual system (e.g., visual opsins). It might be that these are vestiges in the evolutionary process of disappearing. Or, it might be that they allow for sufficient photo-stimulation (in the "dark") to be an advantage to a species that might not need acute vision.

Thermoreceptors The influence of temperature changes on all levels of biological activity is well documented. Every student of general biology has learned about the basic relationships between temperature and rates of metabolic reactions. Furthermore, even the casual observer has noticed that many organisms' activity levels range from lethargy at low temperatures to hyperactivity at elevated temperatures and that thermal extremes can result in death. The problem is determining whether the organism is simply responding to the effects of temperature at a general physiological level, or whether discrete thermoreceptor organs are also involved.

There is considerable circumstantial evidence that at least some invertebrates are capable of directly sensing differences in environmental temperatures, but actual receptor units are for the most part unidentified. A number of insects, some crustaceans, and horseshoe crabs (Xiphosura) apparently can sense thermal variation. The only nonarthropod invertebrates that have received much attention in this regard are certain leeches, which apparently are drawn to warm-blooded hosts by some heat-sensing mechanism. Other ectoparasites (e.g., ticks) of warm-blooded vertebrates may also be able to sense the "warmth of a nearby meal," but little work has been done on this subject.

Independent Effectors

Independent effectors are specialized sensory response structures that not only receive information from the environment but also elicit a response to the stimulus directly, without the intervention of the nervous system per se. In this sense, independent effectors are like closed circuits. As discussed in later chapters, the stinging capsules (nematocysts) of cnidarians and the adhesive cells (colloblasts) of ctenophores are, at least under most circumstances, independent effectors.

Bioluminescence

Bioluminescence, the production of light by living creatures, occurs in a great variety of organisms in the sea and in some land animals, but it is, curiously, rare in fresh waters. On land, it is seen in a number of beetle groups, as well as some flies and springtails, centipedes and millipedes, a few earthworms, and at least one snail (as well as some fungi). In fresh water it has been reported from only a few insect larvae and a freshwater limpet. In the sea, bioluminescence plays a significant role in animal communication, and it has been recorded from various cnidarians, ctenophores, chaetognaths, annelids, molluscs, numerous arthropods, echinoderms, hemichordates, tunicates, at least one nemertean, and, of course, numerous fishes (as well as protists, bacteria, and fungi). Most bioluminescence commonly seen in the sea is produced by dinoflagellates emitting rapid (one-tenth of a second) flashes. But the patient nighttime observer will also discover that flashes of light are produced by some species of medusae, ctenophores, copepods, benthic ostracods, brittle stars, sea pansies and sea pens, chaetopterid and syllid polychaetes, limpets, clams, tunicates, and others.

Luminescence is the emission of light without heat. It involves a special type of chemical reaction in which the energy, instead of being released as heat, as occurs in most chemical reactions, is used to excite a product molecule that releases energy as a photon. In all cases, the reaction involves the oxidation of a substrate called **luciferin**, catalyzed by an enzyme called **luciferase**. The structures of these chemicals differ among taxa, but the reaction is similar. The color of light varies from deep blue (shrimp and dinoflagellates) to blue-green or green (certain millipedes, ostracods, and tunicates), to yellow and even red (fireflies). Bioluminescence serves several functions, including offense, defense (counter-illumination), prey attraction, and intraspecific communication. In some cases, the luminescence of metazoans (particularly bobtail squids and fishes) is not intrinsic but it is produced by symbiotic colonies of microorganisms hosted in a light organ. Some deep-sea fishes living at depths sunlight cannot reach have an extraordinary increase in the number of genes for rhodopsins, retinal proteins that detect dim light. Hence, despite the darkness of their habitat, they are able to see the faint bioluminescence of deep-sea shrimp, octopuses, bacteria, other fishes, etc.

Nervous Systems and Body Plans

The nervous systems of all animals are always receiving information by way of their associated receptors, processing this information, and eliciting appropriate responses. Nervous systems among Metazoa encompass a staggering diversity, from those in which a distinct system of identifiable neurons does not even exist (e.g., sponges and placozoans), to nerve nets of just a few hundred neurons, to the highly centralized systems of arthropods that may contain a million neurons, to cephalopods and vertebrates that can contain hundreds of millions or even billions of neurons. Yet all these architectures probably evolved out of a group of key components that were in place very early in

animal evolution, most having been retained since at least the Cambrian, if not earlier. Arthropods with well-preserved central nervous systems occur in Cambrian fossils more than 514 million years old.

The molecular components of nervous systems are also similar throughout the animal kingdom, with the same sets of proteins and signaling molecules being used again and again, though often in different contexts. Indeed, a compelling case is emerging that there exists a conserved suite of genes involved in molecular patterning of the nervous system across all Metazoa. Even in groups as distant as flies and vertebrates, similarities in the mechanisms that define the position of the central nervous system on either the dorsal or ventral side of the body reveals fundamental patterning similarities that define the formation of the neuroectoderm in both groups. Geoffroy Saint-Hilaire in 1822 originally proposed this dorsal-ventral axis inversion idea in his hypothesis that the dorsoventral axis of vertebrates and arthropods are essentially the same if arthropods were flipped over on their backs. The idea insinuates that the ventral nerve cords of nonvertebrates and the dorsal nerve cords of vertebrates are homologous.

The structure of the nervous system of any animal is related to its body plan and mode of life. Consider first a radially symmetrical animal with limited powers of locomotion, such as a planktonic jellyfish or a sessile sea anemone. In such animals the major receptor organs are more or less regularly (and radially) distributed around the body; the nervous system itself is a noncentralized, diffuse meshwork generally called a **nerve net** (Figure 3.31A). Radially symmetrical animals tend to be able to respond equally well to stimuli coming from any direction—a useful ability for creatures with either sessile or free-floating lifestyles. Interestingly, at least in cnidarians there are both polarized and nonpolarized synapses within the nerve net. Impulses can travel in either direction across the nonpolarized synapses because the neuronal processes on both sides are capable of releasing synaptic transmitter chemicals. This capability, coupled with the gridlike form of the nerve net, enables impulses to travel in all directions from a point of stimulation. From this brief description, it might be assumed that such a simple and "unorganized" nervous system would not provide enough integrated information to allow complex behaviors and coordination. In the absence of a structurally recognizable integrating center, the nerve net does not fit well with our earlier description of the sequence of events from stimulus to response. But many cnidarians are in fact capable of fairly intricate behavior, and the system works, often in ways that are not yet fully understood.

The tremendous evolutionary success of bilateral symmetry and unidirectional locomotion must have depended in large part on associated changes in the organization of the nervous system and the distribution of sense organs. The evolutionary trend among animals has been to centralize and concentrate the major coordinating elements of the nervous system. This central nervous system is usually made up of an anteriorly located neuronal mass (ganglion) from which arise one or more longitudinal nerve cords that often bear additional ganglia (Figure 3.31B). The anterior ganglion is referred to by a variety of names. Many authors have abandoned the term "brain" for such an organ because of the multifaceted implications of

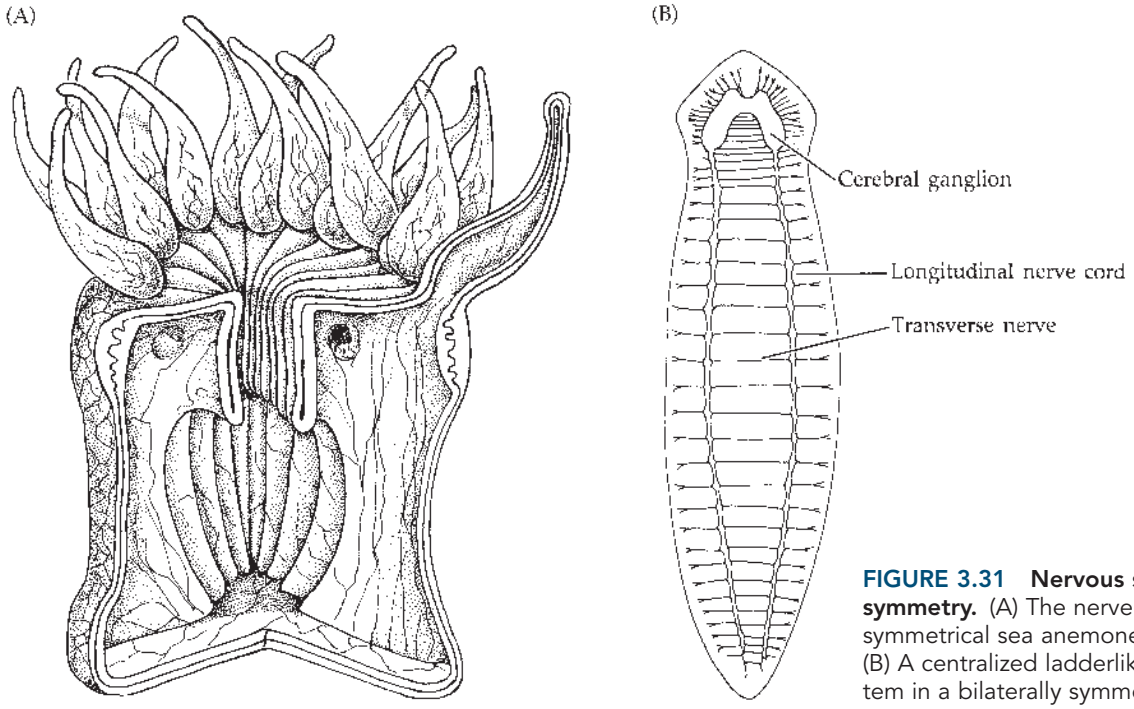

FIGURE 3.31 Nervous systems and symmetry. (A) The nerve net in a radially symmetrical sea anemone (cutaway view). (B) A centralized ladderlike nervous system in a bilaterally symmetrical flatworm.

for more ebook/ testbank/ solution manuals Request: Email:960126734@qq.com

that word and adopt the more neutral term **cerebral ganglion** (or cerebral ganglia) for the general case. In many instances, a term denoting its relative position to some other organ is applied. For example, the cerebral ganglion commonly lies dorsal to the anterior portion of the gut and is thus a supraenteric (or supraesophageal, or suprapharyngeal) ganglion.

In addition to the cerebral ganglion, most bilaterally symmetrical animals have many of the major sense organs placed anteriorly. The concentration of these organs at the front end of an animal is called **cephalization**—the formation of a head region. Even though cephalization may seem an obvious and predictable outcome of bilaterality and mobility, it is nonetheless extremely important. It simply would not do to have information about the environment gathered by the trailing end of a motile animal, lest it enter adverse and potentially dangerous conditions unawares. Hunting, tracking, and other forms of food location are greatly facilitated by having the appropriate receptors placed anteriorly—toward the direction of movement.

In 1888, the brilliant Austrian zoologist Berthold Hatschek recognized three major groups of Bilateria, based largely on the structure and position of the central nervous system. He named these Zygoneura (what we now call Protostomia), Chordonia (what we now call Chordata), and Ambulacraria. Today, the central nervous system of Bilateria remains an important indicator of phylogenetic relatedness, not just in adults but also in larvae.

The central nervous system of bilaterians includes three principal elements: (1) the apical organ, present in almost all ciliated larvae but degenerating before or at metamorphosis; (2) at least a pair of cerebral ganglia that begin developing in the larval stage and persist into adulthood; and (3) an often paired longitudinal nerve cord.

Ciliated larvae are found in numerous lineages of Porifera, Cnidaria, Spiralia, and Ambulacraria, but they are absent in Ecdysozoa and Chordata (except for the nonfeeding amphioxus larva). These widespread ciliated larvae are thought to be homologues at some fundamental level and have been called **primary larvae**. One of the most characteristic organs of these larvae is the **apical organ**. This organ develops from the most apical embryonic blastomeres. The apical organ appears to be sensory, and it is probably involved in metamorphosis. Gene expression studies show that the apical poles of cnidarians and bilaterians are homologous. Protostome primary larvae have ganglia/nerve cords that are retained as an integral part of the adult central nervous system. These include two structures: (1) a pair of cerebral ganglia, which will form the major part of the adult brain; and (2) a circumblastoporal nerve cord, which becomes differentiated into a perioral loop, paired or secondarily fused ventral nerved cords, and a small perianal loop. Thus, in bilaterians the adult central nervous system begins to develop as ciliary structures during the larval state.

Although the origin of deuterostome central nervous system is more difficult to interpret, gene expression studies support the homology of echinoderm and enteropneust apical organs with those of other bilaterians. Even though the nerve cord is ventral in protostomes and dorsal in deuterostomes (in the phyla Hemichordata and Chordata), gene expression patterns during development are the same in both, suggesting homology. In echinoderms a consolidated cerebral ganglion does not exist, and instead there are radial nerves that develop from invaginations of the ectoderm along the developing radii. The radial nerves have been interpreted as homologues of the chordate neural tube, from which the chordate central nervous system develops and which is specialized in different ways in the three chordate phyla Cephalochordata, Urochordata, and Vertebrata.[6]

Longitudinal nerve cords receive information through peripheral sensory nerves from whatever sense organs are placed along the body, and they carry impulses from the cerebral ganglion to peripheral motor nerves to effector sites. Additionally, nerve cords and peripheral nerves often serve animals in reflex actions and in some highly coordinated activities that do not depend on the cerebral ganglion. The most primitive centralized nervous system may have been similar to that seen today in xenacoelomorph worms and some free-living flatworms, where pairs of longitudinal cords may attach to one another by transverse connectives in a ladderlike fashion (Figure 3.31B). Among those Metazoa that have developed active lifestyles (e.g., errant polychaetes, most arthropods, cephalopod molluscs, vertebrates), the nervous system has become increasingly centralized through a reduction in the number of longitudinal nerve cords. However, a number of invertebrates (e.g., ectoprocts, tunicates, echinoderms) have secondarily taken up sedentary or sessile modes of existence. Within these groups there has been a corresponding decentralization of the nervous system and a general reduction in and dispersal of sense organs.

In animals, two distinct strategies for achieving increased neuronal conduction speed evolved. In some clades, greatly increased axon diameter improves conduction speed and hence body speed and reaction time (e.g., cephalopod molluscs). The other strategy has been the evolution of myelinated sheaths around the axon of neurons. Cnidaria (and probably Xenacoelomorpha) have naked axons, while in Nephrozoa a glial plasma membrane covers both axons and somata of nerve cells. Although myelinated axons (in which a

[6]The "cydippid stage" of ctenophores is better interpreted as a juvenile, rather than a larva, because it lacks special larval organs and because it can, in certain cases, carry out sexual reproduction. Further, the "apical organ" of ctenophores is structurally different from that of cnidarians and bilaterians and is generally not considered homologous to the apical organ of those taxa.

glial layer is modified by great expansion into a myelinated sheath) are ubiquitous among the vertebrates, they are relatively rare among invertebrates, but they do occur in species of at least three phyla—chordates, annelids, and crustacean arthropods. Myelin forms as an enormously expanded glial plasma membrane, and the sheaths comprise multiple layers of the membrane. The myelinated sheaths in these three phyla differ in their fine anatomy and conduction velocity (vertebrate sheaths have the fastest conduction rate), and it has been suggested that myelin sheaths may have arisen independently in each of these groups. Myelin sheaths greatly increase the rate of nerve transmission, accommodating rapid body movements such as escape responses and retraction of vulnerable body parts (e.g., copepod first antennae, crab eyestalks).

Hormones and Pheromones

We have stressed the significance of the integrated nature of the parts and processes of living organisms and have discussed the general role of the nervous system in this regard. Organisms also produce and distribute within their bodies a variety of chemicals that regulate and coordinate biological activities. This very broad description of what may be called chemical coordinators obviously includes almost any substance that has some effect on bodily functions. One special category of chemical coordinators is **hormones**. This term refers to any chemical that is produced and secreted by some organ or tissue and then carried by the blood or other body fluid to exert its influence elsewhere in the body. In vertebrates, we associate this type of phenomenon with the endocrine system, which includes well-known glands as production sites. For our purposes we may subdivide hormones into two types. First are **endocrine hormones**, which are produced by more or less isolated glands and released into the circulatory fluid. Second are **neurohormones**, which are produced by special neurons called neurosecretory cells.

Much remains unknown concerning hormones in invertebrates. Most of our information comes from studies on insects and crustaceans, although hormonal activity has been demonstrated in a few other taxa and is suspected in most others. Among the arthropods, hormones are involved in the control of growth, molting, reproduction, eye pigment migration, and other phenomena; in at least some other taxa (e.g., annelids), hormones influence growth, regeneration, sexual maturation, and stolon formation in epitokes.

Hormones do not belong to any particular class of chemical compounds, nor do they all produce the same effects at their sites of action: some are excitatory, some are inhibitory. Because endocrine hormones are carried in the circulatory fluid, they reach all parts of an animal's body. The site of action, or target site, must be able to recognize the appropriate hormone(s) among the myriad other chemicals in its surroundings. This recognition usually involves an interaction between the hormone and the cell surface at the target site. Thus, under normal circumstances, even though a particular hormone is contacting many parts of the body, it will elicit activity only from the appropriate target organ or tissue that recognizes it.

In a general sense, pheromones are substances that act as "interorganismal hormones." These chemicals are produced by organisms and released into the environment, where they have an effect on other organisms. Most pheromone research has been on intraspecific actions, especially in insects, where activities such as mate attraction are frequently related to these airborne chemicals. We may view intraspecific pheromones as coordinating the activities of populations, just as hormones help coordinate the activities of individual organisms. There is also a great deal of evidence for the existence of interspecific pheromones. For example, some predatory species (e.g., some starfish) release chemicals into the water that elicit extraordinary behavioral responses on the part of potential prey species, generally in the form of escape behavior. We discuss examples of various pheromone phenomena for specific animal groups throughout the book.

Reproduction

The biological success of any species depends upon its members staying alive long enough to reproduce. The following account includes a discussion of the basic methods of reproduction among invertebrates and leads to the account of embryology and developmental strategies provided in Chapter 4.

Asexual Reproduction

Asexual reproductive processes do not involve the production and subsequent fusion of haploid cells but rely solely on vegetative growth through mitosis. Many invertebrates engage in various types of body fission, budding, or fragmentation, followed by growth to new individuals (Figure 3.32). These asexual processes depend largely on the organism's "reproductive exploitation" of its ability to regenerate (regrow lost parts). Even wound healing is a form of regeneration, but many animals have far more dramatic capabilities. The replacement of a lost appendage in familiar animals such as starfish and crabs is a common example of regeneration. However, these regenerative abilities are not "reproduction" because no new individuals result, and their presence does not imply that an animal capable of replacing a lost leg can necessarily reproduce asexually. Examples of organisms that possess regenerative abilities of a magnitude permitting asexual reproduction include

for more ebook/ testbank/ solution manuals Request: Email: 9601263734@qq.com

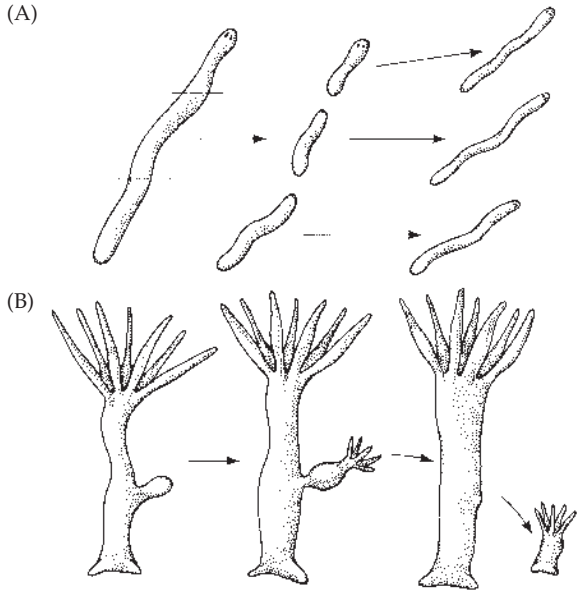

FIGURE 3.32 Some common asexual reproductive processes. (A) Fragmentation, followed by regeneration of lost parts. This process occurs in a number of vermiform invertebrates. (B) Budding may produce separate solitary individuals, as it does in *Hydra* (shown here), or it may produce colonies (see Figure 3.33).

sponges, many cnidarians (corals, anemones, and hydroids), many colonial animals, and certain types of worms. These animals have the property known as "whole body regeneration," meaning that they can regenerate any body part from a set of cells.

In many cases asexual reproduction is a relatively incidental process and is rather insignificant to a species' overall survival strategy. In others, however, it is an integral and even necessary step in the life cycle. There are important evolutionary and adaptive aspects to asexual reproduction. Organisms capable of rapid asexual reproduction can quickly take advantage of favorable environmental conditions by exploiting temporarily abundant food supplies, newly available living space, or other resources. This competitive edge is frequently evidenced by extremely high numbers of asexually produced individuals in disturbed or unique habitats, or in other unusual conditions. In addition, asexual processes are often employed in the production of resistant cysts or overwintering bodies, which are capable of surviving through periods of harsh environmental conditions. When favorable conditions return, these structures grow to new individuals.

A word about colonies A frequent result of asexual reproduction, particularly some forms of budding, is the formation of **colonies**. This phenomenon is especially common in certain taxa (e.g., cnidarians, ascidians, bryozoans) (Figure 3.33). The term "colony" is not easy to define. It may initially bring to mind ant

or bee colonies, or even groups of humans; but these examples are more appropriately viewed as social units rather than as colonies, at least in the context of our discussions. For our purposes, we define colonies as associations in which the constituent individuals are not completely separated from each other, but organically connected together, either by living extensions of their bodies or by material that they have secreted. While occasional mixed colonies may exist (usually due to fusion of two separate colonies, as in some tunicates and bryozoans), most colonies are composed of genetically identical individuals. We describe the nature of numerous examples of colonial life in later chapters.

The formation of colonies not only may enhance the benefits of asexual reproduction in general, but also produces overall functional units that are much greater in size than mere individuals; thus this growth habit may be viewed as a partial solution to the surface-to-volume dilemma. Increased functional size through colonialism can result in a number of advantages for animals: it can increase feeding efficiency; facilitate the handling of larger food items; reduce chances of predation; increase the competitive edge for food, space, and other resources; and allow groups of individuals within the colony to specialize for different functions. Colonies of many animals can use fragmentation as a form of propagation.

Sexual Reproduction

Although reproduction is critical to a species' survival, it is the one major physiological activity that is not essential to an individual organism's survival. In fact, when animals are stressed, reproduction is usually the first activity that ceases, but others release large amounts of gametes to maximize output under severe stress. Sexual reproduction is especially energy costly, yet it is the characteristic mode of reproduction among multicellular organisms.[7]

Given the advantages of asexual reproduction, one might wonder why all animals do not employ it and abandon costly and complicated sexual activities entirely. The most frequently given explanation for the popularity of sexual reproduction (aside from anthropomorphic views, of course) focuses on the long-term benefits of genetic variation. Recombination allows for the maintenance of high genetic heterozygosity in individuals and high polymorphism in populations. Through regular meiosis and recombination, a level of genetic variation is maintained generation after generation, within and among populations; thus species are thought to be more "genetically prepared" for environmental changes, including both shifts in the physical environment and the changing milieu of competitors, predators, prey, and parasites.

Although this advantage must surely be real, does it satisfactorily explain the role of sex in short-term selection (i.e., generation by generation)? Presumably even in the short term an advantage lies in the maintenance of genetic variability. That is, genetic variability in individuals may increase their chances of quickly adapting to environmental fluctuations, predators, parasites, and disease. In 1973, Leigh Van Valen proposed the idea that in order just to "keep up" with changing environments, populations must continually access new and different allele combinations through the process of natural selection—a notion called the "red queen hypothesis" after the Red Queen in *Alice in Wonderland*, who commanded her courtiers to run continuously just to stay in the same place.

Sexual reproduction involves the formation of haploid cells through meiosis and the subsequent fusion of pairs of those cells to produce a diploid zygote (Figure 3.34). The haploid cells are **gametes**—sperm and eggs—and their fusion is the process of fertilization, or **syngamy**. The production of gametes is accomplished by the gonads—**ovaries** in females and **testes** in males—or their functional equivalents. The gonads are frequently associated with reproductive systems that may include various arrangements of ducts and tubes, accessory organs such as yolk glands or shell glands, and structures for copulation or transferring gametes. The different levels of complexity of these systems are related to the developmental strategies used by the organisms in question, as discussed in Chapter 4 and described in the coverage of each phylum. The variation in such matters is immense, but at this point we introduce some basic terminology of structure and function.

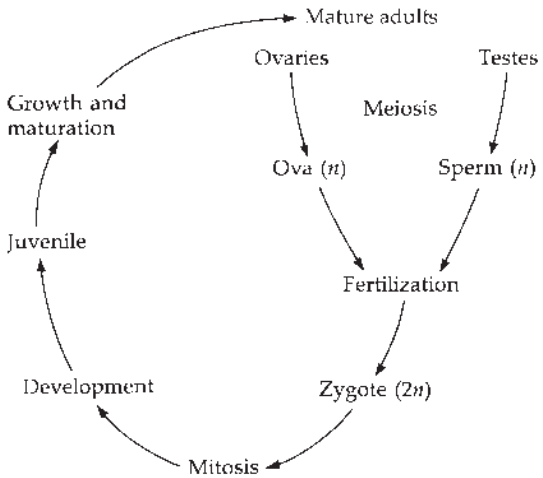

FIGURE 3.34 **A generalized metazoan life cycle.**

[7] In thinking of animals, we typically view "sex" and "reproduction" as one and the same. However, at the cellular level these two processes are opposites: reproduction is the division of one cell to form two, whereas the sexual process incudes two cells fusing to form one! Conventional sex is the alternation of meiosis and fertilization events.

for more ebook/ testbank/ solution manuals Request Email:960126734@qq.com

Many invertebrates simply release their gametes into the water in which they live (**broadcast spawning**), where external fertilization occurs. In such animals the gonads are usually simple, often transiently occurring structures associated with some means of getting the eggs and sperm out of the body. This release is accomplished through a discrete plumbing arrangement (coelomoducts, metanephridia, or gonoducts—sperm ducts and oviducts) or by temporary pores in, or rupture of, the body wall. In such animals, synchronous spawning is critical, and marine species rely largely on this synchrony and the water currents to achieve fertilization. Water temperature, light, phytoplankton abundance, lunar cycle, and the presence of conspecifics have all been implicated in synchronized spawning events of invertebrates.

On the other hand, invertebrates that pass sperm directly from the male to the female, where fertilization occurs internally, must have structural features to facilitate such activities. Figure 3.35 illustrates stylized male and female reproductive systems. A general scenario leading to internal fertilization in such systems is as follows: Sperm are produced in the testes and transported via the **sperm duct** to a precopulatory storage area called the **seminal vesicle**. Prior to mating, many invertebrates incorporate groups of sperm cells into sperm packets, or **spermatophores**. Spermatophores provide a protective casing for the sperm and facilitate transfer with minimal sperm loss. In addition, many spermatophores are themselves motile, acting as independent sperm carriers. Some sort of male copulatory or intromittent organ (e.g., penis, cirrus, or some other modified appendages in arthropods, such as pedipalps or legs, often called gonopods) is inserted through the female's gonopore and into the vagina. Sperm are passed through the male's ejaculatory duct directly, or by way of a copulatory organ, into the female system, where they are received and often stored by a **seminal receptacle**.

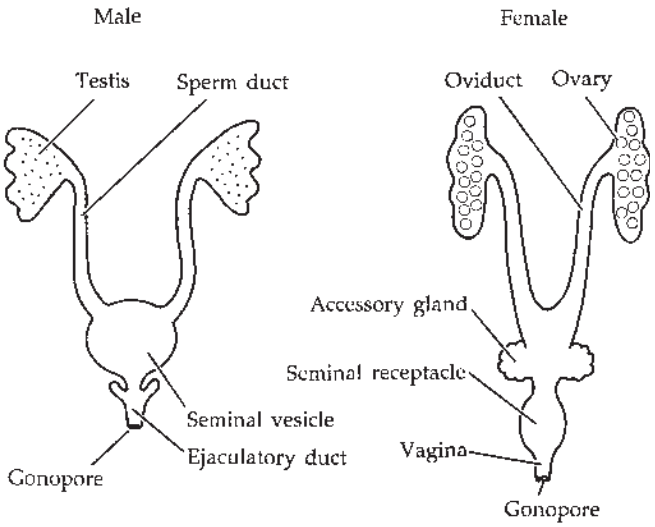

FIGURE 3.35 Schematic and generalized male and female reproductive systems. See text for explanation.

In the female, eggs are produced in the ovaries and transported into the region of the **oviducts**. Sperm eventually travel into the female's reproductive tract, where they encounter the eggs; fertilization often takes place in the oviducts. Among invertebrates, the sperm may move by flagellar or ameboid action or by locomotor structures on the spermatophore packet; they may be aided by ciliary action of the lining of the female reproductive tract. Various accessory glands may be present both in males (such as those that produce spermatophores or seminal fluids) and in females (such as those that produce yolk, egg capsules, or shells). This simple sequence is typical (although with many elaborations) of most invertebrates that rely on internal fertilization, but many others exist, including not uncommon strategies in which the sperm is injected through the epidermis of a female individual.

Animals in which the sexes are separate, each individual being either male or female, are termed **gonochoristic** (or **dioecious**, especially in plants). However, many invertebrates are **hermaphroditic** (or **monoecious,** especially in plants): each animal contains both ovaries and testes and thus is capable of producing both eggs and sperm (though not necessarily at the same time).[8] Although self-fertilization may seem to be a natural advantage in this condition, such is not the case. In fact, with some exceptions, self-fertilization in hermaphrodites is usually prevented. Fertilizing one's self would be the ultimate form of inbreeding and would presumably result in a dramatic decrease in potential genetic variation and heterozygosity (as with asexual reproduction). The rule for many hermaphroditic invertebrates is mutual cross-fertilization, wherein two individuals function alternately or simultaneously as males and exchange sperm and then use the mate's sperm to fertilize their own eggs. The real advantage of hermaphroditism now becomes clear: a single sexual encounter results in the impregnation of two individuals, rather than only one as in the gonochoristic condition.

A common phenomenon among hermaphroditic invertebrates is **protandric hermaphroditism**, or simply **protandry** (Greek *proto*, "first"; *andro*, "male"), where an individual is first a functional male but later in life changes sex to become a functional female. The less common reverse situation, female first and then male, is called **protogynic hermaphroditism**, or simply **protogyny** (Greek *gynos*, "female"). At least some invertebrates alternate regularly between being

[8]Hermaphroditus, the beautiful son of Hermes and Aphrodite, was united with a water nymph at a Carian fountain. Thus his body became both male and female.

functional males and females, as explained by Jerome Tichenor (*Poems in Contempt of Progress*, 1974):

Consider the case of the oyster,
Which passes its time in the moisture;
Of sex alternate,
It chases no mate,
But lives in self-contained cloister.

In addition to the clever oysters immortalized by Professor Tichenor (aka Joel W. Hedgpeth), some other taxa in which the hermaphroditic condition is common include barnacles, arrow worms (Chaetognatha), flatworms, clitellate annelids, tunicates, many gastropods, and cymothoid isopods (Crustacea).

The sexual conditions include myriad variations on the themes described above, including the reproductive systems of nematodes, which may involve three sexes (**trioecy**)—females, males, and hermaphrodites—and the two sexes of *Caenorhabditis elegans*, which include a male and a hermaphrodite. Colonial organisms may include one sex or both sexes, or all individuals may be hermaphroditic.

Parthenogenesis

Parthenogenesis (Greek *parthenos*, "virgin"; *genesis*, "birth") is a special reproductive strategy in which unfertilized eggs develop into viable adult individuals. Parthenogenetic species are known in many invertebrate (and vertebrate and plant) groups, including gastrotrichs, rotifers, tardigrades, nematodes, gastropods, certain insects, and various crustaceans. The taxonomic distribution of parthenogenesis is spotty; it is rare to find a whole genus, let alone any higher taxon, that is wholly parthenogenetic. Some higher taxa that are largely parthenogenetic (e.g., aphids, cladocerans) are cyclically parthenogenetic, and they punctuate their life histories with sex.[9] Among the invertebrates, parthenogenesis usually occurs in small-bodied species that are parasites or that are free-living but inhabit extreme or highly variable habitats such as temporary freshwater ponds. There is a general trend for parthenogenesis to become more prevalent as one moves toward higher latitudes or into harsher environments. Overall, it appears that parthenogenetic taxa arise from time to time and succeed in the short run due to certain immediate advantages, but in the long run they might be condemned to extinction through competition with their sexual relatives.

In most species that have been studied, parthenogenetic periods alternate with periods of sexual reproduction. In temperate freshwater habitats, parthenogenesis often occurs during summer months, with the population switching to sexual reproduction as winter approaches. In some species, parthenogenesis takes place for many generations, or several years, eventually to be punctuated by a brief period of sexual reproduction. In some rotifers, parthenogenesis predominates until the population attains a certain critical size, at which time males appear and a period of sexual reproduction ensues. One whole clade of rotifers (the bdelloids) appears to persist and evolve completely without conventional sex, but it may sustain genetic diversity through high levels of horizontal gene transfer within and between species, including the incorporation of nonrotifer metazoan and nonmetazoan genes. Cladocerans switch from parthenogenesis to sexual reproduction under a number of conditions, such as overcrowding, adverse temperature, or food scarcity, or even when the nature of the food changes. Many parasitic species alternate between a free-living sexual stage and a parasitic parthenogenetic one; this arrangement is seen in some nematodes, thrips (Thysanoptera), gall wasps, aphids, and certain other hemipterans.

One of the most interesting examples of parthenogenesis occurs in honeybees; in these animals the queen is fertilized by one or more males (drones) at only one period of her lifetime, in her "nuptial flight." The sperm are stored in her seminal receptacles. If sperm are released when the queen lays eggs, fertilization occurs and the eggs develop into females (queens or workers). If the eggs are not fertilized, they develop parthenogenetically into males (drones).

The question of the existence or prevalence of purely parthenogenetic species has been debated for decades. Many species once thought to be entirely parthenogenetic have proved, upon closer inspection, to alternate between parthenogenesis and brief periods of sexual reproduction. In some species purely parthenogenetic populations apparently exist only in some localities. In other species, parthenogenetic lineages have been traced to sexual ancestral populations occupying relictual habitats. Nevertheless, for some parthenogenetic animals, males have yet to be found in any population, and these may indeed be purely clonal species. One cannot help but wonder how long such species can exist in the face of natural selection without the benefits of any genetic exchange. One would predict that, as with any form of asexual reproduction, obligatory parthenogenesis would eventually lead to genetic stagnation and extinction. There may, however, be some as yet unexplained genetic mechanisms to avoid this, because some parthenogenetic animals (e.g., some earthworms, insects, and lizards) are capable of inhabiting a wide range of habitats. Presumably they either have a significant level of genetic adaptability or possess "general purpose genotypes."

[9] A number of fishes and amphibians are parthenogenetic, but none seem to have overcome the need for their eggs to be fused with sperm in order to initiate development. The parthenogenetic females usually mate with males of another species, which provide sperm that trigger development (a behavior called **pseudogamy**). A few lizards apparently have no need for a sperm to trigger parthenogenetic development. No parthenogenetic wild birds or mammals have been documented.

Chapter Summary

In this chapter, we explore fundamentals of animal architecture and body plans. Most animal phyla exhibit bilateral symmetry, with associated cephalization. However, some phyla (Cnidaria, Ctenophora, Echinodermata) have various forms of radial symmetry. And a few phyla express no symmetry at all; that is, they are asymmetrical (most Porifera, Placozoa). All animals have some form of locomotion, though sometimes limited to a larval stage. Smaller aquatic animals must contend with Reynolds number effects as they move their body, or body parts, through water. Cilia/flagella play important roles in almost all larger aquatic animal groups, either in direct locomotion or by moving the "environment" closer to their feeding and gas exchange surfaces. Most animals have musculature and a skeleton of some kind, often hydrostatic but usually rigid. Most animals have a complete (through) gut, with both mouth and anus. A few have no gut at all (Porifera, Placozoa, tapeworms, acanthocephalans), while some others have an incomplete gut, lacking an anus (Cnidaria, Xenacoelomorpha, Platyhelminthes).

Many aquatic taxa are suspension feeders, removing particulate food matter from the surrounding water through filter feeding, contact suspension feeding, scan-and-trap feeding, or mucous net feeding. Other animals are deposit feeders. Animals can also be categorized as herbivores, carnivores, or scavengers. In addition to eating particle-sized or larger food matter, many invertebrates can also absorb dissolved organic matter (DOM) directly from the water in which they live. Finally, a good number of animals rely on symbiotic relationships with various microbes, which provide all or part of their nutrition, such as chemoautotrophic bacteria or different types of algae. One group of bone-eating annelid worms (*Osedax*) are carnivorous scavengers that cultivate and consume bacterial endosymbionts that are capable of digesting the bones of dead vertebrates on the seafloor. Other invertebrates rely on a symbiotic aerobic bacterium to break down cellulose in wood that the animals can then digest (e.g., shipworm bivalves).

Almost all animals must osmoregulate and deal with toxic byproducts of protein digestion (e.g., ammonia). Many, especially the Bilateria, use various forms of nephridia for these purposes (e.g., protonephridia or metanephridia). Large-bodied metazoans rely on open or closed circulatory systems for internal transport of nutritional products, oxygen and carbon dioxide, and toxins to be expelled. Pumping structures or general body movement keep the blood or hemolymph circulating in the body. Many invertebrates rely on integumentary or cutaneous gas exchange, but others have external organs (e.g., gills, book lungs), internal organs (e.g., lungs, tracheae), or restricted areas of the body specialized for this. Oxygen binding and transport are usually by special respiratory pigments (e.g., hemoglobins, hemocyanins, hemerythrins, chlorocruorins).

Except in sponges and placozoans, structural nervous systems are found in all metazoan phyla. A wide range of sense organs have evolved among animals, including tactile receptors, georeceptors, proprioceptors, phonoreceptors, baroreceptors, chemoreceptors, thermoreceptors, and photoreceptors—including several types of eyes.

Asexual reproduction occurs in many metazoan phyla, and in some cases this leads to the formation of colonies. Sexual reproduction occurs in every animal phylum and involves the generation and fusion of male and female gametes. Animals may be gonochoristic (dioecious) or hermaphroditic (monoecious), and parthenogenesis is also known from some species in several phyla.

CHAPTER 4

Introduction to the Animal Kingdom

Development, Life Histories, and Origin

The process by which unicellular zygotes transform themselves into multicellular individuals and eventually into reproducing adults is called **ontogeny**. At the core of metazoan ontogeny is **embryogenesis**—the growth and development of the embryo. The embryo is that stage of an organism between fertilization and birth. It is the principal phase of life history that mediates between genotype and phenotype.

As we saw in Chapter 3, the cells of animals are organized into functional units, generally as tissues and organs, with specific roles that support the whole animal. These different cell types are interdependent, and their activities are coordinated in predictable patterns and relationships. The tissues and organs develop through a series of events early in an organism's embryogeny. The embryonic tissues, or **germ layers**, form the framework upon which metazoan body plans are constructed. Thus, the cells of animals (Metazoa) are specialized, interdependent, coordinated in function, and develop through a genetically orchestrated tissue-layering process during embryogeny.

The influence of yolk on early zygotic divisions, as well as on the differentiation of embryonic tissues, is one of the best established principles of zoology, yet one that is more labile than previously believed. So it is not surprising that a large body of detailed descriptive research on animal embryos has accumulated, leading to a strong focus on structure and physical processes in the field of developmental biology. Because particular developmental schemes characterize different animal lineages, developmental biology has compiled detailed descriptions of cell divisions, cell fates, embryonic germ layers, and larval or adult structures in the search for shared evolutionary patterns among animal phyla. Among the most detailed studies in biology are the meticulous accounts of early metazoan development by Wilhelm Roux, Hans Driesch, Edmund Beecher Wilson, Hans Spemann, and others. The apparent tendency for progressive stages of embryonic development to reveal the evolutionary history of animals is what inspired Ernst Haeckel, Karl von Baer, Walter Garstang, and others to formulate their versions of the **recapitulation hypothesis**, or "**biogenetic law**" (see the end of this chapter). And, despite some ongoing philosophical debate, from a morphological perspective ontogeny does appear to recapitulate many aspects of animal phylogeny, at least in some animal groups.

However, the recent emergence of *molecular* developmental biology (a field known as evo-devo) has changed some long-standing embryological principles in subtle but compelling ways. Haeckel's biogenetic law is no longer seen to govern the development of metazoan embryos in the ways embryologists once thought that it did. Taxon-specific patterns, and deviations of those patterns

in animal development, have revealed more complicated interactions than could ever have been anticipated from morphological descriptions alone. For these reasons, developmental biology can no longer consist primarily of descriptions of ova, early cell divisions, and the formation of increasingly complex balls of cells and cell layers, although these classic patterns are still a major part of this field. A modern approach to the study of animal development includes molecular as well as morphological studies with a great deal of experimental biology.

Evolutionary Developmental Biology: Evo-Devo

Molecular biology has had an explosive impact on the study of development and animal phylogenetics and evolution. "**Evo-devo**," the catchy abbreviation for the field of evolutionary developmental biology, is also used for the burgeoning discipline of comparative developmental genetics—the evolutionary study of the spatial and temporal expression of genes that control body architecture among metazoans. Much of evo-devo focuses on the roles of **transcription factors** (**TF**s), which are the products of the genes involved in controlling early development. These genes and TFs define the primary embryonic body axes (e.g., the oral–aboral, anterior–posterior, and dorsal–ventral axes), the directionality of structures developing along these axes, and the appearance of particular structures or organizations such as body cavities, segments, or appendages. Evo-devo investigates the genetic underpinnings of nearly every process described within classical studies of developmental biology. The focus of developmental biology has thus shifted, from the ontogenetic study of animal structural organization, to the comparative ontogenetic study of gene functions and their roles in body organization.

As genomic methods become less expensive and more widely explored, the number of animal species whose full genome is known has dramatically increased, with high-quality genomes now available for nearly all animal phyla. Therefore, the old separation between "model organisms," for which unlimited genomic resources were available, and non-model organisms has blurred, and the ability to sequence whole genomes for a few thousand U.S. dollars has "democratized" the field of evo-devo, with growing opportunities for evolutionary comparison of the different patterns and mechanisms for virtually any animal that can be grown in the laboratory. The use of developmental genomics has therefore become more than the mere determination of whether ontogeny recapitulates phylogeny, an idea that is now seen to be an oversimplification. Instead, the comparison of developmental similarities and differences, as well as how the differences play out in adult organisms, has led to a much more subtle and discerning understanding of how animals are organized and how that organization unfolds within individual lifespans. Although the breadth of these changes is beyond the scope of this book, some general patterns are now apparent, as summarized below.

Developmental Tool Kits

If animals arose from among the Protista, a basic set of genetic factors are likely to have existed in that ancestry that supported multicellularity (which arose several times in the Eukaryota), facilitated its expression, and allowed these traits to be favored by selection. Likely genetic factors may have included a tendency for cells to aggregate rather than disperse after mitosis, the biochemical ability for cells to remain together as a group, and the movement or differentiation of cells bearing one set of specializations in response to proximity with cells bearing another set of specializations.

The possibility that such traits existed implies they were mediated in some way by the transcription products of genes borne by the protistan ancestors of animals. Sets of functional genes that control ontogenetic processes have been called **developmental tool kits**, and with respect to the evolution of multicellularity, they are likely to have been associated with three processes: (1) the adhesion of cells to one another, (2) the transduction of biochemical signals within and between cell types (i.e., **cell signaling pathways**), and (3) differentiation of cells from primordial to specialized states.

The transition to multicellularity from a unicellular state was a fundamental event in metazoan evolution. However, until recently, there were few avenues available for investigating this transition. The possibility that developmental tool kits underlying multicellularity existed at the origin of the Metazoa suggests that recognizable homologous gene sequences in different species, or **orthologs**, and their transcription factors might be found in predictable ways within close relatives of metazoans, as it has been shown for groups including choanoflagellates, ichthyosporeans, and filastereans, as well as throughout the metazoans themselves. Recent genomic studies have shown that despite some of the shared developmental tool kit, a large number of gene families were acquired at the stem of Metazoa, while other genes have been loss at that branch.

The structural organization of choanoflagellates, as well as their similarity to metazoans such as sponges, have made these creatures compelling candidates as metazoan ancestors, and molecular phylogenetic methods have allowed this hypothesis to be directly tested. Analyses of genomic data from diverse metazoan lineages strongly support the idea of animals and choanoflagellates having a common ancestor, and as predicted, a majority of choanoflagellate-expressed genes have homologous sequences (orthologs) in animal genotypes.

for more ebook/ testbank solution manuals requests email 960126734@qq.com

Noteworthy too are observations that choanoflagellates express a surprising diversity of adhesion and cell signaling homologues. Thus, by identifying genes shared among animals and their apparent most recent living relatives, tests of specific developmental hypotheses regarding genome evolution in early animals have become increasingly possible. However, things aren't always as easy as they seem.

The Relationship Between Genotype and Phenotype

A search for genetically conserved tool kits underlying particular events or morphological landmarks in animal development seems exciting indeed. Unfortunately, evidence now suggests that a direct correspondence between genotype and phenotype in metazoan development is rare—things are usually more complicated. Early studies were lured in this direction by the striking degree to which **Hox clusters** (groups of homeotic genes that control the body plan and limb organization of developing embryos along their anterior–posterior axis) seemed to exhibit organizational and functional consistency throughout the Metazoa. The discovery in the late 1970s that animals as diverse as vertebrates and arthropods had structurally and functionally related Hox genes led to the assumption that all animals would contain similar gene clusters. And some gene sequences, including Hox clusters and other similar genes, confirmed this assumption. The developmental gene *brachyury* (*bra*) is a good example. The transcription products of *bra* define the midline of bilaterians, and the gene also is expressed in the notochord of species belonging to the phylum Chordata. Its expression pattern confirms the homologies suggested by morphology, in that its expression in the notochord of chordates provides an example of a homologous gene with a homologous function in a homologous morphological character—the notochord (which is a synapomorphy of the phylum).

The use of gene sequences and gene products for phylogenetic analysis has proven to be more complicated than expected. For example, Hox genes that are apparently homologous in their sequences may not be identical or even necessarily similar in their expression in different taxa, even among closely related taxa. Gene sequence homology, it seems, does not guarantee that the specific functions of the genes will be similar. And, Hox genes have been found to be linearly arranged only in certain taxa, despite their linear representation in most review papers and textbooks (Figure 4.1).

Despite their presumed role as an evolutionary "magic bullet," developmental genes now seem every bit as likely as morphological characters are to exhibit homoplasy (e.g., convergent evolution), not only in their sequence but also in their function! While developmental genetic programs may at first appear to contain phylogenetic information, observed patterns are likely to represent patterns shaped by the needs of the developmental program in different lineages. Because such difficulties are widespread, using particular genes to establish homology of certain anatomical features in different metazoan lineages can be challenging.

The Evolution of Novel Gene Function

New functional roles appear to routinely evolve in developmental genetic systems. Developmental genes, despite being under strong stabilizing selection to perform precise functions, can evolve in unexpected ways. This tendency is called **developmental system drift** or **DSD**. The existence of DSD can be useful for tracking the evolution of particular structures (e.g., visual elements) but can cause confusion because DSD itself often leads to morphological divergences.

DSD appears to occur in two ways. First, a gene that performs a function in one taxon may be co-opted for another use in a different taxon. The process often begins with **gene duplication**, when replication errors create multiple copies of functional genes. Redundancy in regulatory function allows continuation of normal metabolism, but it also allows duplicated gene products to be used elsewhere. For example, the gene *Pax6* is expressed in a range of both eyed and eyeless bilaterians, suggesting that this patterning gene has been co-opted for multiple functions in the regulation of eye development. Large gene expansions have now been mapped to key nodes in animal evolution, including the base of Metazoa, but massive gene loss has also been important in clades such as Deuterostomia and Ecdysozoa.

A second DSD mechanism occurs when differences in gene expression arise due to genetic interactions, or epistasis, occurring within different genetic backgrounds. Identical sequences can produce different phenotypic effects in different species, or even among members of the same species. Although the magnitude of these effects can become increasingly pronounced as species divergence increases, the complexities of epistatic interactions are seldom predictable.

Gene Regulatory Networks

A major contribution of genomic analyses to developmental biology is the conclusion that individual genes do not control cellular or development function. That is, there is no one gene "for" a particular phenotype or structure. Instead, groups of genes, usually called **gene regulatory networks**, are responsible for producing functional traits. Four major groups of these regulatory clusters exist: (1) cell differentiation networks, which appear to allow groups of cells to differentiate in particular ways; (2) subcircuits, developmental gene networks that are repeatedly used in general cell function; (3) switches, regulatory gene networks that turn

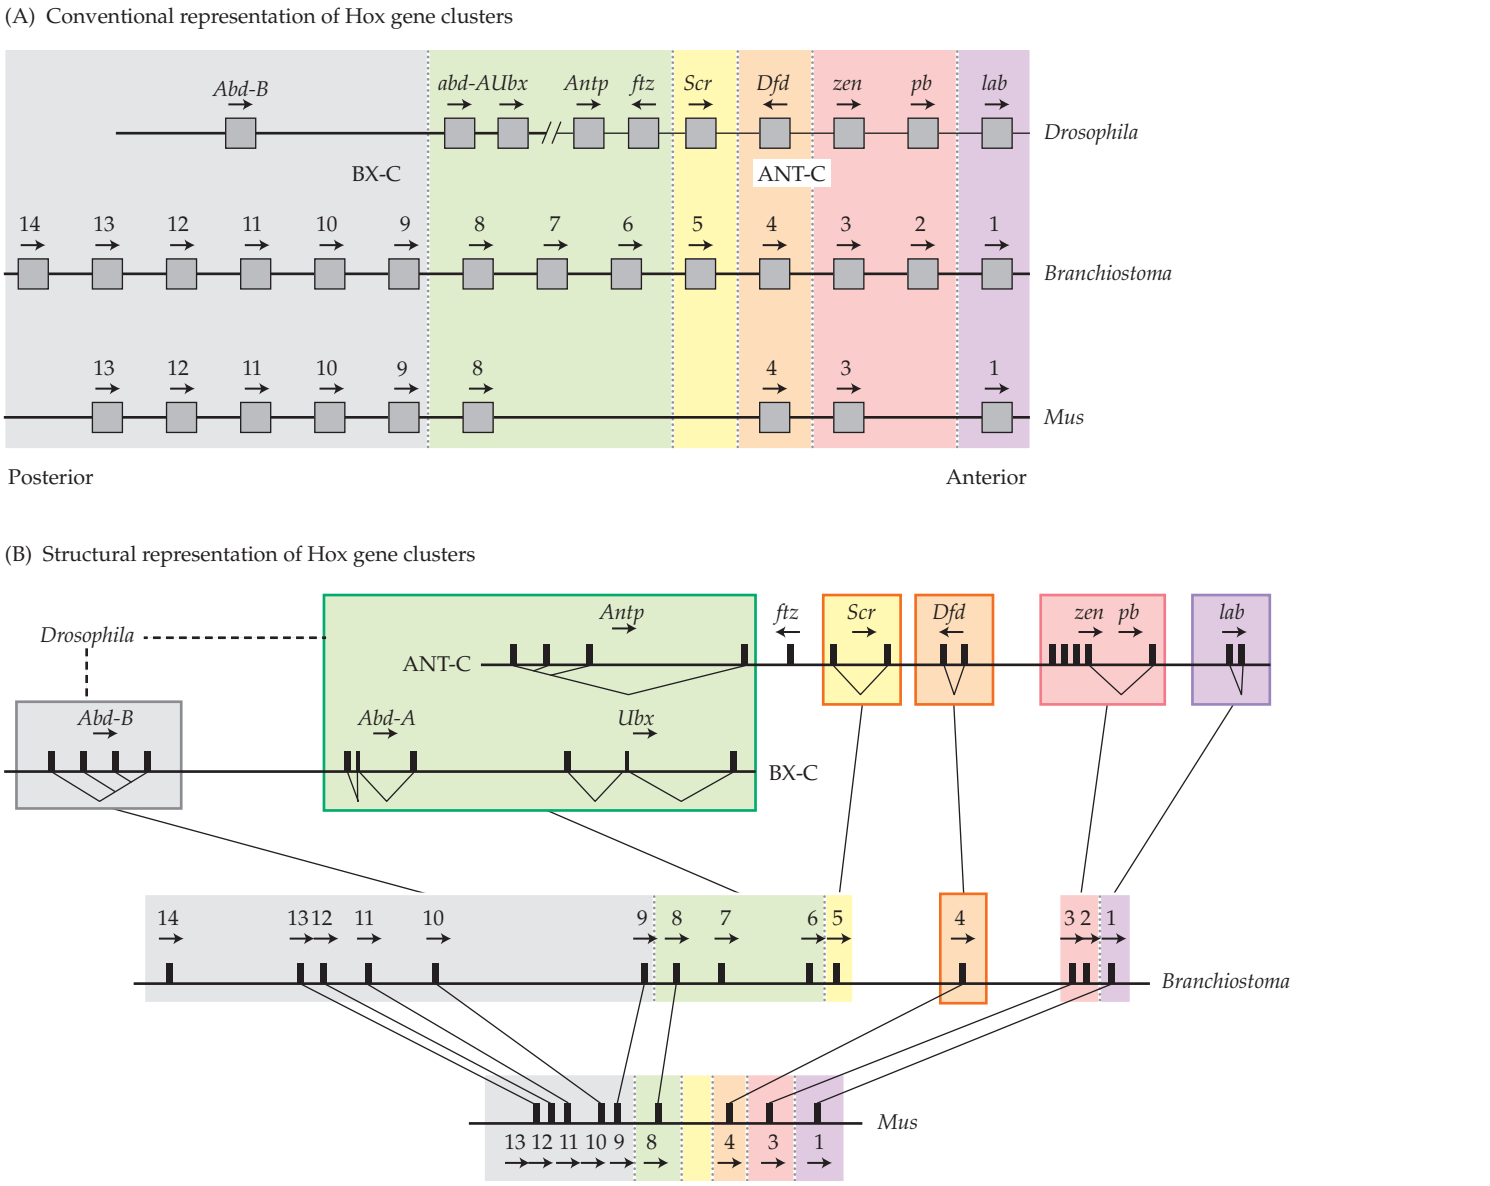

FIGURE 4.1 Representations of Hox genes in textbooks are often oversimplified and thus can lead to erroneous views of metazoan phylogenetic relationships. In this figure, the horizontal lines represent chromosomes. The colored boxes represent Hox gene "clusters," those genes that are related in their sequences and thus appear to be derived from a common ancestral Hox gene, in an insect (*Drosophila melanogaster*), a cephalochordate (amphioxus, *Branchiostoma lanceolatum*), and a vertebrate (mouse, *Mus musculus*). The arrows represent gene orientation, that is, the direction in which transcription of the DNA coding strand proceeds. (A) Hox "clusters" 1 through 14 as they are often represented in textbooks and some scientific articles. In such oversimplified representations, Hox genes, including BX-C (the bithorax complex of *Drosophila* that controls development of abdominal and posterior thoracic segments) and ANT-C (the antennipedia complex of *Drosophila* that controls the formation of legs), are incorrectly shown as being located in close proximity, with clusters that are similar in nucleotide sequence length, and with gene clusters that are arranged in a linear order on chromosomes. (B) A more accurate representation of Hox clusters as they actually exist within *Drosophila*, *Branchiostoma*, and *Mus*, shown to scale with regard to the actual size of the genes (the number of nucleotides involved, including noncoding sequences), the relative distances between the genes (the degree to which genes form "clusters"), and clearer spatial and gene orientation arrangements of Hox elements with respect to one another on the chromosomes. Note that in *Drosophila*, the BX-C and ANT-C complexes are "split" (spatially separated as indicated by the dashed line) on chromosome III, in contrast to the less spatially dispersed arrangements characteristic of chordates (*Branchiostoma* and *Mus*). Note also that while *Drosophila* gene orientations are variable (indicated by arrows), they are consistently unidirectional in *Branchiostoma* and *Mus*. While Hox clusters in chordates (*Branchiostoma* and *Mus*) tend to be more spatially condensed than in other metazoans, they are especially "organized" in this way in vertebrates (e.g., *Mus*). Accurate physical representations of Hox genes are needed to inform the discussion on the structural and functional evolution of Hox clusters.

for more ebook/ testbank solution manuals requests email 960126734@qq.com

cell functions off or on to regulate the timing of particular developmental events; and (4) kernels, complex and tightly conserved gene networks designed to specify the fields of cells from which particular body parts will eventually arise.

Because kernels appear to be the type of network most important for organizing lineage-specific development (e.g., there are likely to be bilaterian, protostome, spiralian, and ecdysozoan kernels), these are considered most likely useful for phylogenetic analyses of the kind originally conceived of for Hox clusters. Nevertheless, it is still possible for gene regulatory networks to undergo substantial evolution within lineages. Thus, as with all such analyses, care must be used in choosing which networks to include.

Eggs and Embryos

The physical (and physiological) attributes that distinguish the Metazoa are the result of their embryonic development. Stated differently, adult phenotypes result from specific sequences of developmental stages. Therefore, both animal unity and diversity are as evident in patterns of development as they are in the body architecture of adults. The patterns of development discussed here reflect this unity and diversity, and serve as a basis for understanding the sections on embryology in later chapters.

Eggs

Biological processes in general are cyclical. Successive generations illustrate this generality, as the term "life cycle" implies, and where the description of a process begins is only a matter of convenience. Here, we begin with the egg, or **ovum**, a single remarkable cell capable of developing into a new individual. Once fertilized, all of the different cell types of an adult animal are derived during embryogenesis from this single totipotent entity. A fertilized ovum contains not only the genetic information necessary to direct development but also some quantity of nutrient material called **yolk**, which sustains the early stages of life. In a few animals, unfertilized eggs can also undergo development through parthenogenesis.

Eggs are polarized along an **animal–vegetal axis**. This polarity may be apparent in the egg itself, or it may be recognizable as development proceeds. The **vegetal pole** is associated with the formation of nutritive organs (e.g., the digestive system), whereas the **animal pole** (often illustrated at the top of the egg) produces other regions of the embryo. Animal ova are categorized primarily by the amount and location of yolk within the cell (Figure 4.2), two factors that greatly influence certain aspects of development. **Isolecithal** eggs contain a relatively small amount of yolk that is more or less evenly distributed throughout the cell. Ova in which the yolk is concentrated at one end (toward the vegetal pole) are termed **telolecithal** eggs; those in which the yolk is concentrated in the center are called **centrolecithal** eggs.

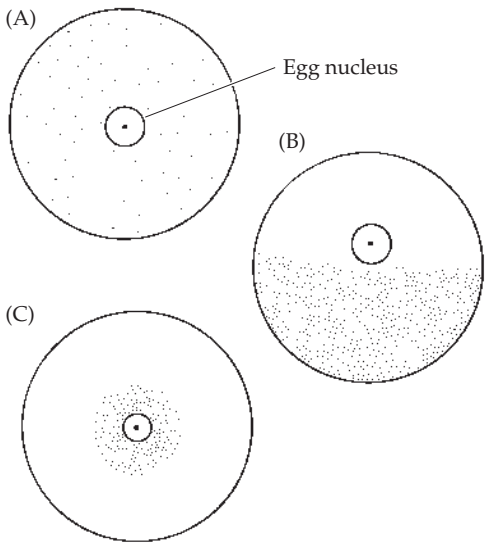

FIGURE 4.2 Types of ova. Stippling denotes the distribution and relative concentration of yolk within the cytoplasm. (A) An isolecithal ovum has a small amount of yolk distributed evenly. (B) The yolk in a telolecithal ovum is concentrated toward the vegetal pole. The amount of yolk in such eggs varies greatly. (C) A centrolecithal ovum has yolk concentrated at the center of the cell.

The actual amount of yolk in telolecithal and centrolecithal eggs is highly variable. Yolk production (**vitellogenesis**) is typically the longest phase of egg production, although its duration varies by orders of magnitude among species. Rates of yolk production depend on the specific vitellogenic mechanism used. In general, opportunistic (so-called *r*-selected) species have evolved vitellogenic pathways for the rapid conversion of food into egg production, while more specialist (so-called *K*-selected) species utilize slower pathways.

Cleavage

The penetration of an ovum by a sperm cell and the subsequent fusion of the male and female nuclei initiate the transformation of an ovum into a **zygote** or fertilized egg. We use the term **cleavage** for the initial cell divisions of a zygote, and the resulting cells are called **blastomeres**. Certain aspects of the pattern of early cleavage are determined by the amount and placement of yolk, whereas other features are inherent in the genetic programming of the particular organism. Isolecithal and weakly to moderately telolecithal ova generally undergo **holoblastic** cleavage. That is, the cleavage planes pass completely through the cell, producing blastomeres that are separated from one another by thin cell membranes (Figure 4.3A).

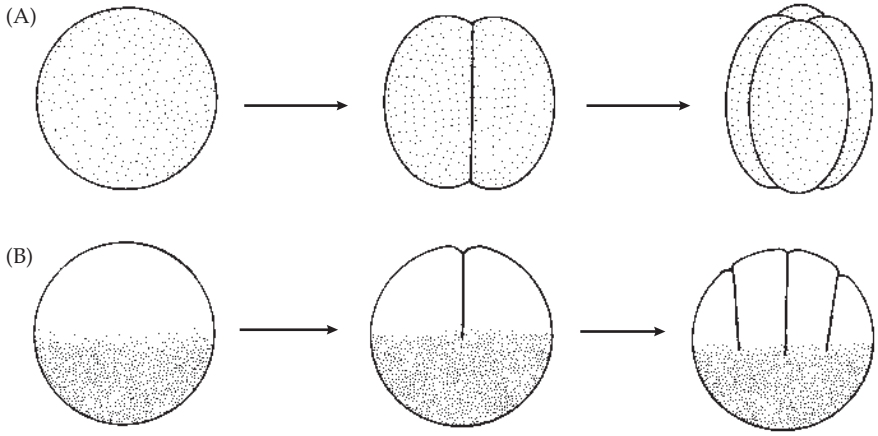

FIGURE 4.3 Types of early cleavage in developing zygotes. (A) Holoblastic cleavage. The cleavage planes pass completely through the cytoplasm. (B) Meroblastic cleavage. The cleavage planes do not pass completely through the yolky cytoplasm. The stippling represents yolk distribution in the egg and early zygote.

Whenever very large amounts of yolk are present (as in strongly telolecithal eggs), the cleavage planes do not pass readily through the dense yolk, so the blastomeres are not fully separated from one another by cell membranes. This pattern of early cell division is called **meroblastic** cleavage (Figure 4.3B). The pattern of cleavage in centrolecithal eggs is dependent on the amount of yolk and varies from holoblastic to various modifications of meroblastic.

Orientation of Cleavage Planes

A number of terms describe the relationship of cleavage planes to the animal–vegetal axis of the egg and the relationships of the resulting blastomeres, one to another (Figure 4.4). Cell divisions during cleavage may be **equal** or **unequal**, indicating the comparative sizes of the resulting groups of blastomeres. The term **subequal** is used when blastomeres are only slightly different in size. When cleavage is distinctly unequal, the larger cells lying at the vegetal pole are called **macromeres.** The smaller cells located at the animal pole are called **micromeres**.

Cleavage planes that pass through or parallel to the animal–vegetal axis produce **longitudinal** (= meridional) divisions; those that pass at right angles to the axis produce **transverse** divisions. Transverse divisions may be equatorial, when the embryo is separated equally into animal and vegetal halves, or simply latitudinal, when the division plane does not pass through the "equator" of the embryo.

Radial and Spiral Cleavage

Most invertebrates display one of two cleavage patterns defined on the basis of the orientation of the blastomeres about the animal–vegetal axis. These patterns are called **radial** cleavage and **spiral** cleavage and are illustrated in Figure 4.5. Radial cleavage involves strictly longitudinal and transverse divisions. Thus, the blastomeres are arranged in rows either parallel or perpendicular to the animal–vegetal axis. The placement

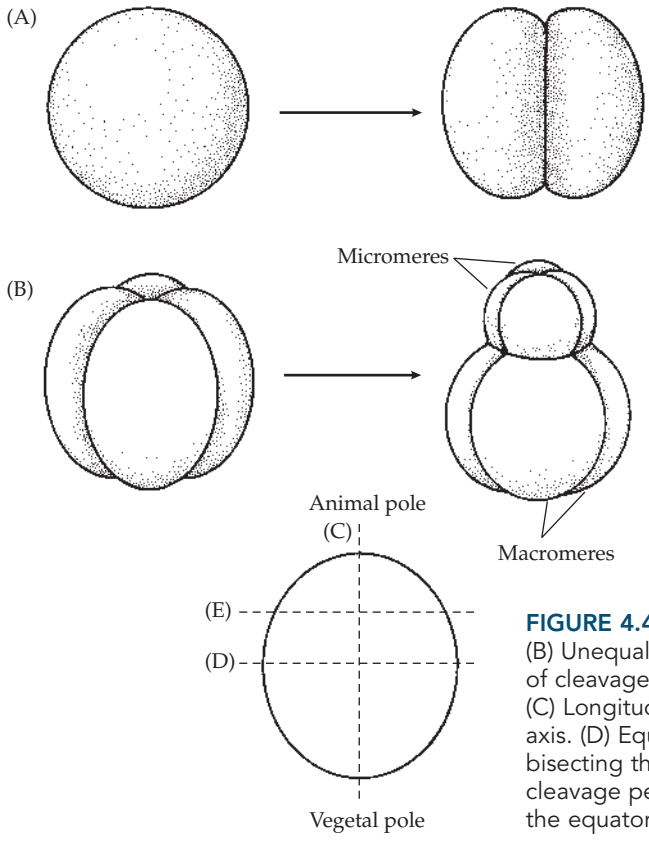

FIGURE 4.4 Planes of holoblastic cleavage. (A) Equal cleavage. (B) Unequal cleavage produces micromeres and macromeres. (C–E) Planes of cleavage relative to the animal–vegetal axis of the egg or zygote. (C) Longitudinal (= meridional) cleavage parallel to the animal–vegetal axis. (D) Equatorial cleavage perpendicular to the animal–vegetal axis and bisecting the zygote into equal animal and vegetal halves. (E) Latitudinal cleavage perpendicular to the animal–vegetal axis but not passing along the equatorial plane.

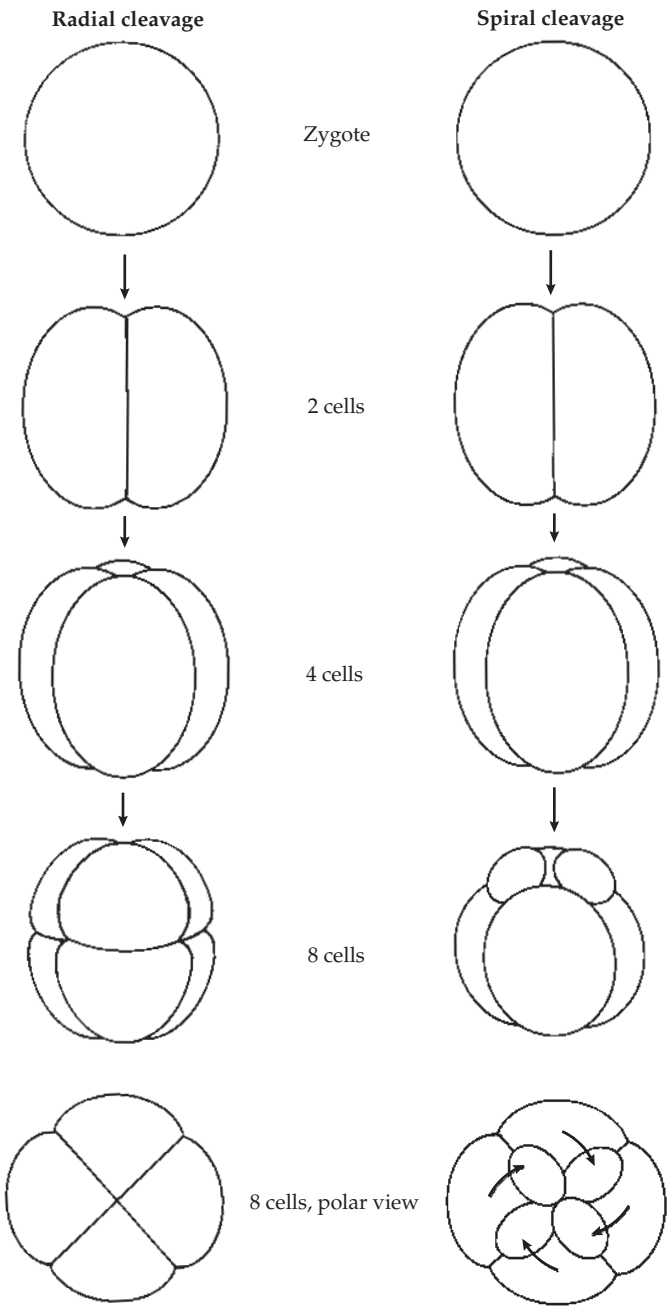

FIGURE 4.5 Comparison of radial versus spiral cleavage through the 8-cell stage. During radial cleavage, the cleavage planes all pass either perpendicular or parallel to the animal–vegetal axis of the embryo. Spiral cleavage involves a tilting of the mitotic spindles, commencing with the division from 4 to 8 cells. The resulting cleavage planes are neither perpendicular nor parallel to the axis. The polar views of the resulting 8-cell stages illustrate the differences in blastomere orientation.

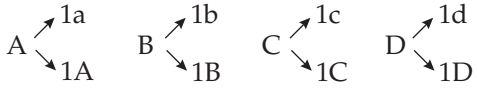
of the blastomeres shows a radially symmetrical pattern in polar view. The chapter opening photo shows the 16-cell-stage embryo of a radially cleaving echinoderm (*Lytechinus pictus*), with 4 large macromeres behind 4 smaller micromeres (and 8 "mesomeres" behind the macromeres).

Spiral cleavage is quite another matter. Although not inherently complex, it can be difficult to describe. The first two divisions are longitudinal, generally equal or subequal. Subsequent divisions, however, displace the blastomeres laterally so that they lie within the furrows between previously divided cells. This condition is a result of the formation of the mitotic spindles at oblique angles rather than parallel to the axis of the embryo; hence the cleavage planes are neither perfectly longitudinal nor perfectly transverse. The division from 4 to 8 cells involves a displacement of the cells near the animal pole in a clockwise (**dextrotropic**) direction (viewed from the animal pole). The next division, from 8 to 16 cells, occurs with a displacement in a counterclockwise (**levotropic**) direction; the next is clockwise, and so on—alternating back and forth until approximately the 64-cell stage. We hasten to add that divisions are frequently not synchronous; not all of the cells divide at the same rate. Thus, a particular embryo may not proceed from 4 cells to 8, to 16, and so on, as neatly as in our generalized description.

During his extensive studies on the polychaete worm *Alitta succinea*, conducted at the Marine Biological Laboratory at Woods Hole, E. B. Wilson established an elegant coding system for spiral cleavage, one that allows us to follow the developmental lineage of every embryonic cell. Wilson's system, published in 1892, is usually applied to spiral cleavage in order to trace cell fates and compare development among species. Our account of spiral cleavage is a general one, but it provides a point of reference for later consideration of the patterns in different groups of animals.

At the 4-cell stage, following the initial longitudinal divisions, the cells are given the codes of A, B, C, and D and are labeled clockwise in that order when viewed from the animal pole (Figure 4.6A). These 4 cells are referred to as a **quartet** of macromeres, and they may be collectively coded as simply Q. The next division is more or less unequal, with the 4 cells nearest the animal pole being displaced in a fashion, as explained previously. These 4 smaller cells are called the first quartet of micromeres (collectively the lq cells) and are given the individual codes of 1a, 1b, 1c, and 1d. The numeral "1" indicates that they are members of the first micromere quartet to be produced; the letters correspond to their respective macromere origins. The capital letters designating the macromeres are now preceded with the numeral "1" to indicate that they have divided once and produced a first micromere set (Figure 4.6B). We may view this 8-celled embryo as four pairs of daughter cells that have been produced by the divisions of the 4 original macromeres as follows:



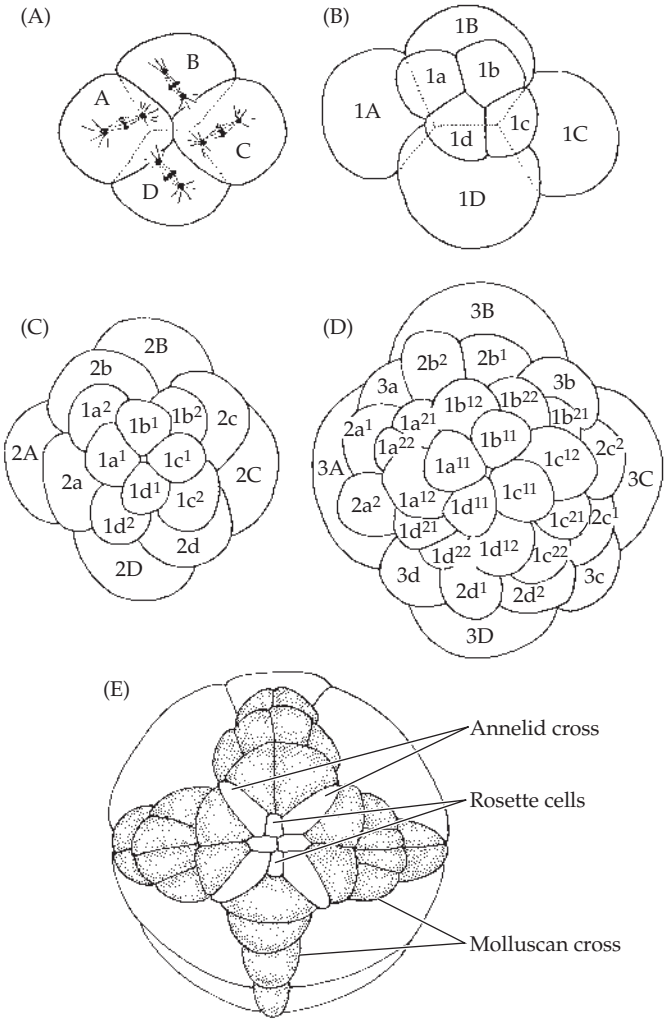


FIGURE 4.6 Spiral cleavage. (A–D) Spiral cleavage through 32 cells (assumed synchronous) labeled with E. B. Wilson's coding system (all diagrams are surface views from the animal pole). (E) Schematic diagram of a composite embryo at approximately 64 cells showing the positions of the rosette, annelid cross, and molluscan cross.

Note that although the macromeres and micromeres are sometimes similar in size, these terms are nonetheless always used in describing spiral cleavage. Much of the size discrepancy depends upon the amount of yolk present at the vegetal pole in the original egg; this yolk tends to be retained primarily in the larger macromeres.

The division from 8 to 16 cells occurs levotropically and involves cleavage of each macromere and micromere. Notice that the only code numbers that are changed through subsequent divisions are the prefix numbers of the macromeres. These are changed to indicate the number of times these individual macromeres have divided and to correspond to the number of micromere quartets thus produced. So at the 8-cell stage, we can designate the existing blastomeres as the 1Q (= 1A, 1B, 1C, 1D) and the lq (= 1a, 1b, 1c, 1d). The macromeres (1Q) divide to produce a second quartet of micromeres (2q = 2a, 2b, 2c, 2d), and the prefix numeral of the daughter macromeres is changed to "2." The first micromere quartet also divides and now comprises 8 cells, each of which is identifiable not only by the letter corresponding to its parent macromere but now by the addition of superscript numerals. For example, the 1a micromere (of the 8-cell embryo) divides to produce two daughter cells coded as $1a^1$ and the $1a^2$ cells. The cell that is physically nearer the animal pole of the embryo receives the superscript "1," the other cell the superscript "2." Thus, the 16-cell stage (Figure 4.6C) includes the following cells:

$$\text{Derivatives of the 1q} \begin{cases} 1a^1 & 1b^1 & 1c^1 & 1d^1 \\ 1a^2 & 1b^2 & 1c^2 & 1d^2 \end{cases}$$

$$\text{Derivatives of the 1Q} \begin{cases} 2q = 2a & 2b & 2c & 2d \\ 2Q = 2A & 2B & 2C & 2D \end{cases}$$

The next division (from 16 to 32 cells) again involves dextrotropic displacement. The third micromere quartet (3q) is formed, the daughter macromeres are now given the prefix "3" (3Q), and all of the 12 existing micromeres divide. Superscripts are added to the derivatives of the first and second micromere quartets according to the rule of position as stated previously. Thus, the $1b^1$ cell divides to yield the $1b^{11}$ and $1b^{12}$ cells; the $1a^2$ cell yields the $1a^{21}$ and $1a^{22}$ cells; the 2c yields the $2c^1$ and $2c^2$, and so on. Do not think of these superscripts as double-digit numbers (i.e., "twenty-one" and "twenty-two"), but rather as two-digit sequences reflecting the precise lineage of each cell ("two-one" and "two-two").

The elegance of Wilson's system is that each code tells the history as well as the position of the cell in the embryo. For instance, the code $1b^{11}$ indicates that the cell is a member (derivative) of the first quartet of micromeres, that its parent macromere is the B cell, that the original 1b micromere has divided twice since its formation, and that this particular cell rests uppermost in the embryo relative to its sister cells. The 32-cell state (Figure 4.6D) is composed of the following:

$$\text{Derivatives of the 1q} \begin{cases} 1a^{11} & 1b^{11} & 1c^{11} & 1d^{11} \\ 1a^{12} & 1b^{12} & 1c^{12} & 1d^{12} \\ 1a^{21} & 1b^{21} & 1c^{21} & 1d^{21} \\ 1a^{22} & 1b^{22} & 1c^{22} & 1d^{22} \end{cases}$$

$$\text{Derivatives of the 2q} \begin{cases} 2a^1 & 2b^1 & 2c^1 & 2d^1 \\ 2a^2 & 2b^2 & 2c^2 & 2d^2 \end{cases}$$

$$\text{Derivatives of the 2Q} \begin{cases} 3q = 3a & 3b & 3c & 3d \\ 3Q = 3A & 3B & 3C & 3D \end{cases}$$

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

The division to 64 cells follows the same pattern, with appropriate coding changes and additions of superscripts. The displacement is levotropic and results in the following cells:

Derivatives of the 1q

$1a^{111}$	$1b^{111}$	$1c^{111}$	$1d^{111}$
$1a^{112}$	$1b^{112}$	$1c^{112}$	$1d^{112}$
$1a^{121}$	$1b^{121}$	$1c^{121}$	$1d^{121}$
$1a^{122}$	$1b^{122}$	$1c^{122}$	$1d^{122}$
$1a^{211}$	$1b^{211}$	$1c^{211}$	$1d^{211}$
$1a^{212}$	$1b^{212}$	$1c^{212}$	$1d^{212}$
$1a^{221}$	$1b^{221}$	$1c^{221}$	$1d^{221}$
$1a^{222}$	$1b^{222}$	$1c^{222}$	$1d^{222}$

Derivatives of the 2q

$2a^{11}$	$2b^{11}$	$2c^{11}$	$2d^{11}$
$2a^{12}$	$2b^{12}$	$2c^{12}$	$2d^{12}$
$2a^{21}$	$2b^{21}$	$2c^{21}$	$2d^{21}$
$2a^{22}$	$2b^{22}$	$2c^{22}$	$2d^{22}$

Derivatives of the 3q

$3a^{1}$	$3b^{1}$	$3c^{1}$	$3d^{1}$
$3a^{2}$	$3b^{2}$	$3c^{2}$	$3d^{2}$

Derivatives of the 3Q

4q =	4a	4b	4c	4d
4Q =	4A	4B	4C	4D

Notice that no two cells share the same code, so exact identification of individual blastomeres and their lineages is always possible. This is not the case with some other types of embryos.

Late in the spiral cleavage of certain animals, distinctive cell patterns appear, formed by the orientation of some of the apical first-quartet micromeres (Figure 4.6E). The topmost cells ($1q^{111}$ micromeres) lie at the embryo's apex and form the **rosette**. In some groups (e.g., annelids), other micromeres ($1q^{112}$ micromeres) produce an **annelid cross** roughly at right angles to the rosette cells. In molluscs, the annelid cross may appear (often called peripheral rosette cells in these groups), but an additional **molluscan cross** forms from the $1q^{12}$ cells and their derivatives. The arms of the molluscan cross lie between the cells of the annelid cross (Figure 4.6E), and this configuration is not known to occur in any other metazoan phylum. Some phylogenetic significance has been given to the appearance of these crosses, as we discuss in later chapters.

Cell Fates

Tracing the fates of cells through development has been a popular and productive endeavor of embryologists for over a century. Such studies have played a major role in allowing researchers to describe development as well as propose homologies among the attributes in different animals. The cells of embryos eventually become established as functional parts of tissues or organs, but before they do, there is much variation in the timing and degree to which cell fates become firmly fixed. Although under normal conditions their functions are specialized, even in adults, the cells of some animals (e.g., sponges) retain the ability to change their structure and function. Other animal taxa have remarkable power to regenerate lost parts or entire bodies, wherein cells dedifferentiate and then generate new tissues and organs. In still other taxa, cell fates are relatively fixed and cells are able only to produce more of their own kind.

Carefully watching the development of any animal makes it clear that certain cells predictably form certain structures. Here too, the emerging field of molecular developmental biology has shown that many molecular components of development are also widely conserved throughout the animal kingdom. For example, some transcription factors and cell signaling systems from widely divergent phyla are clearly homologous and evidently operate in much the same way. On the other hand, these highly conserved molecular components can also be used in diverse ways by embryos. The pattern of orthologous gene expression in early metazoan embryos illustrates both aspects of this relationship. Even such basic developmental features as adult body axis formation and cleavage geometry differ among the metazoan phyla (Figure 4.7). Such fundamental developmental variations appear to have been essential in fabricating the highest levels of animal body plans.

In some cases, cell fates are determined very early during cleavage—as early as the 2- or 4-cell stage. If one experimentally removes a blastomere from the early embryo of such an animal (as Roux did), then that embryo will fail to develop normally; the fates of the cells have already become fixed, and the missing cell cannot be replaced. Animals whose cell fates are established very early are said to have **determinate cleavage**. On the other hand, the blastomeres of some animals can be separated at the 2-cell, 4-cell (as Driesch did), or even later stages (as Spemann did), and each separate cell will develop normally; in these cases the fates of the cells are not fixed until relatively late in development. Such animals are said to have **indeterminate cleavage**. Eggs that undergo determinate cleavage are often called **mosaic ova** because the fates of regions of undivided cells can be mapped. Eggs that undergo indeterminate cleavage are called **regulative ova**, in that they can "regulate" to accommodate lost blastomeres and thus cannot easily be predictably mapped prior to division.

In any case, formation of the basic body plan is generally determined by the time the embryo comprises about 104 cells (usually after one or two days). By this time, all available embryonic material has been apportioned into specific cell groups, or "founder regions." These regions are relatively few, each forming

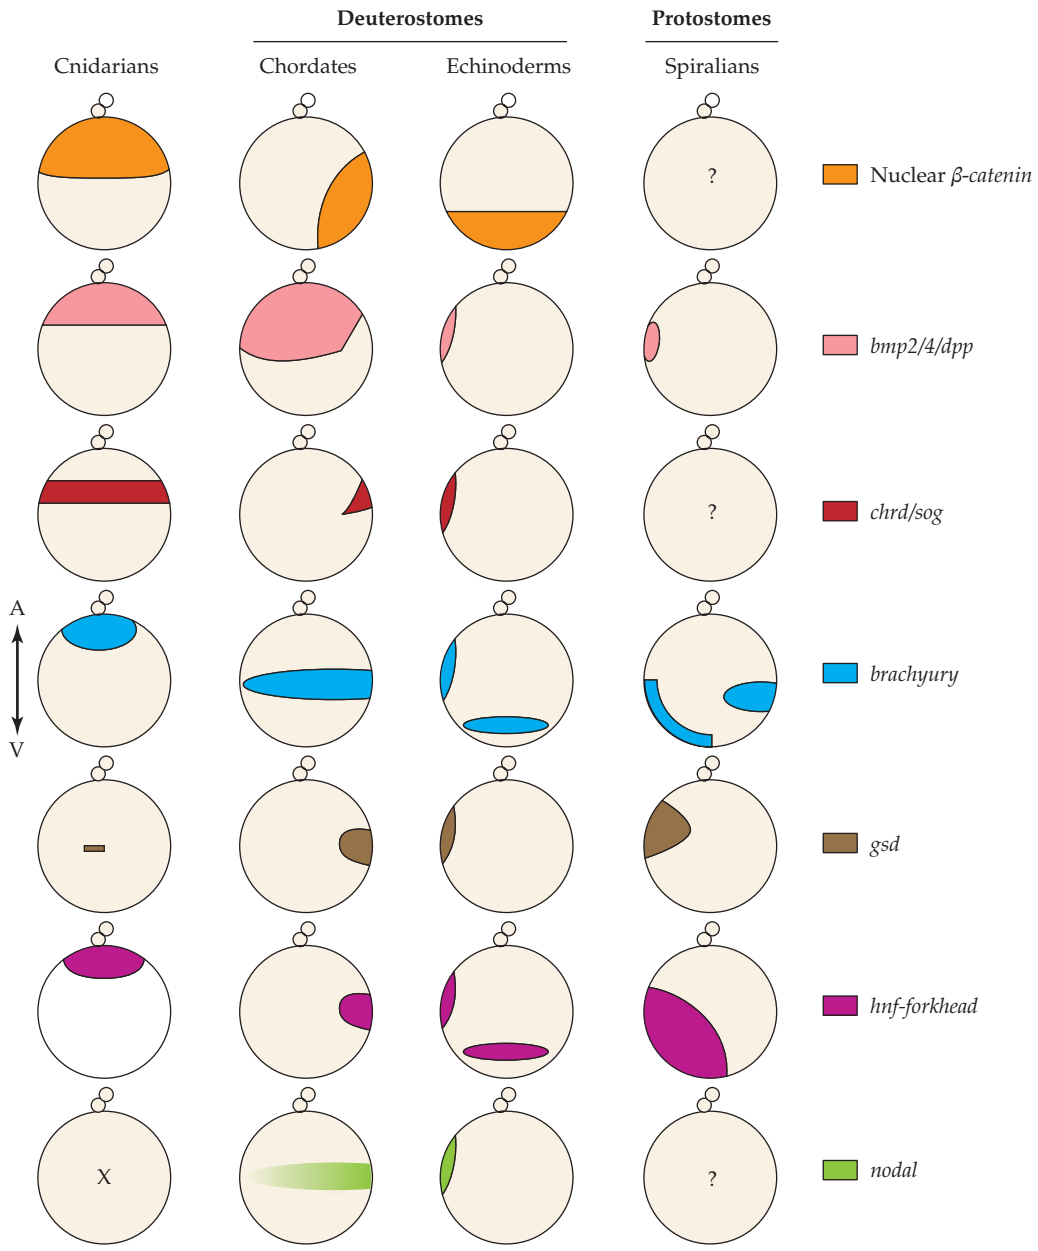

FIGURE 4.7 Locations and patterns of expression in some genes at the beginning of gastrulation in diverse metazoan embryos (cnidarians, chordates, echinoderms, spiralians). A↔V represents the animal–vegetal axis. All but one of the genes shown (*nodal*) are present in cnidarians as well as in chordates. While some genes (e.g., nuclear *β-catenin*) seem to track the changing location of gastrulation across taxa, other genes (e.g., *chordin* [*chrd*] and *goosecoid* [*gsd*] in echinoderms) are associated with gastrulation in some species and disassociated from such activity in others. The two circles at the animal pole represent polar bodies, X indicates that the gene is not present in the genome of a lineage, and ? indicates that the gene has not been recovered in a lineage. Gene abbreviations: *bmp*, bone morphogenetic protein; *dpp*, decapentaplegic; *sog*, short gastrulation; *hnf-forkhead*, hepatocyte nuclear factor, a forkhead homolog. (After M. Q. Martidale. 2005. *Nat Rev Genet* 6: 917–927. https://www.nature.com/articles/nrg1725)

a territory within which still more intricate developmental patterns unfold. As these zones of undifferentiated tissue are established, the unfolding genetic code drives them to develop into their "preassigned" body tissues, organs, or other structures. Graphic representations of these regions are called **fate maps**.

In the past, mosaic eggs and determinate cleavage have been equated with spirally cleaving embryos, and regulative ova and indeterminate cleavage with radially cleaving embryos. However, surprisingly few actual tests for determinacy have been performed, and what evidence is available suggests that there are many exceptions to this generalization. That is, some embryos with radial cleavage appear determinate.

In spite of the variations and exceptions, there is a remarkable underlying consistency in the fates of

for more ebook/ testbank/ solution manuals requests from Animals email 960126734@qq.com

blastomeres among embryos that develop by typical spiral cleavage. Many examples of these similarities are discussed in later chapters, but we illustrate the point by noting that the germ layers of spirally cleaving embryos tend to arise from the same groups of cells. The first three quartets of micromeres and their derivatives give rise to **ectoderm** (the outer germ layer); the 4a, 4b, 4c, and 4Q cells to **endoderm** (the inner germ layer); and the 4d cell to **mesoderm** (the middle germ layer). Many students of embryology view this uniformity of cell fates as strong evidence that taxa sharing this pattern are related to one another in some fundamental way and that they share a common evolutionary heritage. We will have much more to say about this idea throughout this book.

Evo-devo analyses, for their part, provide an objective means for assessing germ layer homology by identifying genes that are transcribed at different developmental times, rather than identifying pools of cells by eventual fate (Figure 4.7). Genes that have proven useful for such analyses include *GATA 4*, *5*, and *6*, genes associated with mucus production in endodermal tissue; *twist*, a gene associated with mesodermal development; *snail*, a repressor of E-cadherin, and thus important for downregulating ectodermal genes within mesoderm and allowing mesenchymal development; and *brachyury*, a gene important in defining the midline of many bilaterians. However, this approach is complicated by the fact that even among closely related taxa, similar structures may be derived from different germ layers (e.g., Malpighian tubules are derived from ectoderm in insects but arise from endoderm in chelicerates). As we have explained, traits used for evolutionary comparative analyses, even at the molecular level, must be selected with caution.

Blastula Types

The product of early cleavage is called the **blastula**, which may be defined developmentally as the embryonic stage preceding the formation of embryonic germ layers. Several types of blastulae are recognized among invertebrates. Holoblastic cleavage generally results in either a hollow or a solid ball of cells. A **coeloblastula** (Figure 4.8A) is a hollow ball of cells, the wall of which is usually one cell layer thick. The space within the sphere of cells is the **blastocoel**, or primary body cavity. A **stereoblastula** (Figure 4.8B) is a solid ball of blastomeres; obviously there is no blastocoel at this stage. Meroblastic cleavage sometimes results in a cap or disc of cells at the animal pole over an uncleaved mass of yolk. This arrangement is appropriately termed a **discoblastula** (Figure 4.8C). Some centrolecithal ova undergo odd cleavage patterns to form a **periblastula**, similar in some respects to a coeloblastula that is centrally filled with noncellular yolk (Figure 4.8D).

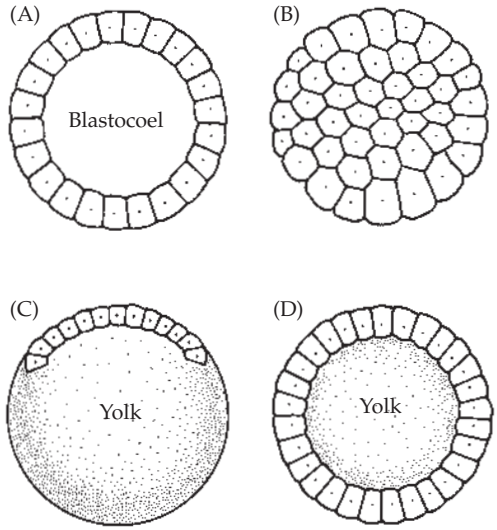

FIGURE 4.8 Types of blastulae. These diagrams represent sections along the animal–vegetal axis. (A) Coeloblastula. The blastomeres form a hollow sphere with a wall one cell layer thick. (B) Stereoblastula. Cleavage results in a solid ball of blastomeres. (C) Discoblastula. Cleavage has produced a cap of blastomeres that lies at the animal pole, above a solid mass of yolk. (D) Periblastula. Blastomeres form a single cell layer enclosing an inner yolky mass.

Gastrulation and Germ Layer Formation

Through one or more of several methods the blastula develops toward a multilayered form, a process called **gastrulation** (Figure 4.9). The structure of the blastula dictates to some degree the nature of the process and the form of the resulting embryo, the **gastrula**. Gastrulation is the formation of the embryonic germ layers, the tissues on which all subsequent development eventually depends. In fact, we may view gastrulation as the embryonic analogue of the transition from protistan to metazoan grades of complexity. It achieves separation of those cells that must interact directly with the environment (i.e., locomotor, sensory, and protective functions) from those that process materials ingested from the environment (i.e., nutritive functions).

The initial inner and outer sheets of cells are the **endoderm** and **ectoderm**, respectively; in most animals a third germ layer, the **mesoderm**, is produced between the ectoderm and the endoderm. One striking example of the unity among the Metazoa is the consistency of the fates of these germ layers. For example, ectoderm always forms the nervous system, the outer skin and its derivatives; endoderm forms the main portion of the gut and associated structures; mesoderm forms the coelomic lining, the circulatory system, most of the internal support structures, and the musculature. The process of gastrulation, then, is a critical one in establishing the basic materials and their locations for building the whole organism.

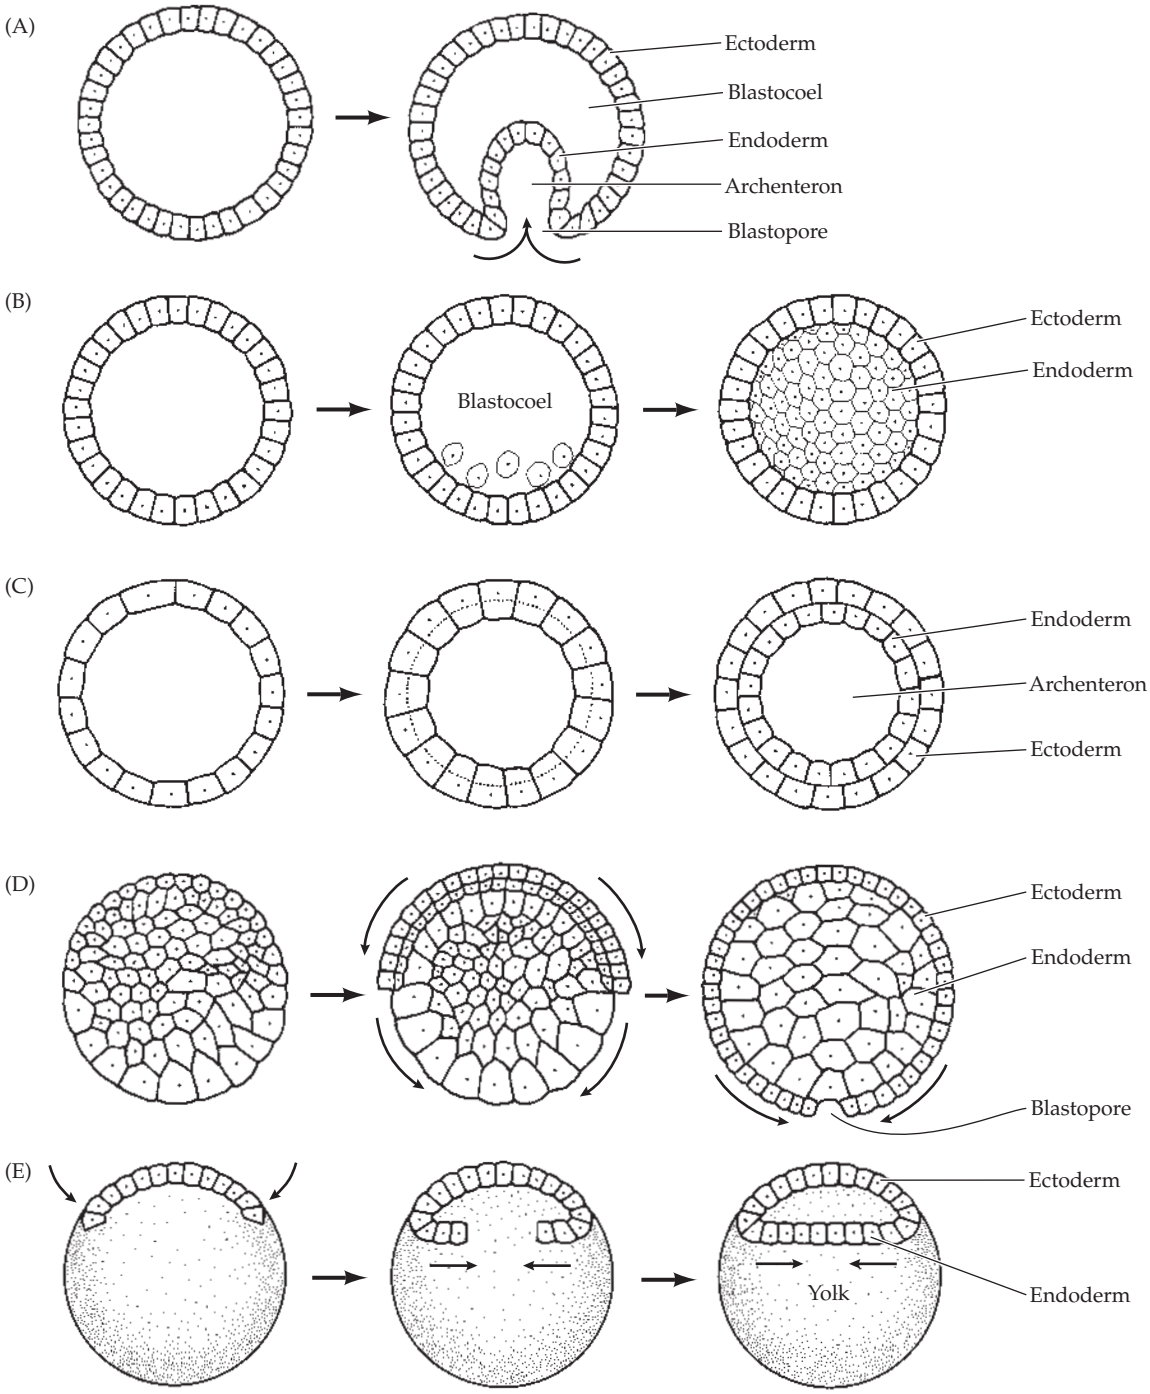

FIGURE 4.9 Forms of gastrulation. (A) Invagination of a coeloblastula to form a coelogastrula. (B) Unipolar ingression of a coeloblastula to form a stereogastrula. (C) Delamination of a coeloblastula to form a double-layered coelogastrula. (D) Epiboly of a stereoblastula to form a stereogastrula. (E) Involution of a discoblastula to form a discogastrula.

Coeloblastulae often gastrulate by **invagination**, a process commonly used to illustrate gastrulation in general zoology classes. The cells in one area of the surface of the blastula (frequently at or near the vegetal pole) pouch inward as a sac within the blastocoel (Figure 4.9A). These invaginated cells are now called the endoderm, and the sac thus formed is the embryonic gut, or **archenteron**; the opening to the outside is the **blastopore**. The outer cells are now called ectoderm, and a double-layered hollow coelogastrula has been formed. The blastopore may become the primordial mouth or anus, depending on the animal lineage. If this structure becomes the mouth, the ectoderm lining the interior of the blastopore is considered **stomodeal**. If the blastopore becomes the anus, the ectoderm lining the interior of this structure is

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

considered **proctodeal**. Note that the diagrams in Figure 4.9 represent cross sections of three-dimensional embryos. Thus, the **coelogastrula** (Figure 4.9A) actually resembles a balloon with an invisible finger poking into it at the vegetal pole.

The coeloblastulae of many cnidarians undergo a gastrulation process that results in a solid gastrula (**stereogastrula**). Usually the cells of the blastula divide such that the cleavage planes are perpendicular to the surface of the embryo. Some of the cells detach from the wall and migrate into the blastocoel, eventually filling it with a solid mass of endoderm. This process is called **ingression** (Figure 4.9B) and may occur only at the vegetal pole (**unipolar** ingression) or more or less over the whole blastula (**multipolar** ingression). In a few instances (e.g., certain hydroids), the cells of the blastula divide with cleavage planes that are parallel to the surface, a process called **delamination** (Figure 4.9C). This process produces a layer or a solid mass of endoderm surrounded by a layer of ectoderm.

Stereoblastulae that result from holoblastic cleavage generally undergo gastrulation by **epiboly**. Because there is no blastocoel into which the presumptive endoderm can migrate by any of the methods mentioned earlier, gastrulation of this form involves a rapid growth by a sheet of presumptive ectodermal cells around the presumptive endoderm (Figure 4.9D). Cells of the animal pole proliferate rapidly, growing down and over the vegetal cells to enclose them as endoderm. The blastopore forms where the edges of this ectodermal sheet converge from all sides upon a single point at the vegetal pole. The archenteron typically forms secondarily as a space within the developed endoderm.

Figure 4.9E illustrates gastrulation by **involution**, a process that usually follows the formation of a discoblastula. The cells around the edge of the disc divide rapidly and grow beneath the disc, thus forming a double-layered gastrula with ectoderm on the surface and endoderm below. There are several other types of gastrulation, mostly variations or combinations of the processes just described. These gastrulation methods are discussed in later chapters.

During gastrulation, subtle shifts in the timing of regulatory gene expression, in the timing of cell fate specification, or in the movement of cells relative to one another can generate distinct developmental pathways. Such developmental divergences may dramatically shift larval or even adult formation within a lineage. For example, sea urchin larvae appear to have switched from **planktotrophy** (feeding larvae) to **lecithotrophy** (nonfeeding larvae) at least 20 times within the history of this echinoderm clade. Among nonfeeding larvae, egg size is often greater, cleavage is significantly altered, and the average larval life span is shorter.

Mesoderm and Body Cavities

During or soon after gastrulation, a middle layer forms between the ectoderm and the endoderm. This middle layer may be derived from ectoderm, as it is in members of the diploblastic phylum Cnidaria, or from endoderm, as it is in members of the triploblastic phyla. In the first case the middle layer is sometimes called **ectomesoderm**, and in the latter case it is called **endomesoderm** (or "true mesoderm"). Thus, the triploblastic condition, by definition, includes endomesoderm. In this text, and most others, the term "mesoderm" in a general sense refers to endomesoderm rather than ectomesoderm. Although endomesoderm is characteristic of triploblastic metazoans, in many lineages some ectomesoderm is also produced.

In diploblastic and certain triploblastic phyla (the acoelomates), the middle layer does not form thin sheets of cells; rather it produces a more-or-less solid but loosely organized mesenchyme consisting of a gel matrix (the **mesoglea**) containing various cellular and fibrous inclusions. In a few cases (e.g., the hydrozoans) a virtually noncellular mesoglea lies between the ectoderm and endoderm (see Chapter 6).

In most animals, the area between the inner and outer body layers includes a fluid-filled space. As discussed in Chapter 3, this space may be either a **blastocoelom**, a cavity not completely lined by mesoderm, or a true **coelom**, a cavity fully enclosed within thin sheets of mesodermally derived tissue. Endomesoderm generally originates in one of two basic ways (Figure 4.10), although modifications of these processes are discussed in later chapters. In most phyla that undergo spiral cleavage (e.g., flatworms, annelids, molluscs), a single micromere—the 4d cell, called the **mesentoblast**—proliferates as mesoderm between the developing archenteron (endoderm) and the body wall (ectoderm) (Figure 4.10A). The other cells of the 4q (the 4a, 4b, and 4c cells) and the 4Q cells generally contribute to endoderm. But exceptions exist, for

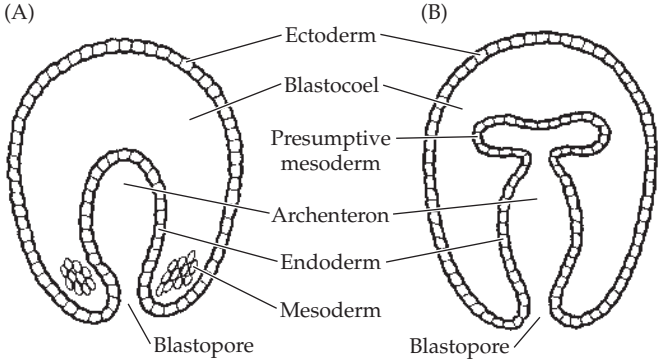

FIGURE 4.10 Methods of mesoderm formation in late gastrulae (frontal sections). (A) Mesoderm formed from derivatives of a mesentoblast. (B) Mesoderm formed by archenteric pouching.

example among the annelids, as in *Capitella teleta*, in which the mesoderm arises from 3c and 3d instead of 4d. In some other taxa (e.g., echinoderms and chordates) the mesoderm arises from the wall of the archenteron itself (i.e., from preformed endoderm), either as a solid sheet or as pouches (Figure 4.11B).

In addition to giving rise to other structures (such as the muscles of the gut and body wall), in coelomate animals mesoderm is intimately associated with the formation of the body cavity. In those instances where mesoderm is produced as solid masses derived from a mesentoblast, the body cavity arises through a process called **schizocoely**. Normally in such cases, bilaterally paired packets of mesoderm gradually enlarge, split internally, and then expand to simultaneously line the body wall, support viscera, and create thin-walled coelomic spaces (Figure 4.11A,B). The number of such paired coeloms varies among different animals and is frequently associated with segmentation, as it is in annelid worms (Figure 4.11C).

The other general method of coelom formation is called **enterocoely**; it accompanies the process of mesoderm formation from the archenteron. In the most direct sort of enterocoely, mesoderm production and coelom formation are one and the same process. Figures 4.10 and 4.12A illustrate this process, which is called **archenteric pouching**. A pouch or pouches form in the gut wall. Each pouch eventually pinches off from the gut as a complete coelomic compartment. The walls of these pouches are defined as mesoderm. In some cases the mesoderm arises from the wall of the archenteron as a solid sheet or plate that later becomes bilayered and hollow (Figure 4.12B). Some authors consider this process to be a form of schizocoely (because of the "splitting" of the mesodermal plate), but it is in fact a modified form of enterocoely. Enterocoely frequently results in a tripartite arrangement of the body cavities, which are designated **protocoel**, **mesocoel**, and **metacoel** (Figure 4.12C).

Following germ tissue establishment, cells begin to specialize and sort themselves out to form the organs and tissues of the body—a poorly understood process known as **morphogenesis**. Cell movements are an essential part of morphogenesis. In addition, in order to sculpt the organs and systems of the body, cells need to "know" when to stop growing and even die. For example, in nematode worms the vas deferens first develops with a closed end; the cell that blocks the end of this tube helps the vas deferens link up to the cloaca. Once the connection has been made, this terminal cell dies and disassociates, creating the opening to the cloaca.

Recent research suggests that the same families of molecules that guide the earliest stages of embryogenesis—setting up the elements of body patterning (Figure 4.7)—also play vital roles during morphogenesis. Communication among adjacent cells is also critical to morphogenesis, and there are three ways cells "talk" to one another during this process, known as **induction**. The first is via diffusible signaling molecules released from one cell and detected by the adjacent cell. These molecules include hormones, growth factors, and special substances called **morphogens**. A second method involves actual contact between the surfaces of adjacent cells, allowing cell surface molecules to interact. Cells selectively recognize other cells, adhering to some and migrating over others. A third method involves the movement of substances through gap junctions between cells. Of all the stages of ontogeny, we know least about morphogenesis.

Life Cycles: Sequences and Strategies

The patterns of early development just described are not isolated sequences of events but are related to the mode of reproduction, the presence or absence of larval stages in the life cycle, and the ecology of the adult. Efforts to classify various invertebrate life cycles and to explain the evolutionary forces that gave rise to them have produced a large number of publications and a great deal of controversy. Most of these studies concern marine invertebrates, on which we center our attention first, and a selection of these are provided in the references for this chapter. We then present some comments on the special adaptations of terrestrial and freshwater forms.

Classification of Life Cycles

Our discussion of life cycles focuses on sexually reproducing animals. Sexual reproduction with some degree of gamete dimorphism is nearly universal among eukaryotes. Male and female gametes may be produced by the same individual (**hermaphroditism**, cosexuality, or in plants, monoecy) or by separate individuals (**gonochory**, or in plants, dioecy). Most terrestrial animals are gonochoristic, but hermaphroditism is widespread among marine invertebrates. Mechanisms of sex determination are diverse; in certain arthropods, females may be diploid and males haploid, a system known as **haplodiploidy**, and in monogonont rotifers, the males are also haploid, derived from an unfertilized egg. Other forms of sex determination involve structurally distinct sex chromosomes. In **male heterogamety**,[1] males carry X and Y sex chromosomes and females are XX, as in some vertebrates. In **female heterogamety**, females are ZW and males ZZ, as seen in many crustaceans. There is typically little or no recombinational exchange between X and Y chromosomes (or between Z and W) because there is almost no genetic homology between the sex chromosomes. Most of the Y (or W) chromosome is devoid of functional gene loci, other than a few RNA genes and some genes required for male (or female) fertility and sex determination. In any event, it is the fusion of male and female gametes that initiates the process of ontogeny and a new cycle in the life history of an organism.

A number of classification schemes for life cycles have been proposed over the past few decades (see papers by Thorson, Mileikovsky, Chia, Strathmann, Jablonsky, Lutz, and McEdward). We have generalized

[1]Not to be confused with heterogamy, the alternation of generations, especially between sexual and parthenogenetic generations.

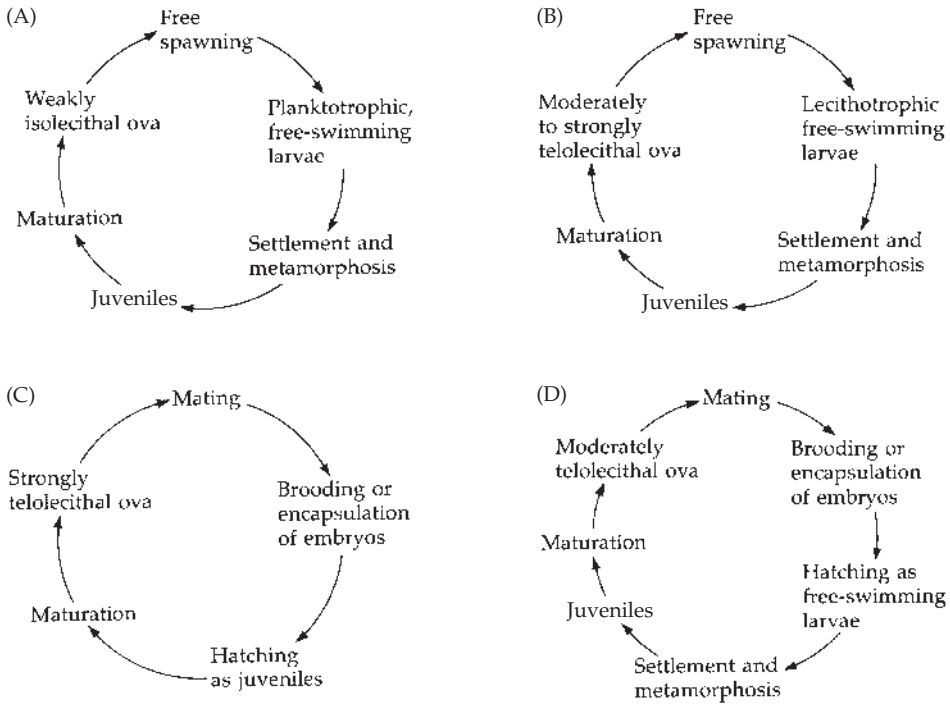

FIGURE 4.13 Some generalized invertebrate life cycle strategies. (A) Indirect development with planktotrophic larvae. (B) Indirect development with lecithotrophic larvae. (C) Direct development. (D) Mixed life cycle. Note that in many marine invertebrates the sperm is broadcast and taken up by the female.

from the works of various authors and suggest that most animals display some form of one of the three following basic patterns (Figure 4.13).

1. **Indirect development** The life cycle includes free spawning of gametes followed by the development of a free larval stage (usually a swimming form), which is distinctly different from the adult and must undergo a more or less drastic metamorphosis to reach the juvenile or young adult stage. The equivalent in terrestrial invertebrates is seen in insects with holometabolous development. In aquatic groups, two basic larval types can be recognized.
   a. Indirect development with **planktotrophic** larvae. The larva survives primarily by feeding, usually on plankton. (The feeding larvae of some deep-sea species are demersal and feed on detrital matter, never swimming very far off the bottom.)
   b. Indirect development with **lecithotrophic** larvae. The larva survives primarily on yolk supplied to the egg by the mother.
2. **Direct development** The life cycle does not include a free larva. In these cases the embryos are often cared for by the parents in one way or another (generally by brooding or encapsulation) until they emerge as juveniles. The equivalent in terrestrial invertebrates is seen in insects with ametabolous or hemimetabolous development.
3. **Mixed development** The life cycle involves brooding or encapsulation of the embryos at early stages of development and subsequent release of free planktotrophic or lecithotrophic larvae. The initial source of nutrition and protection is the adult.

Not every species can be conveniently categorized into just one of these developmental patterns. For example, some species have free larvae that depend on yolk for a time but begin to feed once they develop the ability to do so. Some species actually display different developmental strategies under different environmental conditions—convincing evidence that embryogeny, like so many other aspects of a species or population, is subject to selection pressures and can readily evolve.

These life cycle patterns provoke three basic questions. First, how do different developmental sequences relate to other aspects of reproduction such as egg types and mating or spawning activities? Second, how do overall developmental sequences relate to the survival strategies of larvae and adults? Third, what evolutionary mechanisms are responsible for the patterns seen in any given species? Given the large number of interacting factors to be considered, these are complex questions, and our understanding of them is still incomplete. However, by first examining cases of indirect and direct development, we can illustrate some of the principles that underlie their relationships to different ecological situations. Then we will briefly address some ideas about mixed development.

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

Indirect Development

Consider first a life cycle with planktotrophic larvae (Figure 4.13A). The metabolic expense incurred on the part of the adults involves only the production and release of gametes. Animals with fully indirect development generally do not mate; instead, they shed their eggs and sperm into the water, thus divorcing the adults from any further responsibility of parental care. Such animals typically undergo **synchronous (epidemic) broadcast spawning** of large numbers of gametes, thereby ensuring some level of successful fertilization. This pattern of development is relatively common in opportunistically settling and colonizing (*r*-selected) marine species that make use of tides or ocean currents to disperse their progeny and that are capable of rapid production of high numbers of gametes.

The eggs of animals expressing such traits are usually isolecithal and individually inexpensive to produce. The overall cost—and it is a significant one to each potential parent—is in the production of very large numbers of eggs. Being supplied with little yolk, the embryos must develop quickly into feeding larvae to survive. Mortalities among the embryos and larvae are extremely high and can result from a variety of factors, including lack of food, predation, or adverse environmental conditions. Each successful larva must accumulate enough nutrients from feeding to provide for its immediate survival, as well as for the processes of settling and metamorphosis from larva to juvenile or subadult. That is, it must feed to excess as it prepares for a new lifestyle as a juvenile. Survival rates from zygote to settled juvenile are often less than one percent. Such high mortalities are offset by the initial high production of gametes. But by the same token, high larval mortalities offset the high production of gametes—if all of these zygotes survived, the Earth would quickly be covered by the offspring of animals with indirect development.

What are the advantages and limitations of such a life history, and under what circumstances might it be successful? This sort of planktotrophic development is most common among benthic marine invertebrates in relatively shallow water and the intertidal zones of tropical and warm temperate seas. Here the planktonic food sources are more consistently available (although often in low concentration) than they are in colder or deeper waters, thus reducing the danger of starvation of the larvae. Such **meroplanktonic life cycles** allow animals to take advantage of two distinct resources (plankton in the upper water column as larvae; benthos and bottom plankton as adults). This arrangement reduces or eliminates competition between larvae and adults. Indirect development also provides a mechanism for dispersal, a particularly important benefit to species that are sessile or sedentary as adults. There is good evidence to suggest that animals with free-swimming larvae are likely to recover more quickly from damage to the adult population than those engaging in direct development. A successful set of larvae is a ready-made new population to replace lost adults.

The disadvantages of planktotrophic development result from the unpredictability of larval success. Excessive larval deaths can result in poor recruitment and the possibility of invasion of suitable habitats by competitors. Conversely, unusually high survival rates of larvae can lead to overcrowding and intraspecific competition upon settling.

Animals that produce fully lecithotrophic larvae (Figure 4.13B) must produce yolky and thus more metabolically expensive eggs. This built-in nutrient supply releases the larvae from dependence on environmental food supplies and generally results in reduced mortalities. It is not surprising that these animals produce somewhat fewer ova than those with planktotrophic larvae. The eggs are either spawned directly into the water or are fertilized internally and released as zygotes. Again, the adults' parental responsibility ends with the release of gametes or zygotes into the environment. Although survival rates of lecithotrophic larvae are generally higher than those of planktotrophic types, they are low compared with those of embryos that undergo direct development.

Marine invertebrates that live in relatively deep benthic environments tend to produce lecithotrophic larvae. Here, some of the advantages of indirect development are realized, but larvae do not require environmental food supplies and therefore avoid the intense predation commonly encountered in surface water. The trade-off is clear: in deeper water fewer, more expensive zygotes are produced, but they can survive where more numerous, less expensive planktotrophic larvae cannot.

Settling and Metamorphosis

Of particular importance to the successful completion of animal life cycles with free larval stages are the processes of settlement and metamorphosis. These are crucial and dangerous events in an animal's life cycle because they often require rapid and dramatic changes in individual habitats and lifestyle. Free-swimming larvae usually metamorphose into benthic juveniles, a process that involves the shedding of larval structures and the rapid growth or mobilization of juvenile ones. Surviving this transformation in form and function and adopting a new mode of life, often sessile or more sedentary, require adequate stored resources, appropriate responses to internal and external conditions, and considerable luck.

Throughout their free-swimming lives larvae "prepare" for these events, until they reach a condition in which they are physiologically capable of metamorphosis. Such larvae are termed **competent**. The duration of the free-swimming period varies greatly among

metazoan larvae and depends on factors such as original egg size, yolk content, and the availability of food for planktotrophic forms. Once a larva becomes competent, it generally begins to respond to certain environmental cues that induce settling behavior, a fascinating field of inquiry that includes chemical as well as physical cues, such as the noise of waves in reef environments. Metamorphosis is often preceded by settling, although some species metamorphose prior to settling and still others engage in both processes simultaneously. In any case, larvae typically become negatively phototactic and/or positively geotactic and move toward the bottom to settle. In species that are planktonic both as larvae and as adults (**holoplanktonic species**), the larvae obviously do not settle on the benthos.

Once contact with a substratum is made, a larva tests it, to determine its suitability as a habitat. This act of substratum selection may involve processing physical, chemical, and biological information. A number of studies show that important factors include substratum texture, composition, and particle size; presence of conspecific adults (or dominant competitors); presence of key chemical cues; presence of appropriate food sources; sound; and the nature of bottom currents or turbulence. Contact with the substrate includes risks. Previously settled planktivores and predators are likely to be common in many potentially suitable habitats. Once again, larval mortalities at this stage are high.

Many invertebrate larvae touch down on the bottom for a few minutes, then launch themselves back up into the current again and again until a suitable substratum is found. Assuming an appropriate situation is encountered, metamorphosis is induced and proceeds to completion. Interestingly, some feeding larvae are able to postpone metamorphosis and resume planktonic life if they initially encounter an unsuitable substratum. In such cases, however, the larvae become gradually less selective; eventually, metamorphosis ensues regardless of the availability of a proper substratum. The ability to prolong the larval period until conditions are favorable for settlement has obvious survival advantages, and invertebrates differ greatly in this capability. Those that can postpone settlement may do so by several hours, days, or even months (based on laboratory experiments).

Direct Development

Direct development avoids some of the disadvantages but also misses some of the advantages of indirect development. A typical scenario involves the production of relatively few, very yolky eggs, followed by some sort of mating activity and internal fertilization (Figure 4.13C). The embryos receive prolonged parental care, either directly (by brooding in or on the parent's body) or indirectly (by encapsulation in egg cases provided by the parent). Animals that simply deposit their fertilized eggs, either freely or in capsules, are said to be **oviparous**. A great number of invertebrates as well as some vertebrates (amphibians, many fishes, reptiles, birds, and monotremes) display oviparity. Animals that brood their embryos internally and nourish them directly, such as placental mammals or peracarid crustaceans, are described as **viviparous**. **Ovoviviparous** animals brood their embryos internally but rely on the yolk within the eggs to nourish their developing young. Most internally brooding invertebrates are ovoviviparous, but in velvet worms, in addition to oviparity, multiple types of viviparity are found.

The large, yolky eggs of most invertebrates with direct development are metabolically expensive to produce, and they are a rich source of food for potential predators. But while only a few eggs are possible, the investment is protected though parental effort, and survival rates are relatively high. The dangers of planktonic larval life and metamorphosis are avoided, and the embryos eventually hatch as juveniles.

What sorts of environments and lifestyles might result in selection for such a developmental sequence? At the risk of overgeneralizing, we can say that there is a tendency for specialist (e.g., *K*-selected) species to display direct development. Another situation in which direct development occurs is when the adults have no dispersal problems. We find, for example, that holoplanktonic species with pelagic adults (e.g., arrow worms, phylum Chaetognatha; pelagic gastropods) often undergo direct development, either by brooding or by producing floating egg cases. A second situation is one in which critical environmental factors (e.g., food, temperature, water currents) are highly variable. There is a trend among benthic invertebrates to switch from planktotrophic indirect development to direct development at increasingly higher latitudes. The relatively harsh conditions and strongly seasonal occurrence of planktonic food sources in polar and subpolar areas partially explain this tendency for the high proportion of direct developing (and brooding) species.

In addition to avoiding some of the danger of larval life, direct development has another distinct advantage. The juveniles hatch in suitable habitats where the adults brooded them or deposited the eggs in capsules. Thus, there is a reasonable assurance of appropriate food sources and other environmental factors for the young.

Mixed Development

As defined earlier, mixed life histories involve some period of brooding prior to release of a free larval stage. Costly, yolky zygotes are protected for some time and then are released as larvae, exploiting the advantages of dispersal. This developmental pattern is often ignored when classifying life histories, but in fact it is

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

widespread among gastropods, insects, crustaceans, sponges, cnidarians, and a host of other animal groups. Some workers view mixed development as either the "best" or the "worst" of both worlds (i.e., fully indirect or direct). Others suggest that such sequences are evolutionarily unstable and that local environmental pressures are driving them toward direct or indirect development. There are, however, other possible explanations. It may very well be that under some environmental situations a brooding period followed by a larval phase is adaptive and stable.

Furthermore, at least some species show population variability in the relative lengths of time embryos exist in a brooded versus a free larval phase. If this variability responds to local environmental pressures, then clearly such a species might adapt quickly to changing conditions or even exploit this ability by extending its geographic range to live under a variety of settings. In this regard, mixed life histories may represent **developmental polymorphism**, in which the frequency and intensity of particular environmental cues influence the proportion of the population that expresses or does not express a particular larval phenotype. Such **phenotypic plasticity** in life history expression is an area in need of further investigation.

Our short description of life history strategies certainly does not explain all observable patterns in nature. The historical and evolutionary forces acting on invertebrates (and their larvae) are highly complex. For example, larvae are subject to all manner of oceanographic variables (e.g., diffusion, lateral and vertical transport, sea floor topography, storms) as well as their self-directed vertical movements, seasonality, and biotic factors (predators, prey, competition, nutrient availability). Life history predictions based strictly on environmental conditions do not always hold true. Invertebrates living in the deep sea and at the poles do not always brood (as was once thought), although many echinoderms in Antarctic waters do brood. We now know that all life history strategies occur in these regions, and many deep-sea and polar species release free-swimming larvae, and even planktotrophic larvae. Even some invertebrates of deep-sea hydrothermal vent communities produce free-swimming larvae. In many cases, this may be due to evolutionary constraints: vent gastropods, for example, belong to lineages that are almost strictly lecithotrophic, regardless of latitude or habitat. Thus, vent gastropods are apparently constrained by their phylogenetic histories. Other vent species that release free larvae, however, are not so constrained: mytilid bivalves, for example, possess a wide range of reproductive modes and tend to release planktotrophic larvae in deep-sea and vent environments. Furthermore, reproductive cycles in many abyssal invertebrates appear to be seasonal, perhaps cued by annual variations in surface water productivity. There is still much to be learned.

Adaptations to Land and Fresh Water

The foregoing account of life cycle strategies applies largely to marine invertebrates. Many invertebrates, however, have invaded land or fresh water, and their success in these habitats requires not only adaptation of the adults to special problems, but also adaptation of the developmental forms. As discussed in Chapter 1, terrestrial and freshwater environments are more rigorous and unstable than the sea, and they are generally unsuitable for reproductive strategies that involve free spawning of gametes or the production of delicate larval forms. Most groups of terrestrial and freshwater invertebrates have adopted internal fertilization followed by direct development, while their marine counterparts often exhibit external fertilization and produce free-swimming larvae.

Parasite Life Cycles

The evolutionary success of parasites is clear. Every animal species examined for symbionts appears to provide habitat for at least one, and usually many, associated species. These symbionts often draw benefits from their hosts at their hosts' expense, and thus they are parasites. Most parasites have rather complicated life cycles, and specific examples are given in later chapters. For now, we will examine parasitic lifestyles in a general way to understand their central features and to introduce some basic terminology.

As outlined in Chapter 1, parasites may be classified as **ectoparasites** (living upon the host), **endoparasites** (living internally, within the host), or **mesoparasites** (living in some cavity of the host that opens directly to the outside, such as the oral, nasal, anal, or gill cavities). While associated with a host, a parasite may engage in sexual or asexual reproduction, but the eggs or embryos are usually released to the outside via some avenue from the host's body. The problems at this point are very similar to those encountered during indirect larval development: some mechanism must be provided to ensure adequate survival through the developmental stages, and some sequence of events must bring the parasite back to an appropriate host (the proper "substratum") for maturation and reproduction. As explained earlier, habitat transitions are risky. Thus, many parasites are **parthenogenetic**—a form of reproduction in which the ovum undergoes embryonic development and produces a new individual without fertilization. Parthenogenesis produces offspring that are genetically identical to their parent. Other parasites may be capable of asexual reproduction by way of fission or budding. The production of asexual progeny appears to be one mechanism by which parasites offset the high mortality that attends transitions from one host to the next.

Parasites exploit at least two different habitats in their life cycles. This practice is essential because when hosts die, their parasites usually die with them. Thus,

the developmental period from zygote to adult parasite involves either the invasion of another host, or a free-living period between host invasions. When more than one host species is utilized for the completion of the life cycle, the organism harboring the adult parasite is called the **primary** or **definitive** host. Hosts in which developmental or larval forms reside are called **intermediate** hosts. The completion of complex life cycles often requires elaborate methods of transfer from one host to the other (this could involve more than two hosts), and again, surviving the changes from one habitat to another can be problematic. Losses are routinely high. Thus, we find that many parasites enjoy some of the benefits of indirect development (e.g., dispersal and exploitation of multiple resources) while being subjected to accompanying high mortalities and the dangers of very specialized lifestyles.

We emphasize again that our discussions of life cycles are generalities to which there are many exceptions. But given these basic patterns, you should recognize and appreciate the adaptive significance of life history patterns of the different invertebrate groups discussed later. You might also be able to predict the sorts of sequences that would be likely to occur under different conditions. For example, given a situation in which a particular species is known to produce very high numbers of free-spawned, isolecithal ova, what might you predict about cleavage pattern, blastula and gastrula type, presence or absence of a larval stage, type of larva, adult lifestyle, and ecological settings in which such a sequence would be advantageous? We hope you will develop the habit of asking these kinds of questions and thinking in this way about all aspects of your study of invertebrates.

The Relationships Between Ontogeny and Phylogeny

Of the many fields of study from which we draw information used in phylogenetic investigations, embryology has been one of the most important and productive. The construction of phylogenies may be accomplished and subsequently tested by several different methods (Chapter 2). But regardless of method, one of the principal problems of phylogeny reconstruction—in fact, central to the process—is separating true homologies from similar character traits that are the result of evolutionary convergence. Even when these problems involve comparative adult morphology, one must often seek answers in studies of the development of the organisms and structures in question. The search is for developmental processes or structures that are homologues and thus demonstrate relationships between ancestors and descendants. Changes that take place in developmental stages are not trivial evolutionary events. It has been effectively argued that developmental phenomena may themselves provide the evolutionary mechanisms by which entire new lineages originated (Chapter 1). As Stephen Jay Gould (1977) noted,

> *Evolution is strongly constrained by the conservative nature of embryological programs. Nothing in biology is more complex than the production of an adult . . . from a single fertilized ovum. Nothing much can be changed very radically without discombobulating the embryo.*

Indeed, the persistence of distinctive body plans throughout the history of life is testimony to the resistance to change of complex developmental programs. (See Hall 1996 for an excellent analysis of these issues.)

Although few workers would argue against a significant relationship between ontogeny and phylogeny, the exact nature and extent of the relationship have historically been subjects of considerable controversy, a good deal of which continues today. (Gould 1977 presents a fine analysis of these debates.) Central to much of the controversy is the concept of recapitulation.

The Concept of Recapitulation

In 1866 Ernst Haeckel, a physician who found a higher calling in zoology and never practiced medicine, introduced his **law of recapitulation** (or the **biogenetic law**), most commonly stated as "ontogeny recapitulates phylogeny." Haeckel suggested that a species' embryonic development (ontogeny) reflects the adult forms of that species' evolutionary history (phylogeny). According to Haeckel, this was no accident but a result of a close mechanistic relationship between the two processes: phylogenesis is the actual cause of embryogeny. Restated, animals have an embryogeny *because* of their evolutionary history. Evolutionary change over time has resulted in a continual adding on of morphological stages to the developmental process of organisms. The implications of Haeckel's proposal are immense. Among other things, it means that to trace the phylogeny of an animal, one need only examine its development to find therein a sequential or "chronological" parade of the animal's adult ancestors.

Ideas and disagreement concerning the relationship between ontogeny and phylogeny were by no means new even at Haeckel's time. Over 2,000 years ago Aristotle described a sequence of "souls" or "essences" of increasing quality and complexity through which animals pass in their development. He related these conditions to the adult "souls" of various lower and higher organisms, a notion suggestive of a type of recapitulation.

Descriptive embryology flourished in the nineteenth century, stimulating vigorous controversy regarding the relationship between development and evolution. Many of the leading developmental biologists of the time were in the thick of things, each proposing his own explanation (Meckel 1811; Serres 1824; von Baer 1828; and others). It was Haeckel, however, who really stirred

for more ebook/ testbank/ solution manuals requests from email:901267340@qq.com

the pot with his discourse on the "law" of recapitulation. He offered a focal point around which biologists argued pro or con for 50 years; sporadic skirmishes still erupt periodically. Walter Garstang critically examined the biogenetic law and gave us a different line of thinking. His ideas, presented in 1922, are reflected in many of his poems (published posthumously in 1951). Garstang made clear what a number of other biologists had suggested: evolution must be viewed not as a succession of ancestral adult forms, but as a succession of ontogenies. Each animal is a result of its own developmental processes, and any change in an adult must represent a change in its ontogeny. So what we see in the embryogeny of a particular species are not tiny replicas of its adult ancestors, but rather an evolved pattern of development in which clues or traces of ancestral ontogenies, and thus phylogenetic relationships to other organisms, may be found.

Arguments over these matters did not end with Garstang, and they continue today in many quarters. In general, we tend to agree with the approach (if not all of the details) of Gosta Jägersten in *Evolution of the Metazoan Life Cycle* (1972). Recapitulation per se should not categorically be accepted or dismissed as an "always" or "never" phenomenon. The term must be clearly defined in each case investigated, not locked into Haeckel's original definition and implications. For instance, similar, distinctive, homologous larval types within a group of animals reflect some degree of shared ancestry (e.g., crustacean nauplii or molluscan veligers). And we may speculate on such matters at various taxonomic levels, even when the adults are quite different from one another (e.g., annelids and molluscs are very different but have similar trochophore larvae). These phenomena may be viewed as developmental evidence of relatedness through shared ancestry, and thus they are examples of "recapitulation" in a broad sense.

Jägersten's example of vertebrate gill slits is particularly appropriate because, to him, it provides a case in which Haeckel's strict concept of recapitulation is manifest. In writing of this feature Jägersten (1972) stated:

> *The fact remains . . . that a character which once existed in the adults of the ancestors but was lost in the adults of the descendants is retained in an easily recognizable shape in the embryogenesis of the latter. This is my interpretation of recapitulation (the biogenetic "law").*

Hyman (1940) perhaps put it most reasonably when she wrote:

> *Recapitulation in its narrow Haeckelian sense, as repetition of adult ancestors, is not generally applicable; but ancestral resemblance during ontogeny is a general biological principle. There is no need to quibble over the word recapitulation; either the usage of the word should be altered to include any type of ancestral reminiscence during ontogeny, or some new term should be invented.*

Other authors, however, are not comfortable with such flexibility and have made great efforts to categorize and define the various possible relationships between ontogeny and phylogeny, of which strict recapitulation is considered only one (see especially chapter 7 of Gould 1977). Although much of this material is beyond the scope of this book, we discuss a few commonly used terms here because they bear on topics in later chapters. We have drawn on a number of sources cited in this chapter to mix freely with our own ideas in explaining these concepts.

Heterochrony and Paedomorphosis

When comparing two ontogenies, one often finds that some features appear earlier or later in one sequence than in the other. Such temporal displacement during development is called **heterochrony**. When comparing suspected ancestral and descendant embryogenies, for example, we may find the very rapid (accelerated) development of a particular feature and thus its relatively early appearance in a descendant species or lineage. Conversely, the development of a trait may be slower (retarded) in a descendant than in an ancestor and thus appear later in the descendant's ontogeny. This retardation may be so pronounced that a structure may never develop to more than a rudiment of its ancestral condition. (For excellent reviews of heterochrony and its impact on phylogeny see Gould 1977, and McKinney and McNamara 1991.)

Particular types of heterochrony result in a condition known as **paedomorphosis**, wherein sexually mature adults possess features characteristically found in early developmental stages of related forms (i.e., juvenile or larval features). Paedomorphosis results when adult reproductive structures develop before completion of the development of all the adult nonreproductive (somatic) structures. This condition can result from two different heterochronic processes. These are **neoteny**, in which somatic development is retarded, and **progenesis**, in which reproductive development is accelerated. These two terms are frequently used interchangeably because it is not always possible to know which process has given rise to a particular paedomorphic condition. Recognition of paedomorphosis may play a significant role in examining evolutionary hypotheses concerning the origins of certain lineages. For example, the evolution of precocious sexual maturation of a planktonic larval stage (that would "normally" continue developing to a benthic adult) might result in a new diverging lineage in which the descendants pursue a fully pelagic existence. Such a scenario, for example, may have been responsible for the origin of some small planktonic crustaceans. Paedomorphosis has also played major roles in theories regarding the origin of the vertebrates.

Myriad questions about the role of embryogenesis in evolution and the usefulness of embryology in

constructing and testing phylogenies persist. As the following accounts show, different authors continue to hold a variety of opinions about these matters.

The Origin of the Metazoa

One theme we develop throughout this book is the evolutionary relationships within and among the invertebrate taxa (see Chapters 8 and 28). Life has probably existed on this planet for nearly 4 billion years; humans have been observing it scientifically for only a few thousand years, and evolutionarily for only about 150 years. Thus, the thread of evolutionary continuity we actually see around us today looks a bit like frazzled ends, representing the many successful animal lineages that survive today, but omitting the legions of extinct species and lineages whose identities could provide a clearer understanding of the history of life on Earth. It is only through conjecture, study, inference, and the testing of hypotheses that we are able to trace phylogenetic strands back in time, joining them at various points to produce hypothetical pathways of evolution. We do not operate blindly in this process but use rigorous scientific methodology to draw upon information from many disciplines in attempts to make our evolutionary hypotheses meaningful and (we hope) increasingly closer to the truth—to the actual biotic history of Earth (Chapter 2).

In Chapter 1 we briefly reviewed the history of life, in part inferred from the fossil record, and in Chapter 28 we present a phylogenetic tree of the animal kingdom. However, many workers have not been satisfied to develop phylogenetic analyses based solely upon known (extant and extinct) animal groups but have felt compelled to speculate on hypothetical ancestors that might have occurred along the evolutionary road to modern life. A variety of evolutionary stories have been proposed to describe these sequences of hypothetical metazoan ancestors. We discuss some of these next, and some key works are cited in the references at the end of this book.

Origin of the Metazoan Condition

The origin of the metazoan condition has received attention for more than a century. One of the most spectacular phenomena in the fossil record is the seeming sudden appearance of nearly all of the metazoan phyla living today in a brief span of 30 million years, at the Precambrian–Cambrian transition (approximately 541 million years ago). There is now little doubt that animals—the Metazoa—arose as a monophyletic group from a protist ancestor shared with choanoflagellates 650 million years ago or earlier (Chapter 1). The debates now concern what these first animals were like, what oceanic habitats they inhabited, and how the changes from unicellularity to multicellularity took place.

Historical Perspectives on Metazoan Origins

What intermediate forms might have linked protists and metazoans? Some authors have chosen to design logical but hypothetical creatures for this purpose. Others rummage among extant types, arguing the advantages of using "real" organisms. Although it is probable that the actual precursor of the Metazoa is long extinct, the existence of modern-day forms that combine protist and metazoan traits keeps this debate alive, although it is well established that the closest living relatives are choanoflagellates, ichthyosporeans, and filastereans. Figure 4.14 illustrates some creatures that were once proposed to be "intermediates" between protists and metazoans, even though today we know that many of them are actually derived metazoans (thus illustrating the flaw in nonempirical narratives of "hypothetical ancestor" scenarios).

Before molecular tools convincingly linked protists to metazoan ancestry, several theories of metazoan evolution enjoyed support. In 1892, Johannes Frenzel described one such organism collected from salt pans in Argentina (Figure 4.14F). Tiny *Salinella* possessed a mouth and an anus, fed on organic detritus, and a single layer of cells formed its entire body wall. Although this creature lacked the layered cellular construction of the Metazoa, it displayed a higher level of organization than colonial protists, and the phylum Monoblastozoa was erected for it. Sadly, *Salinella* has not been seen since the original report, and many zoologists, including some who went sampling in the same purported salt pans, suspect that Frenzel seriously misinterpreted whatever creature he saw. Other so-called "mesozoan" phyla, Dicyemida and Orthonectida (Figure 4.14G,H), are also structurally simple, but these animals are endoparasites of invertebrates and have complex life cycles. While possibly resembling early metazoans, their body organization, life cycles, and phylogenetic position have all shown them to be more derived than ancestral.

The **colonial theory** of metazoan evolution was first expressed by Ernst Haeckel (1874), who proposed that a colonial flagellated protist gave rise to a planuloid metazoan ancestor (the planula is the basic larval type of cnidarians; see Chapter 7). The ancestral protist in this theory was a hollow sphere of flagellated cells that developed anterior–posterior locomotor orientation, and specialization of cells into separate somatic and reproductive functions. Similar conditions are common in living colonial protists, including freshwater, colonial, photosynthetic flagellates such as *Volvox* (Figure 4.14A). Haeckel called this hypothetical protometazoan ancestor a **blastea** (Figure 4.15A) and supported its validity by noting the widespread occurrence of coeloblastulae among modern animals.

In Haeckel's scenario, the first Metazoa arose by invagination of the blastea; the resulting animals had a double-layered, gastrula-like body (a **gastrea**) with a

blastopore-like opening to the outside (Figure 4.15B) similar to the gastrulae of many modern animals. Haeckel believed that these ancestral creatures (the blastea and gastrea) were recapitulated in the ontogeny of modern animals, and the gastrea was viewed as the metazoan precursor to the cnidarians. It has been said that the monociliated cells of the body wall of Porifera and Cnidaria support this hypothesis, but other animals, including deuterostomes and gnathostomulids also have monociliated epithelia. Haeckel's original ideas were somewhat modified over the years by various authors (e.g., Elias Metschnikoff, Libbie Hyman). Some have argued that the transition to a layered construction occurred by ingression rather than by invagination and that the original Metazoa were solid, not hollow, based in large part on the view that ingression is the primitive form of gastrulation among cnidarians (Figure 4.15C).

In 1883, Otto Bütschli presented another variant of the colonial theory, a bilaterally symmetrical, flattened creature consisting of two cell layers, which fed by crawling over its food and using its ventral layer as a digestive surface. Bütschli called this creature a **plakula**. In amazing support of the plakula hypothesis, a tiny, flagellated, multicellular creature was discovered in a marine aquarium at the Graz Zoological Institute (Austria) in the late nineteenth century. *Trichoplax adhaerens* was placed in its own phylum, the Placozoa (see Chapter 6), and like Bütschli's plakula has an outer, partly flagellated epithelium surrounding an inner mesenchymal cell mass. Its body margins

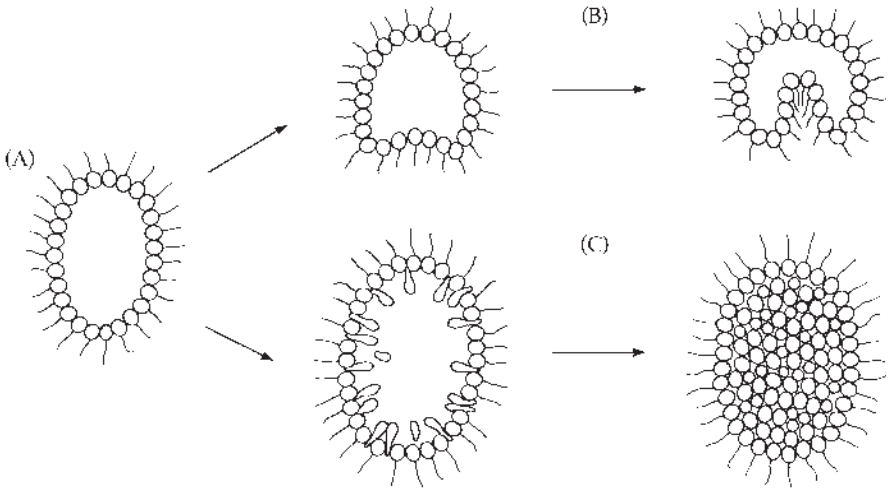

FIGURE 4.15 Two versions of the colonial theory of the origin of the Metazoa. (A) The hypothetical colonial flagellate ancestor, Haeckel's "blastea" (section). (B) According to Haeckel, the transition to a multicellular condition occurred by invagination, a developmental process that resulted in a hollow "gastrea." (C) According to Metschnikoff, the formation of a solid "gastrea" occurred by ingression.

are irregular, its cells show some specialization for somatic and reproductive function, and when feeding, *Trichoplax* "hunches up" to form a temporary digestive chamber on its underside (Figure 4.14E)—producing a form strikingly similar to Bütschli's hypothetical creature. While this hypothesis is compelling, molecular phylogenetic analyses do not place *Trichoplax* at the base of the metazoan tree.

In the 1950s and 60s J. Hadži and E. D. Hanson envisioned the metazoan ancestor as a multinucleate, bilaterally symmetrical, benthic ciliate, crawling about with its oral groove directed toward the substratum. This **syncytial theory** proposed that a cellular epidermis surrounding an inner syncytial mass could form if this creature's surface nuclei partitioned themselves off from one another with cell membranes, producing an acoel wormlike creature. Arguments in support of this hypothesis rested upon similarities between modern ciliates and acoels (Chapter 9), including shape, symmetry, mouth location, surface ciliation, and size; large ciliates are larger than small acoels. However, objections to this hypothesis were more convincing. Acoels undergo complex embryonic development; nothing of this sort occurs in ciliates. Acoel guts are cellular, not syncytial. And molecular phylogenetics has shown acoels to be basal bilaterians, not primitive metazoans. Not surprisingly, the syncytial theory enjoys little support today.

The Origin of Multicellularity

Molecular phylogenetic studies have revealed that multicellularity likely evolved in a dozen or more eukaryotic clades and has led to monophyletic lineages of such disparate groups as plants, animals, several different groups of amoebas, and others. Conditions favoring unicellularity persisted for protists for over 1.5 billion years, by most accounts, until two events occurred. First, atmospheric oxygen of sufficient concentration to support multicellular organization became available due to the activities of photosynthetic algae. Second, predation pressure from heterotrophic protists, capable of phagocytizing or otherwise devouring other unicellular individuals, appears to have favored aggregation of cells after mitosis.

Once a tendency to aggregate arose, there appears to have been competition within individuals for certain functions. If, as appears likely, the first multicellular animals were flagellated, these individuals faced a trade-off between the ability to swim and the ability to engage in mitotic division. The cellular machinery for the two functions appears to compete, as is evidenced even today by the fact that animal cells bearing flagella or cilia never replicate until they have retracted and inactivated their flagellar or ciliary apparatus. In xenacoelomorphs, worn-out ciliated epidermal cells are simply reabsorbed (Chapter 9). A balance may have arisen between the ability to move and the ability to replicate cells, favoring a tendency toward cellular specialization. If selection favored a shift in the location of nonflagellated cells toward the interior of the individual, with flagellated cells remaining outside, further specialization of internal cells may have become possible, necessitating the evolution of layers of cells with flexible ontogenetic fates, as well as biochemical mechanisms that distinguished or allowed particular cellular interactions.

Most evidence today points to the protist phylum Choanoflagellata as the likely ancestral group from which the Metazoa arose. Choanoflagellates possess collar cells essentially identical to those found in sponges. Choanoflagellate genera such as *Proterospongia*, *Sphaeroeca*, and others are animal-like colonial protists (Figure 4.14C,D) and are commonly cited as typifying a potential metazoan precursor. However, some recent molecular evidence suggests that ctenophores, not sponges, lie at the base of the metazoan tree. Clearly, debate on the emergence of Metazoa from

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

their protist ancestor will continue for some time to come (Chapter 28).

The Origin of the Bilateral Condition and the Coelom

We discussed the functional significance of bilaterality briefly in Chapter 3. The evolution of an anterior–posterior body axis, unidirectional movement, and cephalization almost certainly coevolved to some degree, and it probably coincided with the invasion of benthic environments and the development of creeping locomotion. Furthermore, the origin of the triploblastic condition likely took place soon after the appearance of the first bilateral forms. Among modern-day invertebrates, bilaterality and triploblasty generally co-occur.

Various hypotheses concerning the origin of the coelom are summarized in R. B. Clark's fine book *Dynamics in Metazoan Evolution* (1964). Clark's personal approach was a functional one that emphasized the adaptive significance of the coelom as the central criterion for evaluating ideas concerning its origin. When early soft-bodied, bilaterally symmetrical animals larger than a few millimeters assumed a benthic, crawling, or burrowing lifestyle, a fluid (hydrostatic) skeleton was essential for certain types of movement. The evolution of a body cavity filled with fluid against which muscles could operate would have offered a tremendous locomotory advantage in addition to providing a circulatory medium and space for organ development. How might such spaces have originated?

Most of the ideas concerning the evolutionary origin of the coelom were developed from the mid-nineteenth to early twentieth century, during the heyday of comparative embryology. Most of these hypotheses shared the premise of monophyly—that the coelomic condition arose only once. The inherent problem with a monophyletic approach is the difficulty of relating existing coelomate animals to a single common coelomate ancestor. Considering the advantages of possessing a coelom, the very different methods of embryonic development (schizocoely and various forms of enterocoely), and the variety of adult coelomic body plans, it may be more biologically reasonable to suggest that the coelomic condition arose twice. There are several current ideas about how this might have happened, and a number of others have mostly been discarded as being incompatible with existing evidence or with our standard definition of the coelom.

The coelom may have originated by the pinching off and isolation of embryonic gut diverticula, as occurs in the development of many extant enterocoelous animals (Figure 4.16). This so-called **enterocoel theory** (in several versions) enjoyed relatively strong support by many authors since it was originally proposed by Sir E. Ray Lankester in 1877. An obvious point in favor of this general idea is that enterocoely does occur in many living animals, thus retaining the hypothetical ancestral process. In addition, various authors cite examples of noncoelomate animals (anthozoans and flatworms) in which gut diverticula exist in arrangements that resemble possible ancestral patterns.

Another popular idea concerning coelom origin is the **gonocoel theory** (see publications by Bergh, Hatschek, Meyer, Goodrich, and others). This hypothesis suggests that the first coelomic spaces arose by way of mesodermally derived gonadal cavities that persisted subsequent to the release of gametes (Figure 4.17). The serial arrangement of gonads, as seen in animals such as flatworms and nemerteans, could have resulted in serially arranged coelomic spaces and linings such as occurs in annelids, where they often still produce and store gametes. A major argument against this hypothesis is that in no modern-day coelomate animals do gonads develop before coelomic spaces. As we have seen, however, heterochrony can account for such turnabouts.

Another idea on coelom origin is called the **nephrocoel theory** (see publications by Lankester, Ziegler, Faussek, Snodgrass, and others). The association

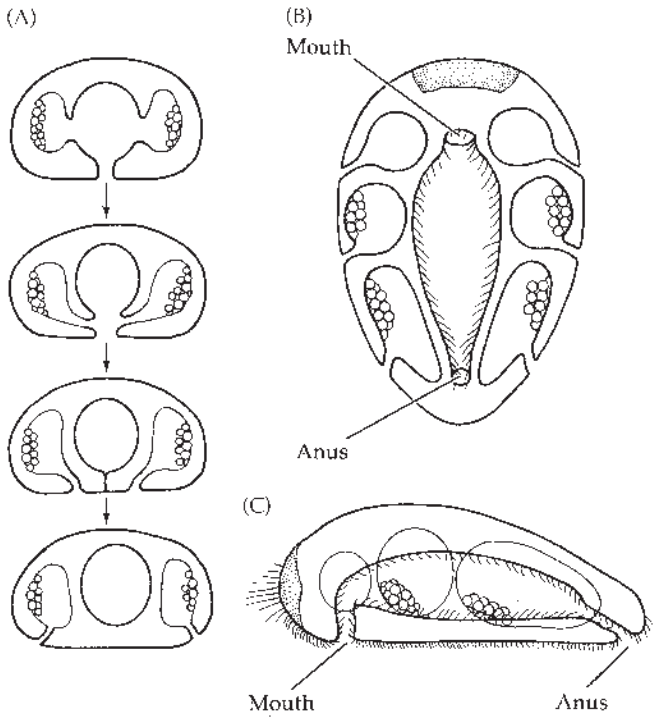

FIGURE 4.16 Jägersten's bilaterogastrea theory, according to which the coelomic compartments arise by enterocoelic pouching. (A) The formation of paired coeloms from the wall of the archenteron. The slitlike blastopore of the bilaterogastrea closes midventrally, leaving mouth and anus at opposite ends (B). (B,C) The tripartite coelomic condition in Jägersten's hypothetical early coelomate animal (ventral and lateral views).

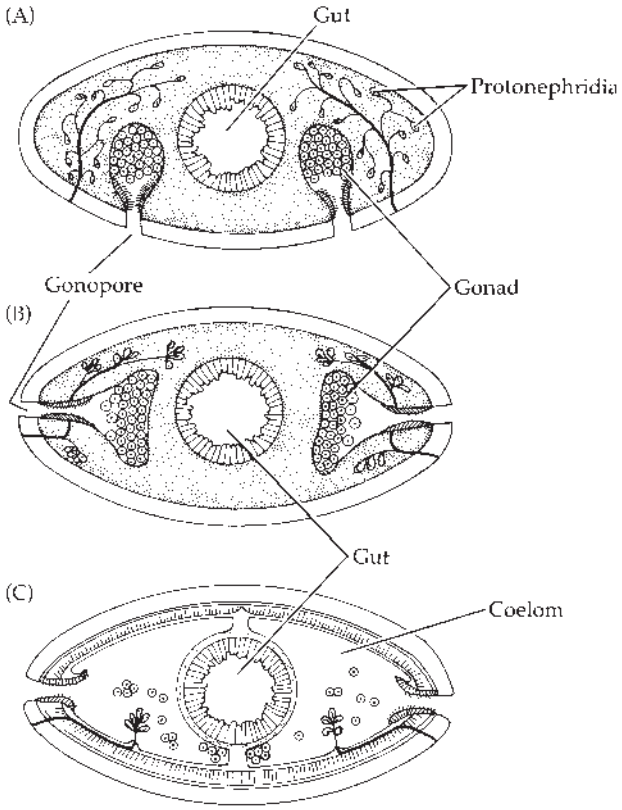

FIGURE 4.17 A version of the gonocoel theory (schematic cross sections). (A) The condition in flatworms, which have mesodermally derived gonads leading to ventral gonopores. (B) The condition in nemerteans, which have serially arranged gonadal masses leading to laterally placed gonopores. (C) The condition in polychaetes, in which the linings of the gonads have expanded to produce coelomic spaces with coelomoducts to the outside.

between the coelom and excretion has prompted different versions of this hypothesis over the years. One idea is that the protonephridia of flatworms expanded to coelomic cavities, arguing that the coelom first arose from ectodermally derived structures. Another view is that coelomic spaces arose as cavities within the mesoderm and served as storage areas for waste products. Certainly the coelomic cavities of many animals are related to excretory functions, but there is no convincing evidence that this relationship was the primary selective force in the origin of the coelomate condition.

Clark (1964) speculated that schizocoely, as we know it today, could have evolved by the formation of spaces within the solid mesoderm of acoelomate animals and then have been retained in response to the positive selection for the resulting hydrostatic skeleton. This is a very straightforward view, in part because, like the enterocoel theory, it accommodates a real developmental process.

As we mentioned earlier, these hypotheses share the fundamental constraint of arguing a monophyletic origin to all coelomate animals. The basic developmental differences between the two great clades of coelomate animals (the Protostomia and the Deuterostomia) suggest that the coelom may have arisen separately in these two lineages. Given the strong similarities between the coelomate Protostomia and acoelomorph worms, it is easy to envision the protostome clade arising from a triploblastic acoelomate ancestor. Hollowing of the mesoderm in such a precursor to produce fluid-filled hydrostatic spaces can be easily explained both developmentally (modern-day schizocoely) and functionally (peristaltic burrowing, increased size, and so on).

To derive the Deuterostomia and Protostomia from an immediate coelomate ancestor creates a complicated scenario. The simplest hypothesis might be to view the deuterostome ancestor as a diploblastic animal, perhaps a planuloid form, in which enterocoely occurred. Deriving the Deuterostomia separately from the evolution of spiral cleavage and the other features of protostomes avoids many of the complications inherent in a monophyletic view of coelom origin. Imagine a hollow, invaginated, gastrula-like metazoan swimming with its blastopore trailing, as do the planula larvae of some cnidarians. Enterocoely may have accompanied a tendency toward benthic life, giving the animal a peristaltic burrowing ability. The archenteron may have then opened anteriorly as a mouth, with the new coelomate creature adopting a deposit-feeding lifestyle. If such a story began at the level of diploblastic Metazoa (e.g., cnidarians), then the radial cleavage seen today in the Bilateria was also present in the ancestor to that group.

The Trochaea Theory

The Danish zoologist Claus Nielsen has envisioned the two major bilaterian clades, Protostomia and Deuterostomia, arising from an ancient common ancestor that conforms to Haeckel's radially symmetrical gastrea. Nielsen's theory proposes that Protostomia arose by way of at least two hypothetical ancestral forms, called the **trochaea** and the **gastroneuron**. The deuterostome line was originally believed to have led to the Deuterostomia by way of a hypothetical **notoneuron** ancestor. (The names "gastroneuron" and "notoneuron" referred to the ventral versus dorsal positions of the major nerve cords in most protostomes and deuterostomes, respectively.)

The theory provided a scenario of the evolution of the ancestral Protostomia, which possessed a trochophore larva and a ventral nervous system. The early ancestor in this model was a holopelagic planktotrophic gastraea with a ring of compound cilia (the **archaeotroch**) around the blastopore, which was used in swimming and particle collection by the downstream method (Figure 4.18A). It was presumed that after settling, the adult form of this animal would creep on the bottom, collecting detritus, using monociliated cells around the blastopore. An anterior–posterior axis evolved along with

the establishment of a creeping lifestyle. Transport of food particles into and out of the archenteron may have become enhanced by compression of the lateral blastopore lips, which were fused in the adult, leaving an anterior mouth and a posterior anus (i.e., a through gut). This fusion of the blastopore lips may soon have become established in the larval stage. The archaeotroch was lost in the creeping adult but retained in the pelagic larva.

The anterior part of the archaeotroch around the mouth could have become laterally extended, with the anterior region becoming the **prototroch** and the posterior region the **metatroch**, bordering a lateral extension of the perioral ciliary area, the **adoral ciliary zone** (Figure 4.18B). Over evolutionary time, this may have created the characteristic trochophore ciliary feeding and swimming structures seen in modern protostomes, wherein the posterior part of the archaeotroch became the **telotroch**. The ciliary bands of the trochophores rely on downstream ciliary feeding, in which the larvae capture food particles from the water on the downstream side of the ciliary feeding bands, and these particles then are transported to the mouth by the adoral ciliary band. The lateral blastopore closure may have resulted in a differentiation of a circumblastoporal ring nerve into an anterior loop around the mouth, the paired (or secondarily fused) ventral nerve cords, and a small loop around the anus (in both the trochophore larva and the adult). The brain of the trochophore and the adult ancestor consisted of the anterior-most part of the perioral nerve loop and a new paired structure, the large cerebral ganglion developing from the **episphere** of the larva, that is, from the area in front of the prototroch.

Owing to the realization that Deuterostomia have the neural tube morphologically ventral, and that deuterostomy occurs in several phyla of Protostomia, Nielsen has revised his views on the origin of the former, and in the latest version of his theory the gastroneuron is seen as the latest common ancestor of *all* bilaterians.

Closing Thoughts

As you can see, when one attempts to describe hypothetical ancestors, evolutionary analysis at the level of phyla can be convoluted and problematical. Many different viewpoints of the same phenomena will inevitably arise. We trust, however, that you have gained some insights into the particular hypotheses discussed here. A fundamental caveat should be kept in mind: any number of evolutionary pathways can be proposed and made to appear convincing on paper by imagining appropriate hypothetical ancestors or intermediates, but one must always ask whether these marvelous hypothetical creatures would have worked as functional organisms and whether rigorous phylogenetic

analyses support the hypotheses. Clark (1964: p. 258) spends a good deal of time on this point and emphasizes it in his conclusion with the following passage:

> *The most important and least considered of these [principles] is that hypothetical constructs which represent ancestral, generalized forms of modern groups, or stem forms from which several modern phyla diverge, must be possible animals. In other words, they must be conceived as living organisms, obeying the same principles that we have discovered in existing animals.*

In such terms, evolutionary hypotheses can be evaluated. From a phylogenetic point of view, it may be best to avoid initial speculation on what a hypothetical ancestor might have looked like and to instead rely on the analysis of known taxa to establish genealogical relationships or branching patterns. Once a tree has been constructed, the pattern of features associated with the taxa on the tree will themselves predict the nature (character combination) of the ancestor for each branch. This method attempts to avoid the potential problem of circular reasoning, in which a hypothetical ancestor is established first and hence constrains and foretells the nature of the taxa descended from it. In either case, for the hypotheses to be truly scientific, they must be testable with new data gathered outside the framework of that used in their initial formulation.

Chapter Summary

This chapter introduced you to some fundamental aspects of invertebrate development and life history and to the role these fields have played in understanding animal evolution. Many discussions on invertebrate biology and evolution have relied on these data and biological patterns since the earliest days of embryology, and today the field of evo-devo has integrated key components, taking a step forward toward the goal of connecting genotype to phenotype. Fundamental concepts of evo-devo and embryology presented in this chapter will help you better understand the origin of mesoderm and body cavities in metazoans, as well as the anatomical features that have long been central to discussions of animal relationships. You have learned that there are several types of animal life cycles, including direct development, indirect development (with metamorphosis), and complex parasitic life cycles that may include multiple hosts and habitats (marine, freshwater, terrestrial), and about the evolutionary consequences of adopting one or another lifestyle. Finally, we explored some theories related to animal evolution and the putative connection between ontogeny and phylogeny, concluding with a brief discussion on the origin of metazoans and some key aspects relevant to animal phylogeny.

CHAPTER 5

Phylum Porifera

The Sponges

Chapters 1 through 4 provide a detailed introduction to the animal kingdom, Metazoa, or Animalia. Metazoans are a clade (monophyletic group) of eukaryotes, those creatures whose cells contain membrane-enclosed organelles and have a membrane-enclosed nucleus. However, animals differ from other eukaryotes (i.e., fungi, plants, and the myriad protist clades) in their combination of multicellularity, heterotrophic and ingestive nutrition, and unique style of tissue formation through embryonic germ layering. Thus, **metazoans are heterotrophic multicellular eukaryotes that undergo embryogenesis by way of tissue layering.** Metazoan synapomorphies include: gastrulation; unique modes of oogenesis and spermatogenesis; a unique sperm structure; mitochondrial gene reduction; epidermal epithelia with septate, tight, or zonula adherens junctions; striate myofibrils; actin-myosin contractile elements; type IV collagen; and the presence of a basal lamina or basement membrane beneath epidermal layers (of course, some of these features have been secondarily lost in a few groups). The formation of embryonic germ layers takes place through a process called gastrulation, and even the primitive living metazoans (e.g., sponges) undergo this process. Gastrulation is a process that achieves separation of those cells that must interact directly with the environment (e.g., locomotor, sensory, and protective functions) from those that process materials obtained from the environment (e.g., nutritive functions). Evidence is strong that Metazoa share a common ancestor with the choanoflagellate protists.

However, despite these fundamental shared similarities, there are four phyla of Metazoa that are so ancient and possess such a simple body construction that their relationships to other animals continue to

challenge us—these are the four nonbilaterian phyla: Cnidaria, Ctenophora, Placozoa, and Porifera. Porifera, the sponges, are covered in this chapter, the other three in the following chapters. In addition to lacking bilateral symmetry, these four phyla lack true mesoderm development. The current consensus of phylogenetic analyses suggests that either Porifera or Ctenophora are the first offshoot of all living animal phyla.

Phylum Porifera: The Sponges

The phylum Porifera (Latin *porus*, "pore"; *ferre*, "to bear") comprises those odd but fascinating animals called sponges. At first glance, sponges may seem difficult to reconcile within the animal kingdom—adults lack a gut, muscles, nerves and conventional neuronal signaling systems, typical metazoan organs, gap junctions between cells, an obvious anterior–posterior polarity (except in larvae), and some of the key metazoan developmental genes, such as a ParaHox cluster. In addition, they have cross-striated ciliary rootlets in larval cells and choanocytes—a feature characteristic of many protists. However, they do possess the metazoan-defining attributes of multicellularity derived by embryonic layering, specialized junctions between cells, actin-myosin contractile elements, and type IV collagen. In addition, recent genomic analyses of species spanning the four extant classes of Porifera reveal the presence of certain homeobox genes and representatives of most higher metazoan molecules involved in cell–cell communication, signaling pathways, postsynaptic processes, complex "sealing" epithelia (impermeable or selectively permeable and regulating epithelia), reproduction, and immune recognition. Sponges also undergo typical animal-like sexual reproduction and the development of embryos through a structured series of cellular divisions (cell cleavages) that result in a spatially organized larva with multiple cell layers and sensory capabilities. Most larvae have an obvious anterior–posterior polarity, and many adult sponges possess an apical–basal polarity, defined by the presence of a large osculum at one end (although the positions of oscula are often dictated purely by hydrodynamic forces in the environment). Others show such polarity by virtue of their pedunculate or pinnate growth form, often even with stems/stalks and rootlike structures. Molecular genetic analyses indicate Porifera is monophyletic and clearly within Metazoa. In fact, sponge genes have been recently discovered that are implicated in regulating anterior–posterior polarity and specifying particular tissues during the development of other basal metazoans, supporting the contention that sponges undergo true gastrulation during embryogenesis. Figures 5.1 and 5.2 illustrate a variety of sponge body forms and some sponge anatomy. Box 5A lists the major characteristics of sponges.

Sponges are sessile, primarily suspension-feeding, multicellular animals that utilize flagellated cells called choanocytes to circulate water through a unique system of water canals. Most rely on an internal skeleton of calcium carbonate or silicon dioxide spicules to support their body, which can be quite large. It was long thought that Porifera lacked distinct embryological germ layering that leads to definable tissues, a condition sometimes referred to as "the parazoan grade of body construction." However, we now know that sponges undergo distinct gastrulation events from which the adult tissues derive, and the old concept of "Parazoa" is finally laid to rest. However, some of the adult tissues in sponges are somewhat transmutable and not fixed, due to a degree of cellular pluripotency—most cells are capable of changing form (although pinacocytes and sclerocytes cannot do so), and two cellular lineages are kept in a totipotent state to be recruited "on demand" (archaeocytes and choanocytes). So, despite the fact that sponges are large-bodied multicellular animals typically supported by an internal skeleton of spicules or stiffened collagen (spongin), in some ways they function like organisms at the unicellular grade of complexity. In fact, as you will discover in this chapter, their nutrition, gas exchange, and response to environmental stimuli are

BOX 5A Characteristics of the Phylum Porifera

1. Metazoans partly at the cellular grade of construction, with simple tissues, but with a high degree of cellular pluripotency; adults asymmetrical or with a distinct apical–basal polarity (often superficially appearing as radially symmetrical); larvae usually have anterior–posterior polarity
2. Cells have adherens junctions in some species, but no gap junctions
3. Individuals have unique flagellated cells—choanocytes—that drive water through canals and chambers constituting the aquiferous system
4. Adults are sessile and typically suspension feeders; larval stages are motile and usually lecithotrophic
5. Type IV collagen basement membranes occur in most Homoscleromorpha and also (to a lesser extent) in the other classes
6. Middle layer—the mesohyl—is variable but always includes motile cells and usually some skeletal material
7. Skeletal elements, when present, composed of calcium carbonate or silicon dioxide (typically in the form of spicules) and/or collagen fibers
8. Neurons do not occur; the only true sense organ is the osculum, which utilizes primary cilia to detect water flow rates
9. Ciliated cells of adult sponges bear only a single cilium (largely lacking the rootlet system seen in other metazoans); some larvae have cilia that have rootlet systems; some larvae have bi-ciliated cells on the surface (postulated by some workers to be products of defective cell division)

all very protistlike. So, superficially, sponges might be viewed as tight consortiums of semiautonomous cells, and thus quite simple animals. But, appearances can be deceiving. Read on.

Despite their seeming simplicity, sponges have experimented with various aspects of higher metazoan body organization, and they have developed relatively simple tissues, a sparse basement membrane, in some species even predatory behaviors, and other features typical of the higher Metazoa. Some might argue that poriferans are "caught between two worlds"—the world of protists and the world of higher metazoans—while others would argue they are metazoans in every sense of the word.

(H) *Tethya aurantium*, close-up showing oscula protected by long spicules. (I,J) Tree sponges! Freshwater sponges from all three New World families occur in the rivers of the Amazon Basin—shown here is *Drulia* (?) that lives 5–10 m above the dry-season low-water line (when these photos were taken). (K) The freshwater *Spongilla* (Minnesota, USA). (L) The massive calcareous base of a coralline sponge. (M) A red poecilosclerid sponge growing on the back of a decorator crab makes it nearly invisible (Bounty Islands, New Zealand). (N–P) Hexactinellida. (N) Three specimens of deep-sea glass sponges (from the eastern Pacific) with silica rope stalks. (O) *Euplectella aspergillum* (Venus's flower basket). (P) Close-up of *Euplectella* skeleton showing arrangement of spicule bundles.

One of the most remarkable attributes of sponges is their tendency to maintain symbiotic relationships with a variety of heterotrophic and autotrophic Bacteria, Archaea, Protista, and even some other Metazoa. Some of these intimate relationships have developed to the point that, in some sponges, more biomass is actually contributed by the symbiont than by the sponge, and in these species microscopic examination of the sponge reveals mostly cells of microbes! We are just beginning to explore this community hidden within sponges, but already hundreds of symbiotic species, in over a dozen bacterial and archaean phyla (and several protistan groups), have been documented. As the role of microorganisms in sponges begins to be better understood, the emerging evidence suggests strong mutualism in many cases. Sponges of different types, in different ocean basins, seem to host strikingly similar microbial communities, suggesting the symbiotic relationships are very old. And some of these microbes appear to be transported in the eggs, nurse cells, and even sperm of sponges.

Sponges produce the largest and most diverse storehouse of secondary metabolites of any animal phylum—compounds that function to deter predators, prevent fouling of the sponge's surface, screen ultraviolet radiation, and nurture their symbiotic partnerships. Some sponges even "walk" over rocks, using lobelike extensions of the body that grow and elongate and then disappear, sometimes leaving separate living pieces—progeny—in their wake. At least one lineage of sponges, possibly more, has taken a dramatic evolutionary turn and become predatory carnivores; instead of filter feeding, these magnificent creatures capture and engulf small prey that are caught on highly specialized Velcro-like surfaces formed by spicules. Well over 150 species of carnivorous sponges have been described, mainly in the deep-sea family Cladorhizidae (Poecilosclerida) and two other small families.

Nearly 9,300 living species of sponges have been described, all but about 220 (the freshwater species) being restricted to benthic marine environments. Freshwater species occur at all latitudes, from deserts to equatorial rainforests, and from sea level to alpine lakes and even subterranean habitats. About 60 new sponge species are described each year, and it has been estimated that less than half of the living species have so far been described. Sponges occur at all depths but are most abundant in unpolluted littoral and tropical reef habitats, cold temperate continental shelf regions, and Antarctic seas. However, deep-water "sponge grounds" are also important components of deep-sea ecosystems. Most littoral sponges grow as thick or thin layers, or as erect structures, on hard surfaces. Sponges that live on soft substrata typically are upright and tall or possess funnel-like structures on top of a buried basal body, thus avoiding burial by the shifting sediments of their environment.

Some sponges reach considerable size (up to 2 m in height on Caribbean reefs, and even larger in Antarctica and the deep sea) and may constitute a significant portion of the benthic structure and biomass. In Antarctic seas, sponges can make up almost 75% of the total benthic biomass at depths of 100–200 m. Areas of the deep Antarctic shelf have been called "sponge kingdoms," and here over 300 species have been recorded with high biomass and density. Subtidal and deeper water species that do not confront strong tidal currents or surge are often large and exhibit a stable, even symmetrical (radial), external form. The deeper water hexactinellid sponges often assume unusual shapes, many being delicate glasslike structures, others round and massive, and still others growing in a ropelike fashion. Siliceous sponge reefs have been documented from several periods in Earth history, and they culminated in the Late Jurassic when they formed a discontinuous deep-water reef belt extending more than 7,000 km. This reef system was the largest biotic structure ever built on Earth (at 2,000 km, the Great Barrier Reef of Australia is relatively small compared with the Jurassic sponge reef belt).

Sponges display nearly every color imaginable, including bright lavenders, blues, yellows, crimsons, and pure white, and some are even iridescent. In many species it is the symbiotic bacteria or algae that give color to their host's body, especially in the tropics. And sponges are the only phylum of animals that predominantly utilize silica, rather than calcium carbonate, in their mineral skeleton (in Demospongiae, Homoscleromorpha, and Hexactinellida). In one of the four classes of sponges, Calcarea, the skeleton is composed not of siliceous spicules, but of calcium carbonate spicules (although a few species in other sponge classes are known to secrete a firm calcium carbonate base, upon which the siliceous skeleton rests).

Taxonomic History and Classification

The sessile nature of sponges, and their often amorphous or asymmetrical growth form convinced early naturalists that they were plants. It was not until 1765,

when the nature of their internal water currents was described, that sponges were recognized as animals. The great naturalists of the late eighteenth and early nineteenth centuries (e.g., Jean-Baptiste Lamarck, Carolus Linnaeus, Georges Cuvier) classified sponges under Zoophytes or Polypes, regarding them as allied to anthozoan cnidarians. Throughout much of the nineteenth century they were placed with cnidarians under the name Coelenterata or Radiata. The morphology and physiology of sponges were first adequately understood by Robert E. Grant. Grant created for them the name Porifera, although other names were frequently used (e.g., Spongida, Spongiae, Spongiaria).

Historically, the classes of Porifera have been defined by the nature of their internal skeletons. Until recently, three classes of sponges had long been recognized: Calcarea, Hexactinellida, Demospongiae. For a couple of decades (1970–1990) some workers proposed another class, Sclerospongiae, which included those species that produce a solid, calcareous, rocklike matrix (in addition to the spicular skeleton) on which the living animal grows. Over a dozen species of living sclerosponges, also known as coralline sponges, have been described. Late in the twentieth century, ultrastructural work and DNA analyses showed that the class Sclerospongiae was actually a polyphyletic grouping, and it was thus abandoned, its members relegated to the Calcarea and Demospongiae. Today, the "coralline sponges" are known to be the last survivors of otherwise extinct stromatoporids, sphinctozoans, and chaetetids—ancient reef-building sponges that were highly diversified in Paleozoic and Mesozoic seas. These ancient coralline sponges were probably among the first metazoans to produce a carbonate skeleton. In 2010, the distinctive nature of the Homoscleromorpha (formerly included within the Demospongiae) was seen to merit elevating this group to class status, thus establishing a fourth class of living Porifera.

Demospongiae is the largest sponge class, comprising 81% of the living species. Because of its size and morphological variability, the class Demospongiae presents the greatest number of problems for taxonomists. The only synapomorphy that distinguishes the class Demospongiae is the presence of a spongin-based skeleton, and yet not all species of demosponges possess this feature. For many years, spongiologists followed the classification of C. Lévi, who created two subclasses of demosponges based upon reproductive modes, Tetractinomorpha and Ceractinomorpha. However, by the turn of the century these were widely recognized as polyphyletic, and reproductive modes were recognized as highly labile. In the early twenty-first century, molecular phylogenetics showed both that the class is monophyletic (exclusive of Homoscleromorpha) and that it can be divided into three distinct subclasses, as noted in the following classification.

Although the mainstay of sponge taxonomy has traditionally been the chemical composition, shape, ornamentation, dimensions, and localization of the spicules, additional kinds of information, including secondary metabolite chemistry, and more notably molecular systematics are now being used to develop phylogenetic hypotheses and higher classifications. Indeed, some sponge species lack spicules altogether (e.g., *Oscarella, Hexadella, Halisarca*), whereas many spicule types appear to be homoplastic among sponges (e.g., asters, acanthostyles, sigmata). Sponge specialists also are now using embryological, biochemical, histological, and cytological methods to diagnose and analyze the Porifera. In the past, the considerable difficulty in precisely setting the limits of some sponge species made poriferan taxonomy challenging. Sponges are famous for their paucity of reliable taxonomic characters, and even the great sponge taxonomist Arthur Dendy was known to frequently end a species diagnosis with a question mark.[1]

Since the advent of molecular phylogenetics, the fascinating world of poriferology has grown more tractable, and modern systematics is beginning to build a robust framework for the phylum. In addition to resolving long-standing phylogenetic questions, molecular work has led to the discovery that many "cosmopolitan species" are, in fact, clusters of closely related but distinct species. In addition, since the 1970s important bioactive compounds have been discovered in sponges, many having potential pharmacological significance (e.g., antibacterial, antiviral, anti-inflammatory, antitumor, and cytotoxic compounds, as well as channel blockers and antifouling chemicals). The discovery of these natural products in sponges also has led to a renewed interest in the group.

CLASSIFICATION OF PHYLUM PORIFERA

CLASS CALCAREA Calcareous sponges (Figure 5.1A–C). Spicules of mineral skeleton composed entirely of calcium carbonate laid down as calcite, secreted extracellularly within a collagenous sheath (but with no axial filament); skeletal elements often not differentiated into megascleres and microscleres; spicules usually 1-, 3-, or 4-rayed; body with asconoid, syconoid, leuconoid, or the newly discovered sylleibid and solenoid constructions; many species exhibit superficial radial symmetry around a long axis, but in most there is no visible axial symmetry; early cleavage total and equal; embryonic cleavage patterns probably fundamentally radial; all studied species are viviparous. All marine; occurring at all latitudes; 793 described species. Their microbiome is only starting to be unveiled, with predominance of Proteobacteria and the archaeal

[1]The term a "sleeze" of sponges was coined by Ristau (1978) to describe an aggregation of sponges; the usage is comparable to other such collective nouns that define animal groups (e.g., flock, herd, gaggle).

group Thaumarcheota. Although embryogenesis and larval morphology of the two subclasses differ profoundly, molecular phylogenetics provides evidence that the class and both subclasses are monophyletic.

SUBCLASS CALCINEA Free-living larva is hollow, flagellated "coeloblastula" (calciblastula); choanocyte nuclei located basally, and flagellum arises independent of nucleus (a presumptive synapomorphy of this subclass); with free, regular, triradiate spicules (e.g., *Clathrina*, *Dendya*, *Leucascus*, *Leucetta*, *Soleneiscus*, the coralline genus *Murrayona*).

SUBCLASS CALCARONEA Free-living larva is a unique, partly flagellated amphiblastula, typically forming by way of eversion of earlier stomoblastula "prelarva" (which is held internally)—a presumptive synapomorphy of this subclass; choanocyte nuclei apical, and flagellum arises directly from nucleus; spicules free or fused (e.g., *Amphoriscus*, *Grantia*, *Leucilla*, *Leucosolenia*, *Sycon*, the coralline genus *Petrobiona*).

CLASS HEXACTINELLIDA Glass sponges (Figure 5.1N–P). Skeleton composed of a large array of siliceous spicules of various shapes and sizes, secreted intracellularly around a square proteinaceous axial filament; spicules with fundamental 3-axon or 6-rayed symmetry (triaxonic); both megascleres and microscleres always present. Entire sponge formed by a single continuous syncytial tissue, the trabecular reticulum, which stretches from the outside or dermal membrane to the inside or atrial membrane, enclosing the cellular components of the animal. Body wall cavernous, filled primarily with a trabecular syncytium, connected via open and plugged cytoplasmic bridges to choanosome, with its flagellated chambers; external pinacoderm absent and replaced by a noncellular dermal membrane; choanosome with anucleate choanocytes embedded in a trabecular syncytium. All studied species are viviparous; some produce a unique hexactinellid larva, the trichimella. Long-lived, exclusively marine, usually vase- or tube-shaped (never encrusting), primarily deep-water sponges (maximum diversity is at 300 to 600 m depth); 682 described species. Many species harbor Archaea-dominated microbial communities within their bodies. The hexactinellid body plan is perhaps the most unusual in the entire animal kingdom because nearly all the tissues in adults consist of a giant multinucleated syncytium that forms the inner and outer layers of the sponge, joined by cytoplasmic bridges to limited uninucleate cellular regions. Two subclasses that are both monophyletic.

SUBCLASS AMPHIDISCOPHORA Body anchored in soft sediments by a basal tuft or tufts of spicules; megascleres are discrete spicules, never fused into a rigid network; with birotulate microscleres, never hexasters (e.g., *Hyalonema*, *Monorhaphis*, *Pheronema*).

SUBCLASS HEXASTEROPHORA Usually attached to hard substrata, but sometimes attached to sediments by a basal spicule tuft or mat; microscleres are hexasters; megascleres free, or can be fused into a rigid skeletal framework, in which case sponge may assume large and elaborate morphology (e.g., *Aphrocallistes*, *Caulophacus*, *Euplectella*, *Hexactinella*, *Leptophragmella*, *Lophocalyx*, *Rosella*, *Sympagella*).

CLASS DEMOSPONGIAE Demosponges (Figure 5.1D–M). With siliceous spicules and/or an organic skeleton (or, occasionally, with neither) or, in some groups, a solid calcitic skeleton; spicules secreted intra- or extracellularly around a triangular or hexagonal axial filament; spicules never 6-rayed (i.e., not triaxons); organic skeleton a collagenous network ("spongin"); most produce parenchymella larvae (see Figure 5.18); ancestrally viviparous, ovipary developed in several taxa of the subclasses Verongimorpha and Heteroscleromorpha; marine, brackish, or freshwater sponges occurring at all depths. Many species exhibit a mesohyl community of Eubacteria, mainly Proteobacteria and gram-positive bacteria, as well as species of Archaea. About 7,400 described species. The two subclasses Tetractinomorpha and Ceractinomorpha, long recognized as polyphyletic, have recently been abandoned, and three subclasses are now recognized. Molecular analyses to date support the monophyly of these new subclasses, although not all have been uniquely defined morphologically.

SUBCLASS KERATOSA Skeleton of spongin fibers only, or with a hypercalcified skeleton (*Vaceletia*). Spongin fibers either homogenous or pithed, and strongly laminated with pith grading into bark. Reproduction typically viviparous, larvae are parenchymella. All commercial sponges belong to this subclass (e.g., *Spongia*, *Hippospongia*, *Coscinoderma*, *Rhopaleoides*). Includes two orders: Dendroceratida (Darwinellidae: e.g., *Aplysilla*, *Darwinella*, *Dendrilla*; Dictyodendrillidae: e.g., *Dictyodendrilla*, *Spongionella*) and Dictyoceratida (Spongiidae: e.g., *Spongia*, *Hippospongia*, *Rhopaleoides*; Thorectidae: *Cacospongia*; *Thorecta*, *Phyllospongia*, *Carteriospongia*; Irciniidae: e.g., *Ircinia*, *Sarcotragus*; Dysideidae: e.g., *Dysidea*, *Pleraplysilla*; Verticillitidae: *Vaceletia*).

SUBCLASS VERONGIMORPHA Without a skeleton or with skeleton of spongin fibers only (with a laminated bark and finely fibrillar or granular pith); one genus with skeleton of siliceous asters (*Chondrilla*). All demosponges lacking a skeleton belong to this subclass (e.g., *Chondrosia, Halisarca, Hexadella, Thymosiopsis*). Reproduction oviparous. Two or three orders are now recognized (e.g., *Aplysina, Aplysinella, Chondrosia, Chondrilla, Halisarca, Hexadella, Ianthella, Suberea, Thymosia, Thymosiopsis, Verongula*).

SUBCLASS HETEROSCLEROMORPHA Skeleton composed of siliceous spicules that can be monaxons and/or tetraxons and, when present, highly diversified microscleres. Reproduction mostly viviparous, but oviparous species occur in some genera (e.g., *Agelas, Axinella, Raspailia, Suberites*). This subclass contains most of the Demospongiae (over 5,000 species), usually organized into 14 orders. Most of the sponges

once assigned to Sclerospongiae are in this subclass, including stromatoporoids (e.g., *Astrosclera*), tabulates (*Acanthochaetetes*, *Merlia*), and ceratoporellids (e.g., *Ceratoporella*, *Goreauiella*, *Hispidopetra*, and *Stromatospongia*). The order Tetractinellida includes all sponges with tetractine spicules (e.g., *Astrophorina*, *Cinachyra, Geodia, Penares, Spirophorina, Stelletta, Tetilla*, and most of those formerly known as lithistids: *Discodermia, Neoschrammeniella, Corallistes*). The freshwater sponge order Spongillida is here, which includes 220 species in 6 families (e.g., *Ephydatia, Lubomirskia, Metania, Potamolepis, Spongilla*). Other orders include Haplosclerida (e.g., *Amphimedon, Callyspongia, Haliclona, Niphates, Petrosia, Xestospongia*), Scopalinida (e.g., *Scopalina, Svenzea*), Sphaerocladina (*Vetulina*), Poecilosclerida (including the family Cladorhizidae) (e.g., *Antho, Asbestopluma, Clathria, Crambe, Desmacella, Hymedesmia, Lycopodina, Mycale, Myxilla*), Agelasida (e.g., *Acanthostylotella, Agelas, Astrosclera, Hymerhabdia*), Axinellida (e.g., *Axinella, Eurypon, Higginsia, Myrmekioderma, Raspailia, Stelligera*), Bubarida (e.g., *Bubaris, Phakellia, Dictyonella*), Desmacellida (e.g., *Desmacella*), Merliida (e.g., *Hamacantha*, *Merlia*), Biemnida (e.g., *Biemna, Neofibularia, Sigmaxinella*), Suberitida (e.g., *Halichondria, Hymeniacidon, Terpios*), Clionaida (e.g., *Cliona, Spirastrella, Placospongia*), Polymastiida (e.g., *Polymastia, Sphaerotylus, Spinularia*), and Tethyida (e.g., *Tectitethya*, *Tethya*).

CLASS HOMOSCLEROMORPHA This most recently proposed class of sponges has been shown to be distinct (and monophyletic) on the basis of molecular phylogenetics, anatomy, and embryology (see Figure 5.19B). Spongin skeleton always absent; rigid skeleton almost always absent, but when present, composed of small (mostly <100 μm) tetraxon (4 often unequal rays) siliceous spicules called calthrops,[2] similar but distinct from certain tetraxon spicules seen in demosponges, or peculiar irregular kinked oxeas (2 uneven rays); all spicules are of a similar size, with no differentiation into megascleres and microscleres (hence the class name); with ciliated exopinacocytes and endopinacocytes; a type IV collagen basement membrane underlies both choanoderm and pinacoderm (this type of collagen has also been found in several species of demosponges and calcareans); zonula adherens cell junctions in adult and larval epithelia; spermatozoids with an acrosome (not exclusive to homoscleromorphs); choanocyte chambers oval to spherical, with large choanocytes. To date, septate junctions have not been found in this class. Homoscleromorphs are viviparous (incubate their embryos), form a hollow blastula by multipolar egression, and develop a unique cinctoblastula larva. Although earlier phylogenetic work had suggested this group might be more closely allied with other metazoans than with other sponges, recent data strongly support its inclusion within a monophyletic Porifera, probably as sister group to Calcarea. Homoscleromorpha are exclusively marine sponges, divided into two families: Plakinidae (spiculate species) and Oscarellidae (aspiculate species). Most species inhabit hard bottoms of the continental shelf, but some are known from more than 1,000 m depth. The fossil record, poor as it is, dates from the early Carboniferous. About 126 species (e.g., *Corticium, Oscarella, Placinolopha, Plakina, Plakinastrella, Plakortis, Pseudocorticium*).

[2]A "caltrop" or "calthrop" was an evil-looking medieval landmine, consisting mainly of four short, sharpened spikes radiating from a common center at equal angles. These were scattered in front of defensive positions and covered under a thin layer of dirt, where they tended to inconvenience charging knights. Homoscleromorph tetractine spicules often have the same general shape.

The Poriferan Body Plan

A mind-boggling diversity exists in the shape, color, and size of sponges. Increases in size and surface area are accomplished by folding of the body wall into a variety of patterns, and also from different growth patterns that appear in response to environmental conditions. This plasticity plus the fact that sponges maintain many of their cells in a pluripotent state compensate in part for the absence of true organs. Two unique organizational attributes define sponges and have played major roles in poriferan success: first is the water current channel system, or **aquiferous system**, and its unique all-purpose cells (for pumping, feeding, gas exchange, and waste expulsion) known as **choanocytes**. Second is the highly pluripotent nature of sponge cells in general. The aquiferous system brings water through the sponge and close to the cells responsible for food gathering and gas exchange. At the same time, excretory and digestive wastes are expelled by way of the water currents. The volume of water moving through a sponge's aquiferous system is remarkable. A single 1 × 10 cm individual of the complex sponge *Leuconia* (Calcaronea) pumps about 23 liters of water through its body daily. Researchers have recorded sponge pumping rates that range from 0.002 to 0.84 ml of water per second per cubic centimeter of sponge body. Large sponges filter their own volume of water every 10 to 20 sec.

The Hexactinellida ("glass sponges") might be the most unusual creatures in the entire animal kingdom. Their triaxonal spicules, with a square proteinaceous internal filament, distinguish them from other siliceous sponges. These siliceous spicules are formed using an enzymatic process driven by the protein glassin, which is completely different from the silicification method used by demosponges driven by the enzyme silicatein. Their syncytial body, which arises by fusion of early embryonic cells, is unique among Metazoa. Both the larvae and adults have elegant combinations of multinucleate and cellular cytoplasmic regions unlike anything seen in any other animal. The continuity of this tissue allows food to be transported symplastically

for more ebook/ testbank/ solution manuals requests: email to 2601267346@qq.com

(analogous to plants), and it also allows electrical signals to travel throughout the sponge body (analogous to the nervous system of higher Metazoa).

Sponges are not colonial animals. Any and all sponge material bounded by a continuous outer covering (the pinacoderm) constitutes a single individual. The growth of each individual is dictated by a combination of genetics (e.g., most larvae have anterior–posterior symmetry, many adults have a radial–axial growth form) and environmental factors (e.g., water flow dynamics, contours of the substratum). For most sponges, changes in body form can arise anywhere in or on the organism in response to external factors.

Body Structure and the Aquiferous System

The outer surface cells of a sponge make up the **pinacoderm** and are called **pinacocytes**, typically unciliated flattened cells that are also known as "pavement cells." The pinacoderm is now considered a true epithelium thanks to studies of transepithelial resistance in freshwater sponges. Most of the inner surfaces comprise the **choanoderm** and are composed of flagellated cells called **choanocytes**. Both of these layers are a single cell thick. Between these two thin cellular sheets is the **mesohyl**, which may be very thin in some encrusting sponges, or massive and thick in larger species (Figures 5.2 and 5.3). The pinacoderm is

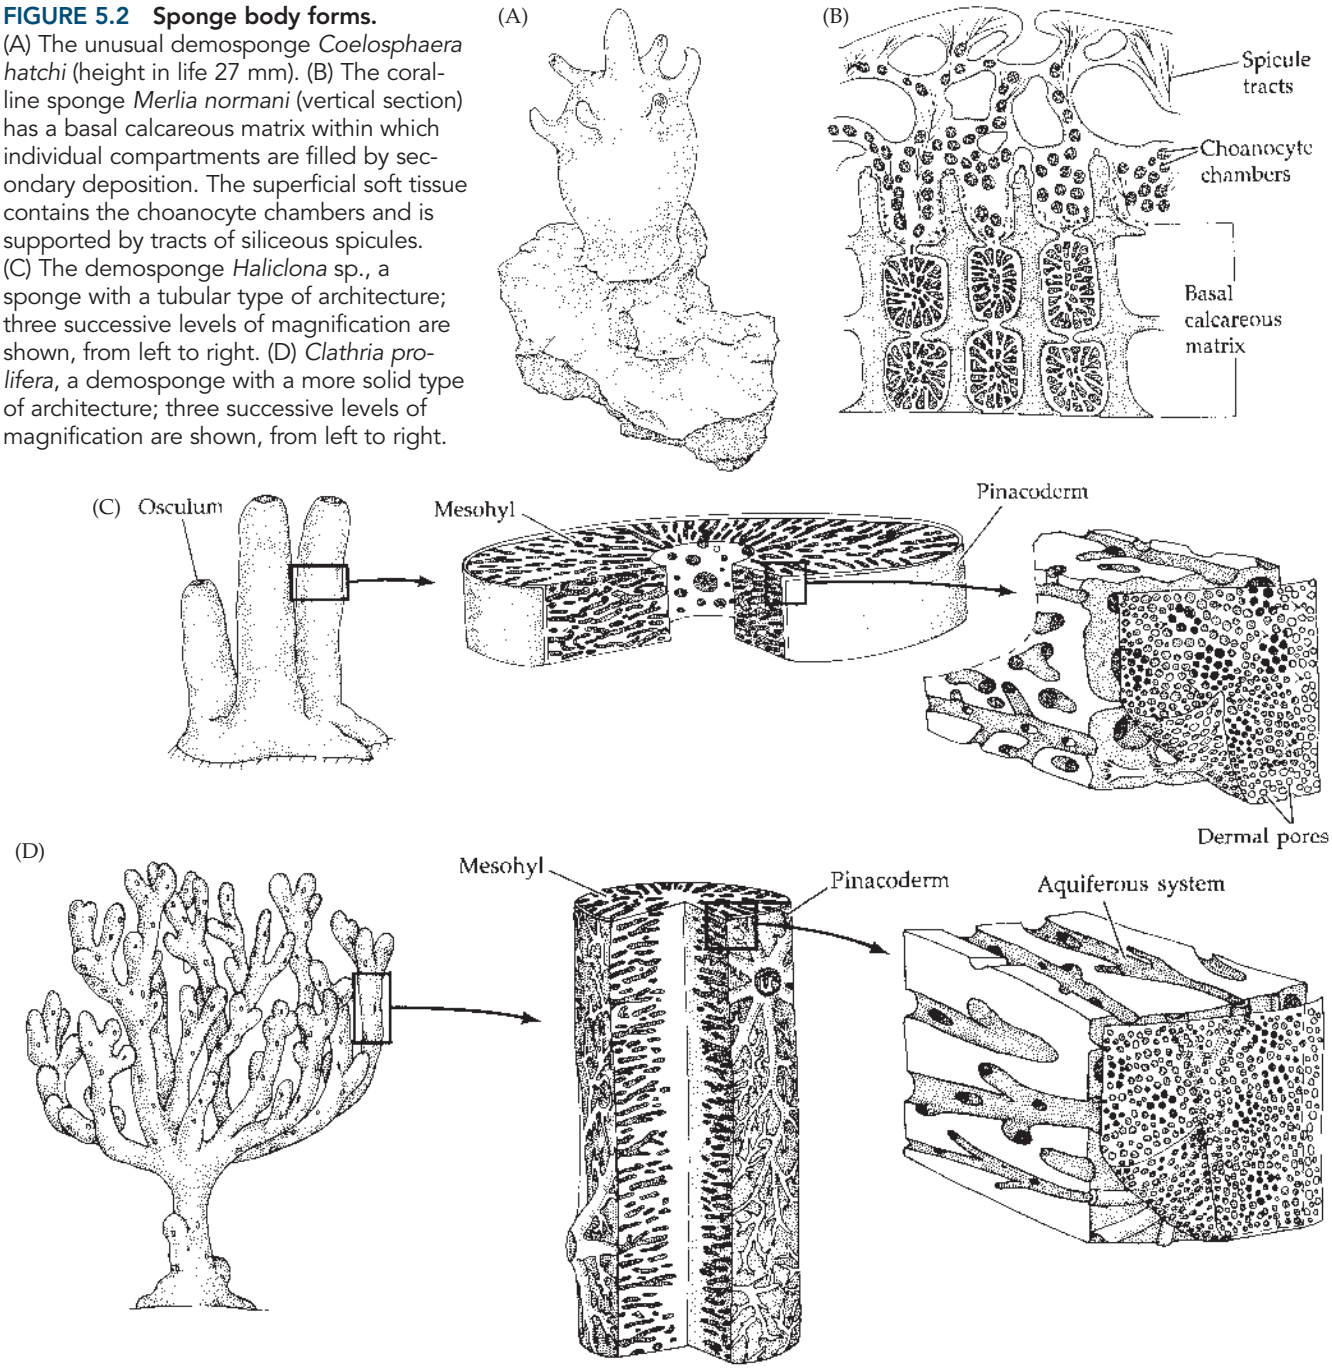

FIGURE 5.2 Sponge body forms. (A) The unusual demosponge *Coelosphaera hatchi* (height in life 27 mm). (B) The coralline sponge *Merlia normani* (vertical section) has a basal calcareous matrix within which individual compartments are filled by secondary deposition. The superficial soft tissue contains the choanocyte chambers and is supported by tracts of siliceous spicules. (C) The demosponge *Haliclona* sp., a sponge with a tubular type of architecture; three successive levels of magnification are shown, from left to right. (D) *Clathria prolifera*, a demosponge with a more solid type of architecture; three successive levels of magnification are shown, from left to right.

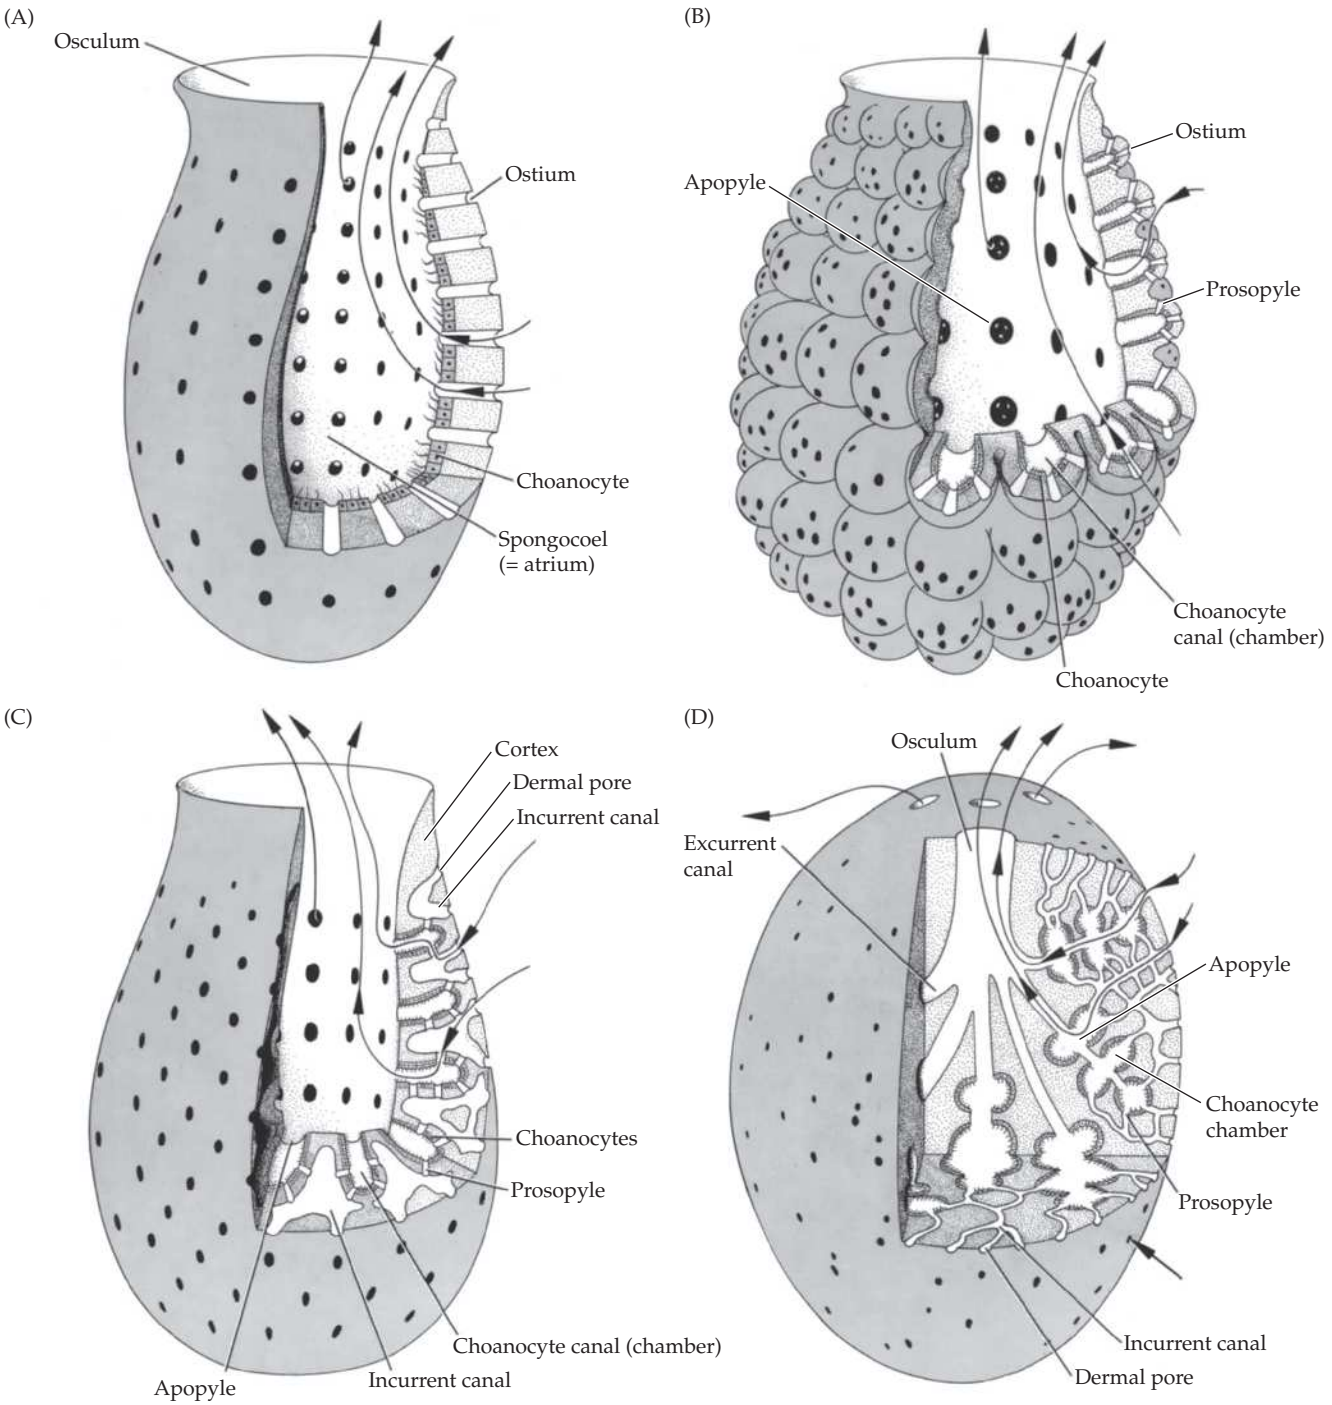

FIGURE 5.3 Body complexity in sponges (arrows indicate flow of water). (A) The asconoid condition. (B) A simple syconoid condition. (C) A complex syconoid condition with ectosomal growth. (D) A leuconoid condition. Asconoid and syconoid anatomies occur only in the class Calcarea.

perforated by small holes called **dermal pores** or **ostia** (sing. ostium), depending on whether the opening is surrounded by several cells or one cell, respectively. Water is pulled through these openings and is driven across the choanoderm by the beating of the choanocyte flagella. The choanocytes pump large volumes of water through the sponge body, thus enabling the aquiferous system. The cost of sponges pushing so much water through the body has been estimated to be about one-third of its overall metabolism. But sponges differ greatly in their pumping capacities, mostly because of their size, effective choanoderm area, and presence/amount of symbiotic microbes.

Sponge choanocytes are thought to be homologous with cells of choanoflagellate protists, although recent studies reveal some differences in organelle ultrastructure (lack of filopodia, cytoplasmic bridges,

for more ebook/ testbank/ solution manuals requests: email to 2673466@qq.com

or glycogen in choanocytes), transcriptional profiles, and flagellum beating dynamics. Choanocytes originate during metamorphosis from the ciliated epithelial cells of larvae, and they can also derive from archaeocytes found in gemmules—in both cases, these precursor cells differentiate into choanoblasts that, in turn, grow collars to become choanocytes. Their long flagellum has a basal, bilaterally arranged pair of wing-shaped projections called **vanes**. The flagellar vanes probably lend support to the flagellum. The flagellum is surrounded by a **collar** of microvilli containing actin filaments, the microvilli being connected to one another via a thin membrane composed of a meshwork of extracellular glycoprotein (the **glycocalyx mesh**) (see Figure 5.7 F–H).[3]

A cuticle, or layer of coherent collagen, may cover the pinacoderm in some species. The pinacoderm itself is a simple external sheet (**exopinacoderm**) of cells (**exopinacocytes**), and it also lines some of the internal cavities of the aquiferous system where choanocytes do not occur (e.g., **the canals**). Pinacocytes that line internal canals form the **endopinacoderm** and are called **endopinacocytes**. The choanoderm can be simple and continuous, or folded and subdivided in various ways. The mesohyl varies in thickness and plays vital roles in digestion, gamete production, secretion of the skeleton, and transport of nutrients and waste products by special ameboid cells. The mesohyl includes a noncellular colloidal mesoglea in which are embedded collagen fibers, spicules, and various cells, including symbiotic microbes; it is therefore really a type of mesenchyme. A great number of cell types may be found in the mesohyl. Most of these cells are able to change from one type to another as required, but some differentiate irreversibly, such as those that commit themselves to reproduction or to skeleton formation.

Some sponges actually move from one place to another—ameboid cells along the base of the sponge "crawl," as others carry forward spicules to support the leading edge of the sponge. Studies suggest that some amebocytes can actually break free from a sponge and move about on their own for a time, eventually returning to the parent sponge body. This "locomotion" in sponges obviously is not sufficient to provide them with a quick escape mechanism from predators; we're talking about millimeters a day here!

As a sponge grows, the pinacoderm and choanoderm remain only a single layer of cells. But by increasing folding as the mesohyl volume increases, these layers maintain a surface-area-to-volume ratio sufficient to sustain adequate nutrient and waste exchange throughout the whole individual. Unique to the class Calcarea, some species go through an ontogenetic sequence in which an increasingly complex body architecture develops; adults may express the most complex structure, or they can retain one of the simpler architectures. Thus, some adult Calcarea may retain a largely unfolded, simple, and continuous choanoderm (the **asconoid condition**; Figure 5.3A), or the choanoderm may become folded (the **syconoid condition**; Figure 5.3B,C), or it may become both folded and subdivided into separate flagellated chambers (the **leuconoid**, **sylleibid**, and **solenoid conditions**; Figure 5.3D). Asconoid, solenoid, and syconoid anatomies occur only in the class Calcarea.

The asconoid condition is found in the early growth stage (olynthus) of newly settled calcareous sponges and in some adult, radially symmetrical calcareous sponges (e.g., *Clathrina*, *Leucosolenia*) (Figure 5.4). Asconoid and syconoid sponges rarely exceed a few centimeters in height and remain as simple, vase-shaped (apical–basal radial symmetry) tubular units, or meandering networks of these vase-shaped units, or occasionally even stalked sponges (e.g., some *Clathrina*). The thin walls enclose a central cavity called the **atrium** (= **spongocoel**), which opens to the outside via a single **osculum** (pl. oscula). The pinacoderm of asconoid and very simple syconoid sponges relies on **ostia** as their incurrent pores. Ostia develop during embryogeny as specialized cells (**porocytes**) that elongate and roll to form cylindrical tubes. Each porocyte extends all the way through the pinacoderm, the thin mesohyl, and the choanoderm and thus into the atrium, where it emerges between adjacent choanocytes like a porthole. Porocytes also occur in a few demosponge groups, particularly the freshwater species. The choanoderm is a simple, unfolded layer of choanocytes lining the entire atrium. Water moving through an asconoid sponge thus flows through the following structures: ostium → atrium/spongocoel (over the choanoderm) → osculum (Figure 5.3A).

As stated above, in calcareous sponges, simple folding of the pinacoderm and choanoderm produces the syconoid condition, within which several levels of complexity are possible (Figure 5.3B,C). As complexity increases, the mesohyl may thicken and appear to have two layers. The outer layer (formerly referred to as the cortical region or cortex) is called the **ectosome**. The ectosome contains an accumulation of spicules that are different from those found in the interior portion of the mesohyl. In calcareous sponges with an ectosome, the incurrent openings are lined by several cells (not formed by a single porocyte) and are referred to as **dermal pores**. In the syconoid condition, choanocytes are restricted to specific chambers or diverticula of the atrium called **choanocyte chambers** (also known as flagellated chambers, or radial canals). Each choanocyte chamber opens to the atrium by a wide aperture called an **apopyle**.

[3]Monociliated cells bearing a collar of microvilli surrounding the cilium have been found in almost all metazoan phyla. However, in other metazoans the cilium is usually immobile, lacks vanes, has a striated rootlet, and is frequently involved in sensory processes. It is therefore thought that such cells are not homologues with sponge choanocytes and choanoflagellate protists.

FIGURE 5.4 The asconoid condition (class Calcarea). (A) An olynthus, the asconoid form that follows larval settlement in calcareous sponges. (B) Major cell types in an asconoid sponge. (C) The simple calcareous sponge *Leucosolenia* shows the asconoid body form and skeleton of $CaCO_3$ spicules.

Syconoid sponges with a thick ectosome possess a system of channels or incurrent canals that lead from the dermal pores through the mesohyl to the choanocyte chambers. The openings from these channels to the choanocyte chambers are called **prosopyles**. In such a complex syconoid sponge, water moving from the surface into the body flows along the following route: dermal (incurrent) pore → incurrent canal → prosopyle → choanocyte chamber → apopyle → atrium → osculum (Figure 5.3B). Syconoid construction is found in many calcareous sponges, including the well-known genera *Grantia* and *Sycon* (formerly known as *Scypha*), and such construction often yields vase-shaped adults, as in many asconoid Calcarea. Some syconoid sponges express a radial symmetry externally, but their complex internal organization is largely asymmetrical.

The leuconoid condition is found in all four sponge classes. Here, the choanoderm is much more highly folded and there is a thickening of the mesohyl by growth of the ectosome. Associated with this is a subdivision of the flagellated surfaces into discrete oval choanocyte chambers (Figure 5.3D). In the leuconoid condition, one finds an increase in number and a decrease in size of the choanocyte chambers, which typically cluster in groups in the thickened mesohyl. The atrium is often reduced to a series of **excurrent canals** that carry water from the choanocyte chambers to the oscula (Figure 5.5). The flow of water through a leuconoid sponge is

FIGURE 5.5 The surface of a living demosponge (*Clathria*). The complex system of ostia opens into underlying incurrent canals, and large oscula receive several excurrent canals, all visible through the thin pinacoderm.

as follows: dermal pore → incurrent canal → prosopyle → choanocyte chamber → apopyle → excurrent canal → (atrium) → osculum (Figure 5.3D). Leuconoid organization is typical of all noncalcareous sponges and many calcareous sponges (e.g., *Leucilla*).

In Calcarea, solenoid systems are uniquely found in the genus *Leucascus*. They differ from the asconoid architecture in that not all internal cavities are lined by choanocytes. And they differ from leuconoid systems in that they possess anastomosed tubes, making the aquiferous system even more complex. Finally, sylleibid organizations are found both in calcareans and homoscleromorphs, and they are characterized by a radial organization of choanocyte chambers around invaginations of the atrial cavity.

It is important to realize that flow rate is not uniform through the various parts of the aquiferous system. Functionally, it is critical that water be moved very slowly over the choanoderm, allowing time for exchanges of nutrients, gases, and wastes between the water and the choanocytes. The changes in water flow velocity through this plumbing system are a function of the effective accumulated cross-sectional diameters of the channels through which the water moves (see Chapter 3, or your old physics notes). Water flow velocity decreases as the cross-sectional diameter increases—liquids move more slowly in larger pipes—or when a single pipe divides into numerous smaller pipes. Thus, in a sponge, velocities are lowest over the choanoderm, which has the largest cross-sectional area. However, water leaving the osculum must be carried far enough away to prevent it from fouling or being immediately recycled by the sponge, so smaller accumulated cross-sectional diameters (and greater water velocity) are found in excurrent canal–oscula systems.

The recognition of the various levels of organization and complexity among calcareous sponges used to be thought to provide important evolutionary clues. However, there is no evidence that the asconoid plan originated first phylogenetically or that all sponge lineages have moved through these three levels of complexity during their evolution. Nor do most sponges pass through these three stages during development. Calcareous sponges of the leuconoid condition usually do pass through asconoid and syconoid (or even sylleibid or solenoid) stages as they grow, but it is only in this class that all five organizational body plans clearly occur.

The hexactinellid sponges differ strikingly from other sponge classes (Figure 5.6). The bodies of hexactinellid sponges often display a considerable degree of superficial radial symmetry. There is not a typical pinacoderm in hexactinellids. Instead, a **dermal membrane** is present, but it is extremely thin and is continuous with all the other parts of the sponge; no discrete or continuous cellular structure supports it. Incurrent pores are simple holes in this dermal membrane. The main tissue of the hexactinellid is called the **trabecular syncytium**—it forms a syncytial, trabecular network stretching across interconnecting internal cavities (the subdermal lacunae) near the surface of the sponge and penetrating into and forming the supporting framework for the **choanosome** (Figure 5.6A). The trabecular network resembles a three-dimensional cobweb. The thimble-shaped flagellated chambers of the choanosome are arranged in a single layer and are supported within the trabecular network. Both the trabecular network and the walls of the flagellated chambers are syncytial. In these sponges, the choanoblasts produce new collars but do not produce new nuclei, thus creating a single-nucleate syncytium with many collar bodies. As new collars "bud off," the expanding, single-cell body of the choanoblast cell recesses itself beneath the trabecular syncytium, leaving just the collars exposed to do the work. Water enters incurrent pores in the dermal membrane, passes into the subdermal lacunae, and from there enters the syncytial choanosome chambers via the prosopyles. The soft tissue of the syncytium serves to deliver food and other metabolites to all parts of a hexactinellid sponge by cytoplasmic streaming.

The unique structure of hexactinellids is so striking that some workers have even suggested the hexactinellids might be regarded as a separate subphylum or phylum (the "Symplasma"), distinct from the other sponge classes (the "Cellularia"). However, as explained in Chapter 2, phylogenetic relationships are best sought in similarities among groups (i.e., shared derived features), not in differences. By this reasoning, and through molecular phylogenetics, we know without doubt that hexactinellids are poriferans (and probably closely related to

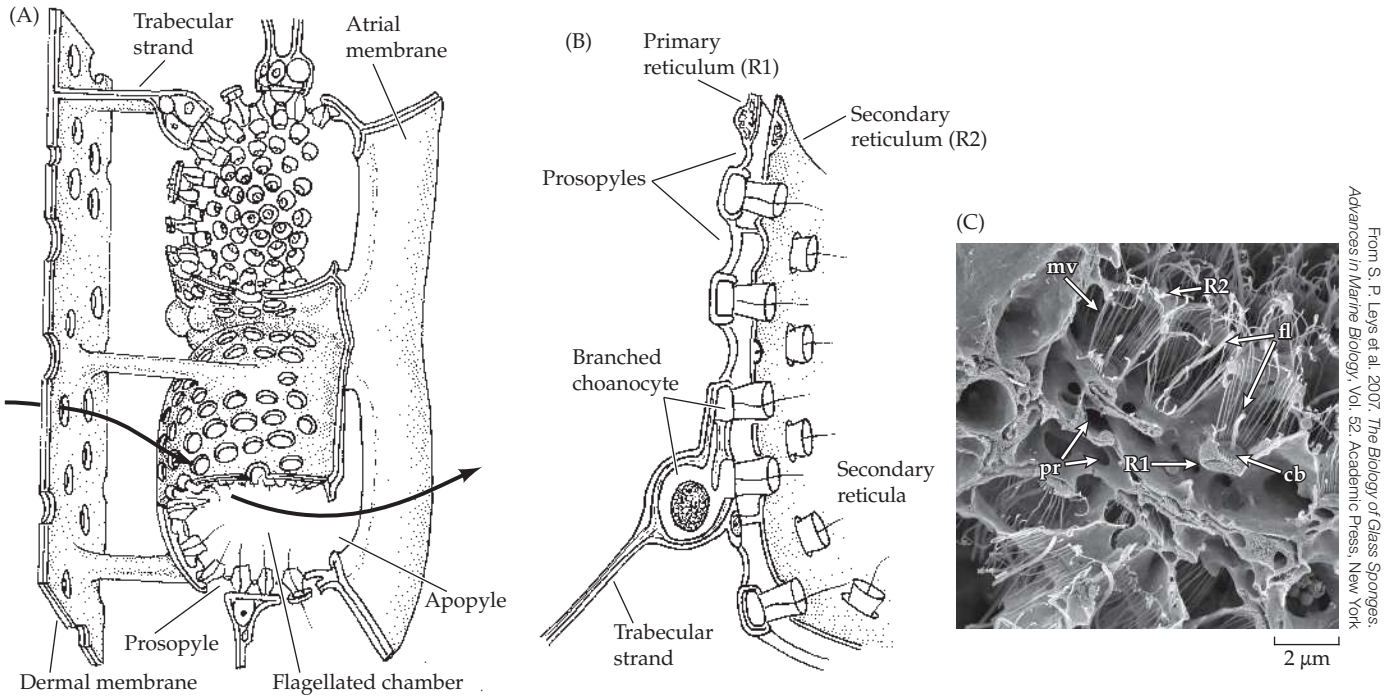

FIGURE 5.6 Internal anatomy of Hexactinellida showing the trabecular network. demosponges). Nevertheless, hexactinellids are striking and bizarre in that no other metazoan group possesses such extensive syncytial tissues.[4]

More on Sponge Cell Types

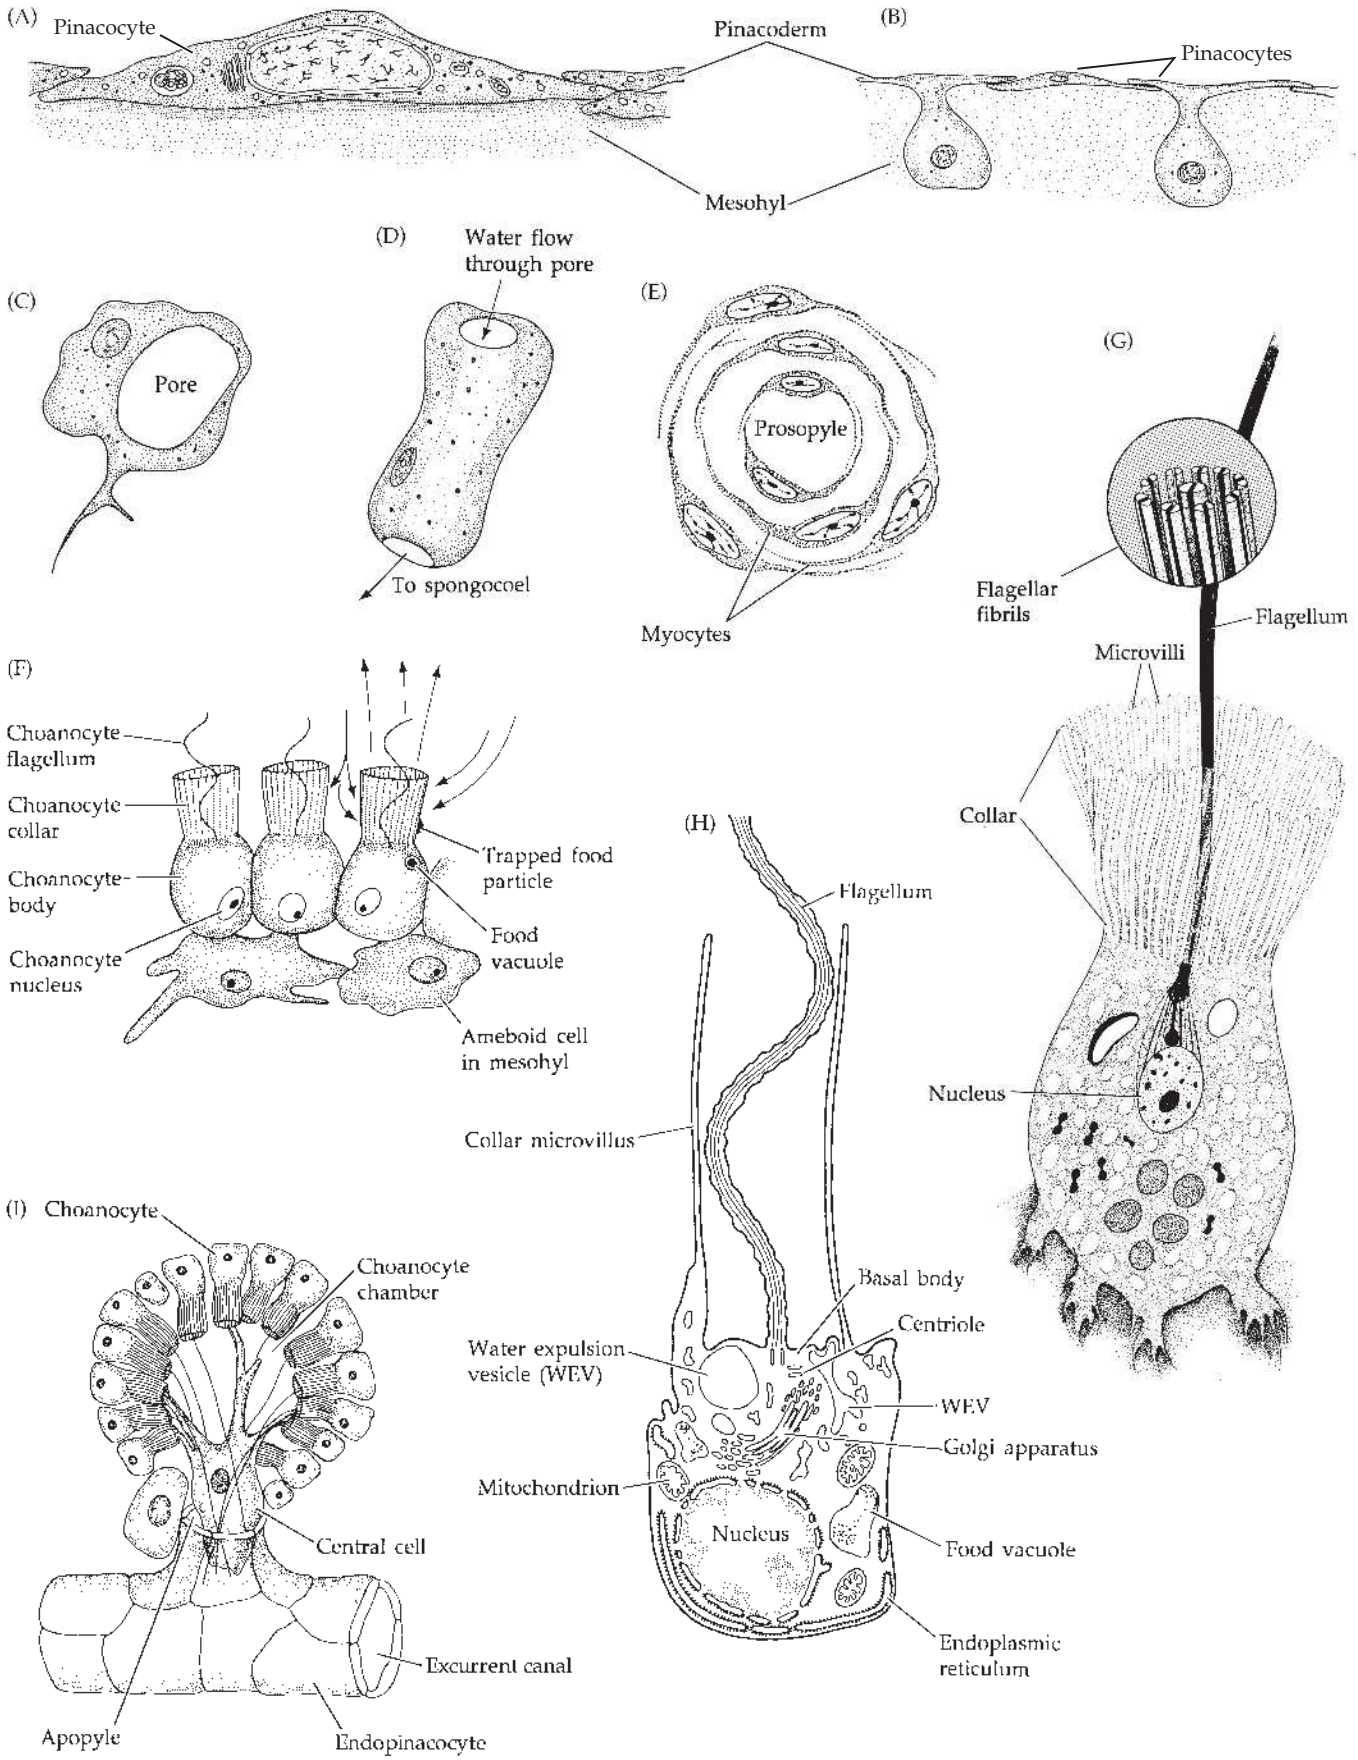
Prior to the 1970s, texts generally recognized only a few basic kinds of poriferan cells. However, subsequent detailed histochemical and ultrastructural studies have revealed a broad variety of cell types. These discoveries make succinct "textbook classification" of their cells difficult. We present below a highly abridged version of sponge cell classification.

Cells that line surfaces As noted above, the pinacoderm forms a continuous layer on the external surface of sponges and also lines all incurrent and excurrent canals. The pinacocytes that make up this layer are usually flattened and usually overlapping (Figure 5.7A,B). The external surface, or exopinacoderm, of demosponges has an extracellular matrix beneath it, and in the Calcarea a loose collagenous mesohyl underlies the pinacoderm. In homoscleromorph sponges, and some species in other classes, a true basement membrane underlies the pinacoderm and the choanoderm. In all cases, this layer of secreted material helps maintain the positional integrity of pinacocytes. Basal membranes are sheetlike complexes of extracellular matrix proteins that are secreted by an epithelial layer; they are highly structured and contain type IV collagen. Such membranes

FIGURE 5.7 Cells that line sponge surfaces. ▶ (A) A pinacocyte from the surface of the demosponge *Halisarca* (drawn from an electron micrograph). The outer surface is covered with a polysaccharide-rich glycocalyx coat. The cell is fusiform and overlaps adjacent pinacocytes. (B) Pinacoderm from a calcareous sponge (section). T-shaped pinacocytes alternate with fusiform pinacocytes. (C,D) A porocyte from the calcareous asconoid sponge *Leucosolenia*. (C) Cross section. (D) Side view. (E) Myocytes surrounding a prosopyle. Brill. 1973. *Z Zellforsch Mikrosk Anat* 144: 231–245.)

[4]Syncytial tissues are seen in some other metazoans. For example, the epithelia of some cnidarians and the skeletogenic tissues of echinoids are syncytial, by way of incomplete cytokinesis. The giant neurons in squid, and vertebrate striated muscle cells (your biceps, for example) are multinucleate by fusion of separate cells.

for more ebook/ testbank/ solution manuals requests: email to 2601267346@qq.com



typically underlie epithelial (and endothelial) tissues in the Metazoa, but not in fungi or plants. They provide an added mechanical function as supporting structures and also play a biological role as molecular sieves. The pinacoderm of Homoscleromorpha is especially well organized, forming a well-developed epithelium (with an underlying basal membrane). In demosponges and calcareous sponges, type IV collagen is also found, but its spatial arrangement (whether loosely distributed across the mesohyl or forming a thick layer underlying epithelial layers) is still unknown. In this sense, the apparent absence of a basal membrane in most Porifera distinguishes sponge pinacoderm from the well-developed tissue epithelia of the higher Metazoa.[5]

Internal, canal-lining pinacocytes (**endopinacocytes**) are usually more fusiform in shape and have less overlap than **exopinacocytes**. Although the endopinacoderm is epithelial in function, it is probably phagocytic as well. External cells of the basal or attaching region of a sponge surface are called **basopinacocytes**. These flattened cells are responsible for secreting a fibrillar collagen–polysaccharide complex by which sponges attach to the substratum. In freshwater sponges, the basopinacocytes are active in feeding and extend ameba-like "filopodia" to engulf bacteria. Freshwater sponge basopinacocytes also play an active role in osmoregulation and contain large numbers of water expulsion vesicles, or contractile vacuoles.

As noted earlier, porocytes are cylindrical or flat, tubelike cells of the pinacoderm that form ostia in some sponge species (Figure 5.7C,D). They are contractile and can open and close the pore and regulate the ostial diameter; however, no microfilaments have been observed in them, and their precise method of contraction and expansion is unknown. Some species are capable of producing a diaphragm-like cytoplasmic membrane across the ostial opening that also regulates pore size.

Choanocytes are the flagellated collar cells that make up the choanoderm and create the currents that drive water through the aquiferous system (Figure 5.7F–H). Choanocytes are not coordinated in their beating, not even within a given chamber. However, they are aligned such that the flagella, which beat from base to tip, are directed toward the apopyle. The long flagellum is always surrounded by the choanocyte collar, which is made up of 20 to 55 cytoplasmic microvilli (= villi). The villi have microfilament cores and are connected to one another by anastomosing mucous strands (a mucous reticulum) that form a glycocalyx band around the collar. Choanocytes rest on the mesohyl, held in place by interdigitation of adjacent basal surfaces. In keeping with their central role in phagocytosis and pinocytosis, choanocytes are highly vacuolated.

[5] Type IV collagen, diagnostic of Metazoa, is a long triple helix molecule; it is one of several collagen types found in sponges and other metazoans, and it occurs in all four sponge classes.

Cells that secrete the skeleton There are several types of ameboid cells in the mesohyl that secrete elements of sponge skeletons. In almost all sponges, the entire supportive matrix is built on a framework of fibrillar collagen. The cells that secrete this material are called collencytes, lophocytes, and spongocytes. **Collencytes** are morphologically nearly indistinguishable from pinacocytes, whereas **lophocytes** are large, highly motile cells that can be recognized by a collagen tail they typically trail behind them (Figure 5.8C). The primary function of both cell types is to secrete the dispersed fibrillar collagen found intercellularly in virtually all sponges. **Spongocytes** produce the fibrous supportive collagen referred to as **spongin** (see Figure 5.11A). Spongocytes operate in groups and are always found wrapped around a spicule or spongin fiber (Figure 5.8D).

Sclerocytes are responsible for the production of calcareous and siliceous sponge spicules (Figure 5.8A,B). They are active cells that possess abundant mitochondria, cytoplasmic microfilaments, and small vacuoles, although the inherently distinct formation of siliceous and calcareous spicules indicates their convergent morphology. Numerous types of sclerocytes have been described; these cells always disintegrate after spicule secretion is complete.

Contractile cells Contractile cells in sponges, called **myocytes**, are found in the mesohyl (Figure 5.7E). They are usually fusiform and grouped concentrically around oscula and major canals. Myocytes are distinguished by the great numbers of microtubules and microfilaments contained in their cytoplasm, and they rely on the classic actin-myosin structure seen in all animals. Because of the nature of their filament arrangement, it has been suggested that myocytes are homologous with the smooth muscle cells of higher invertebrates. However, myocytes are independent effectors with a slow response time, and unlike neurons and true muscle fibers, they are insensitive to electrical stimuli.

Stem cells Both archaeocytes and choanocytes are part of the stem cell lineage in sponges, although with different transdifferentiation properties. **Archaeocytes** are highly versatile, largely totipotent ameboid cells that are capable of quickly differentiating to give rise to virtually any other cell type. These large, highly motile cells also play a major role in digestion and food transport (Figure 5.9). They possess a variety of digestive enzymes (e.g., acid phosphatase, protease, amylase, lipase) and can accept phagocytized material from the choanocytes. They also phagocytize material directly through the pinacoderm of water canals. Archaeocytes carry out much of the digestive, transport, and excretory activities in sponges. And, as cells of maximum totipotency, archaeocytes are essential to the developmental program of sponges and to various asexual processes (e.g., gemmule formation). However, there is not a single type

of archaeocyte, as they differ in their organelle complements, nucleus-to-cytoplasm ratio, and transcriptional profiles. But, since we lack a proper system to differentiate them, this pool of cells is still referred to collectively as archaeocytes (as long as they have a nucleolated nucleus, ameboid shape, and phagocytic capacities).

Other cell types Several sponge cell types are known to produce and secrete different molecules. Among them, **spherulous cells** are very common. They are large mesohyl cells containing various chemical inclusions.

Cell reaggregation Around the beginning of the twentieth century, Henry V. Wilson first demonstrated the remarkable ability of sponge cells to reaggregate after being mechanically dissociated. Although this discovery was interesting in itself, lending insight into the plasticity of cellular organization in sponges, it also foreshadowed more far-reaching cytological research that has since shed light on basic questions about how cells self-recognize, adhere, segregate, and specialize. Many sponges that are dissociated and maintained under proper conditions will form aggregates, and some will eventually reconstitute their aquiferous system. For example, when pieces of the Atlantic "red beard sponge" (*Clathria prolifera*: Poecilosclerida) are pressed through fine cloth, the separated cells immediately begin to reorganize themselves by active cell migration. Within 2 to 3 weeks, a functional sponge reforms and the original cells return to their respective functions. Furthermore, if cell suspensions of two different sponge species are mixed, the cells sort themselves out and reconstitute individuals of each separate species—a remarkable display of cellular self-recognition. The controversial sponge biologist M. W. de Laubenfels described the situation in 1949 in

slightly different terms: "Sponges endure mutilation better than any other known animal." The discovery that dissociated sponge cells will reaggregate to form a functional organism was the basis for the establishment of sponge cell cultures that have been used as a model for the study of fundamental processes in developmental biology and immunology. We now know that sponge cells (like other animal cells) have surface markers that allow for self- versus non-self-recognition.

Support

The skeletal elements of sponges are of two types, organic and inorganic. The former is always collagenous, and the latter either siliceous (hydrated silicon dioxide) or calcareous—calcium carbonate in the form of calcite or aragonite. Sponges are the only animals that use hydrated silica as a skeletal material. Calcite is a common crystalline form of natural calcium carbonate, $CaCO_3$, that is the basic constituent of many protist and animal skeletons, as well as the fossiliferous sedimentary rocks known as limestone, marble, and chalk.[6]

Collagen is the major structural protein in invertebrates; it is found in virtually all metazoan connective tissues. In vertebrates, about 20 different kinds of collagen have been identified, but in Porifera only 3 are known so far: type I–like collagen (fibrillar collagens),

[6]Calcite and aragonite are closely related calcium carbonate ($CaCO_3$) minerals representing the two most common, naturally occurring, crystalline forms. Both are formed by biological and physical processes—primarily precipitation in marine and freshwater environments—and both are used by animals in the construction of their skeletons. Calcite is the more stable of the polymorphs of calcium carbonate. Calcite crystals are trigonal-rhombohedral, though actual calcite rhombohedra are rare as natural crystals. In animal skeletons, calcite occurs as lamellar or compact deposits, or occasionally in a fibrous form. Calcite is transparent to opaque. Single calcite crystals display an optical property called birefringence (double refraction) that causes objects viewed through a clear piece of calcite to appear doubled. Although calcite is fairly insoluble in cold water, acidity can cause its dissolution (a big problem for animals and protists living in an acidifying global ocean). Calcite exhibits an unusual characteristic called retrograde (or inverse) solubility in which it becomes less soluble in water as the temperature increases. Aragonite's crystal lattice differs from that of calcite, resulting in a different crystal shape, an orthorhombic system with needlelike crystals. Aragonite may be columnar or fibrous. Aragonite is thermodynamically unstable at standard temperature and pressure and tends to alter to calcite on scales of 107 to 108 years. Because calcite is more stable than aragonite and dissolves more slowly than aragonite in water, it is more likely to fossilize. Thus, the fossil record for Paleozoic corals is better than the fossil record for Cenozoic corals, the former being made of calcite, the latter of aragonite.

Calcite skeletons occur in most invertebrates that have hard skeletons, including sponges, brachiopods, echinoderms, most bryozoans, and most bivalves. Coccoliths and planktonic foraminiferans also have calcitic skeletons, and certain red algae (coralline red algae) also produce it. Because calcite is so stable, larger calcite shells in the fossil record (e.g., bivalves) thus tend to the "real thing," not mineral replacements. Purely aragonite-based shells do exist, such as in the molluscan class Polyplacophora (the chitons), but they are rare.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

type IV, and short-chain collagens (non-fibrillar collagens). Collagen type IV is a key component of basal membranes, and it has to date been found primarily in the Homoscleromorpha but also in a number of species of demosponges and calcareans.

In sponges, fibrillar collagen is either dispersed as thin fibrils in the intercellular matrix or organized as a fibrous framework called spongin in the mesohyl. Although the dispersed collagen fibers seen in many sponges are sometimes referred to as "spongin," true spongin (fibrillar collagen forming a skeletal framework in the mesohyl) is found only in members of the class Demospongiae (Figure 5.11A). The amount of this fibrillar collagen varies greatly from species to species—in hexactinellids it is quite sparse, whereas in demosponges it is abundant and may form dense bands in the ectosome. Unlike the ectosome of calcareous sponges, which is fundamentally a layer of concentrated spicules with very little collagen, the ectosome of demosponges is a feature of the outer mesohyl and is basically a well-developed collagen layer lacking choanocyte chambers. The network often contains very thick fibers, and it may incorporate siliceous spicules into its structure. Interestingly, the symbiotic bacteria preferentially locate among the collagenous deposits of the mesohyl. Spongin often cements siliceous spicules together at their points of intersection. The encysting coat of the asexual gemmules of freshwater (and some marine) sponges is also composed largely of spongin.

Mineral skeletons of either silica or calcium are found in almost all sponges, except a few species of demosponges and homoscleromorphs. Sponges lacking mineral skeletons possess only fibrous collagen networks, and these are still used as bath sponges despite the prevalence nowadays of synthetic "sponges." Several demosponge and homoscleromorph genera lack both spongin and a spicule skeleton (e.g., *Chondrosia*, *Halisarca*, *Hexadella*, *Oscarella*).

Sponges have been harvested for millennia. There is evidence of an active Mediterranean sponge trade by Egyptians at least as early as 3000 BCE, and later in the ancient Phoenician, Greek, and Roman civilizations (Figure 5.10). Homer and other ancient Greek writers mention a thriving Mediterranean sponge trade. Prior to the 1950s, active natural sponge fisheries existed in southern Florida, the Bahamas, and the Mediterranean. The industry peaked in 1938, when the world's annual sponge catch (including cultivated sponges) exceeded 2.6 million pounds, 700,000 pounds of which came from the United States and the Bahamas. Almost all commercial sponges belong to the genera *Hippospongia* and *Spongia* (subclass Keratosa), but these sponges have now been largely "fished out" in the traditional sponge hunting grounds of the Mediterranean and Florida. In addition, they are prone to current-transmitted epidemic

diseases (three such events wiped out bath sponge populations in both the Old World and the New World in 1938, 1947, and the late 1980s).

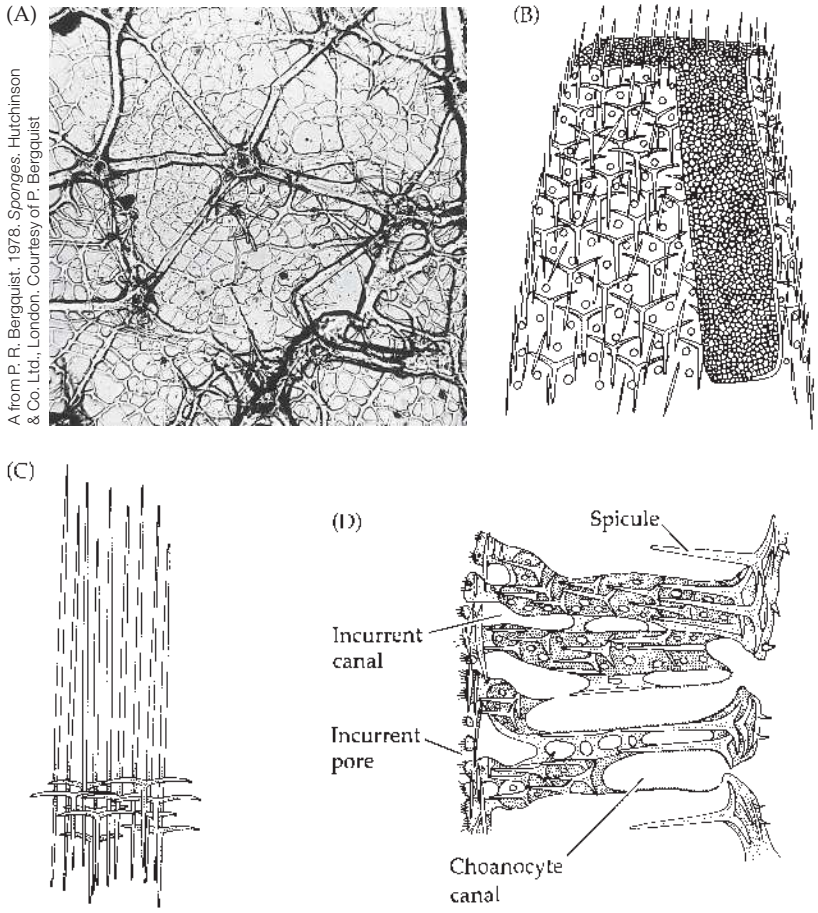
Mineralized sponge spicules (Figure 5.11) are produced by special mesohyl cells called sclerocytes, which are capable of accumulating calcium or silicate and depositing it in an organized way. In some cases, one sclerocyte produces one spicule; in others, several sclerocytes work together cooperatively to produce a single spicule, often two cells per spicule ray (Figure 5.8A–D).

The construction of a siliceous spicule begins with the secretion of an organic axial filament within a vacuole in a sclerocyte. This axial filament is composed of the enzyme silicatein in demosponges and glassin in hexactinellids, but its enzymatic origin in homoscleromorphs is yet unknown. As the axial filament elongates at both ends, hydrated silica is secreted into the vacuole and deposited around the filament core. Recent work suggests that, at least in some homoscleromorph species (e.g., *Corticium candelabrum*), pinacocytes might also be capable of siliceous spicule production. About 92% of all living sponge species are siliceous. One might wonder how a skeleton made of glass (as in the Hexactinellida) could be strong enough to provide support while not being fragile as a windowpane. The trick is that glass sponges have evolved a highly sophisticated, multilayered biomechanical structure to their skeleton. They construct their glass skeleton by first consolidating nanometer-scale silica spheres, arranged in microscopic concentric rings separated from one another by alternating layers of an organic matrix-glue to form laminated spicules. The spicules are then bundled together by an organic, silica-based cement, resulting in the formation of micron-scale, multilayered "beams." The beams are then assembled into the recognizable square-lattice cagelike structure we see in glass sponges, such as *Euplectella*. The lattice itself is further reinforced by diagonal ridges, giving the whole skeleton remarkable strength plus a resilient

flexibility. In species of *Euplectella*, seven hierarchical structural levels have been identified in the skeleton—a textbook example in biomechanical engineering, and perhaps one day an inspiration for glass fiber manufacturers. Even in Demospongiae and Homoscleromorpha, the siliceous spicules exhibit exceptional flexibility and toughness due to their composite, layered construction.

Unlike siliceous spicules, calcium carbonate spicules do not have an organic axial core. Calcareous spicules are produced extracellularly, in intercellular spaces bounded by a number of sclerocytes. Each spicule is essentially a single crystal of calcite or aragonite. The enzymes responsible for its polymerization, carbonic anhydrases, are commonly found in almost all metazoans. In calcareous sponges, there are several carbonic anhydrases that act in coordination, and even more importantly, some of them are spicule-type specific.

Considerable taxonomic weight has been given to spicule morphology, and an elaborate nomenclature exists to classify these skeletal structures. Spicules are termed either **microscleres** or **megascleres**. The former are small to minute reinforcing (or packing) spicules; the latter are large structural spicules. The demosponges and hexactinellids have both types; calcareous sponges often have only megascleres (although the spicules can differ considerably in size). Descriptive terms that designate the number of *axes* in a spicule end in the suffix *-axon* (e.g., monaxon, triaxon). Terms that designate the number of *rays* end in the suffixes *-actine* or *-actinal* (e.g., monactinal, hexactinal, tetractinal). In addition, there is a detailed nomenclature specifying shape and ornamentation of various spicules (Figure 5.11).



A from P. R. Bergquist. 1978. *Sponges*. Hutchinson & Co. Ltd., London. Courtesy of P. Bergquist

A spicular skeleton may be viewed as a supplemental supporting structure. If the amount of inorganic material is increased in relation to organic material, the sponge becomes increasingly solid until the texture approaches that of a rock, as it may in some members of the demosponge order Tetractinellida and a few others (e.g., the formerly named "lithistid" sponges, a polyphyletic group). In contrast to discrete spicules, the massive calcareous skeletons of some species (the coralline sponges, or sclerosponges) have a polycrystalline microstructure; they are composed of needles ("fibers") of either calcite or aragonite embedded in an organic fibrillar matrix. The advantage of incorporating organic matter into the calcareous framework has been compared to that of using lath and plaster, or reinforced concrete. The mix of organic and inorganic materials probably yields fibrous calcite and aragonite that are less prone to fracture while also producing substances that are more easily molded by the organism. In some demosponges (e.g., the "lithistids") and many Hexactinellida, the spicules may be linked or fused into such a rigid framework that it is capable of fossilizing.[7]

Nutrition, Excretion, and Gas Exchange

Although sponges lack the complex organs and organ systems seen in most other Metazoa, they are nevertheless a hugely successful group of animals. As noted above, their success seems partly due to their "ancientness"—the flexibility inherent in their developmental programming, cellular pluripotency, highly versatile aquiferous system, and the general plasticity of their body form.

Unlike most Metazoa, nearly all sponges rely on intracellular digestion, and thus on phagocytosis and pinocytosis as means of food capture. The aquiferous system has already been described; with it, sponges more or less continuously circulate water through their

[7]The order Lithistida has long been recognized as polyphyletic but kept mainly as a matter of convenience, essentially because it is used by paleontologists. However, as with the former taxon Sclerospongiae, it is clearly time to abandon the name "Lithistida" and begin reassigning its component species.

bodies, bringing with it the microscopic food particles upon which they feed. They are size-selective particle feeders, and the arrangement of the aquiferous system creates a series of "sieves" of decreasing mesh size (e.g., dermal pores or ostia → canals → prosopyles → choanocyte villi → intertentacular mucous reticulum). The upper limit of the diameter of incurrent openings is usually around 50 μm, so larger particles do not enter

the aquiferous system. A few species have larger incurrent pores, reaching diameters of 150 to 175 μm, but in most species the incurrent openings range from 5 to 50 μm in diameter. Internal particle capture in the 2 to 10 μm range (e.g., bacteria, small protists, unicellular algae, organic detritus) is by choanocytes and by phagocytic motile archaeocytes that move to the lining of the incurrent canals. As in the choanoflagellate protists, the propagation of the flagellar wave in sponge choanocytes is thought to draw water in through the microvilli of the collar, which then slows or blocks food particles, allowing them to be phagocytized. The smallest particles, large organic molecules and small bacteria in the 0.1–0.2 μm range (the distance between adjacent villi is ~1.5 μm or less), may be trapped on the collar itself. Larger particles, up to ~3 μm, adhere to the body of the choanocyte only to be engulfed by "pseudopodial" extensions (phagocytosis) that may be longer than the collar villi themselves. Undulations of the collar might move some trapped food particles down to the choanocyte cell body, or stalled food might be captured by long phagocytizing pseudopods that form from the collar microvilli and migrate from the base of the collar (as in choanoflagellates) or by pseudopods from the choanocyte cell body itself.

Interestingly, it would seem that food particle capture can take place almost anywhere on the surface of a sponge. Even pinacocytes are known to be capable of phagocytizing particles as large as 6 μm on the surface of a sponge. It has been estimated that the pinacocytes lining canals can take particles as large as 50 μm.

In the case of archaeocyte phagocytosis, digestion takes place in the food vacuole formed at the time of capture. In the case of choanocyte capture, food particles are partly digested in the choanocytes and then quickly passed on to a mesohyl archaeocyte (or other wandering amebocyte) for final digestion. In both cases, the mobility of the mesohyl cells assures transport of nutrients throughout the sponge body.

The efficiency of food capture and digestion was dramatically shown in an elegant study long ago, by Schmidt (1970), using fluorescence-tagged bacteria fed to the freshwater sponge *Ephydatia fluviatilis* (Heteroscleromorpha). By monitoring the movement of the fluorescent material, Schmidt determined that 30 minutes elapsed from the onset of feeding until the bacteria had been captured by choanocytes and moved to the base of the cells. Transfer of the fluorescent material to the mesohyl commenced 30 minutes later. Twenty-four hours later, fluorescent wastes began to be discharged into the water, and no fluorescent material remained in the sponges after 48 hours. Additional studies on this same species led to an estimate of 7,600 choanocyte chambers per cubic centimeter of sponge body, each chamber pumping a phenomenal 1,200 times its own volume of water daily. More complex leuconoid sponges have as many as 18,000 choanocyte chambers per cubic millimeter. In some thin-walled asconoid and simple syconoid sponges, a distinctive mesohyl is hardly present. In these sponges the choanocytes assume both capture and digestive/assimilative functions. More recent studies have shown that sponges are capable of removing up to 95% of the bacteria and heterotrophic protists from the water they filter.

Such a frantic flagellar activity of choanocytes can translate into a relatively short life of these cells, and indeed, substantial expulsion of filtering cells has been observed in the water. Recently, this newly discovered form of discharged organic matter in reef ecosystems has been proposed to fuel the productivity of these otherwise oligotrophic systems (i.e., the "sponge loop").

Many sponges appear to also take up significant amounts of dissolved organic matter (DOM) by pinocytosis from the water within the aquiferous system, and there is some evidence that this is needed by the microbial symbionts within the sponge. Studies have shown that 80% of the organic matter taken in by some shallow-water marine sponges can be of a size below that resolvable by light microscopy. The other 20% comprises primarily bacteria and dinoflagellates. On the other hand, some sponges appear to rely very little on DOM for nutrition (e.g., some hexactinellids that have been studied). Recent studies show that at least some sponges form simple fecal pellets. Experiments on the widespread North Atlantic species *Halichondria panicea* (Heteroscleromorpha) have revealed that undigested material is expelled as discrete pellets coated with a thin layer of mucus. Exactly how these pellets are formed is unclear.

Although the phylum Porifera is characterized by filter feeding, members of the deep-sea demosponge family Cladorhizidae display an entirely different and unique mode of feeding. Species in this group have lost most or all of the characteristic choanocyte-lined aquiferous system and instead feed as macrophagous carnivores; in fact, they are passive suspension-feeding predators, spending a minimal amount of energy during long periods between rare feeding opportunities! They feed by trapping small prey on hook-shaped spicules that protrude from the surfaces of tentacle-like structures (Figures 5.12 and 5.13). Trapped prey are gradually enveloped by migrating feeding cells that undertake digestion and absorption. Most cladorhizids live at great ocean depths, and *Lycopodina occidentalis* is the deepest known sponge, although it can also be found at diving depths on the west coast of Canada. Most cladorhizids probably remain undescribed and, unfortunately, are common on the tops of seamounts—a habitat threatened by fishing and mineral extraction interests. Luckily, one species of *Lycopodina* (*L. hypogea*) lives in shallow caves in the Mediterranean, where it has been the subject of considerable study, shedding light on the biology of this enigmatic sponge. One of the more bizarre cladorhizids is *Chondrocladia lyra*

FIGURE 5.13 More carnivorous sponges (family Cladorhizidae). (A) *Asbestopluma desmophora*, a treelike carnivorous sponge from New Zealand. Large, clear megascleres are aligned vertically along the main "trunk," twisting around it to give a silky sheen to the creature. The small, thin, side branches are covered in microscleres that snare passing prey. (B) The remarkable lyre sponge, *Chondrocladia lyra*, from a depth of 3.5 km off the coast of Monterey, California, reaches 36 cm in height and has up to six long vanes that grow from the main body, each vane with a series of parallel side branches that are used for passive suspension feeding of small invertebrates, particularly crustaceans, using Velcro-like barbed hooks (microscleres). (C) A microsclere from *Abyssocladia carcharias*, named for the remarkable shape of the "abyssochelae" microscleres, which resemble the jaws of the great white shark *Carcharodon carcharias*. (D) Microsclere ("anisochelae") of *Asbestopluma agglutinans*. In carnivorous sponges, microscleres are involved in snaring prey and typically line the sponge's surface.

(the lyre sponge; Figure 5.13B), which has a series of vanes extending from the central body, each vane in turn with a series of upright side branches, creating a lyrelike or harplike structure that works for passive suspension capture of small zooplankters, especially crustaceans. Cladorhizids apparently lack oscula, ostia, and a canal system, and some may even lack choanocytes! Another of the remarkable cladorhizid sponges, *Cladorhiza methanophila*, has been discovered to harbor methanotrophic bacterial symbionts in its cells, such as seen in many animals inhabiting hydrothermal vents and cold seeps. The sponge thus feeds both by predation and by direct consumption of its microbial symbionts. Recently, species in several other deep-sea families have shown evidence of carnivory, suggesting that this habit has perhaps evolved several times among the Demospongiae.

Sponges continuously excrete waste from their body via the osculum. Occasionally, they also undergo a stereotypic series of whole-body contractions, sometimes called a "sneeze." It appears that these contractions are stimulated by a reduction in water flow through the oscula, which would typically be caused by obstruction from an excessive accumulation of particulates that can clog the aquiferous system. The decrease in oscular flow is registered by special short cilia that line the inner osculum epithelium. Unlike most cilia, which possess the classic 9+2 anatomy, these oscular cilia lack the central pair of microtubules and are nonmotile. Their sole function seems to be the detection of flow rates through the oscula. Such cilia, called "primary cilia," are known from other metazoans, where they typically sense changes in fluid movement. Thus, the sponge osculum can be viewed as a true sense organ—the only one known in this phylum! Experimentally de-osculated sponges cannot be triggered to sneeze.

Excretion (primarily ammonia) and gas exchange are by simple diffusion, much of which occurs across the choanoderm. We have already seen how folding of the body, combined with the presence of an aquiferous system, overcomes the surface-to-volume dilemma posed by an increase in size. The efficiency of the poriferan body plan is such that diffusion distances never exceed about 1.0 mm, the distance at which gas exchange by diffusion becomes notably inefficient. In addition, water expulsion vesicles (contractile vacuoles) occur in freshwater sponges and presumably aid in osmoregulation.

Activity and Sensitivity

Sponges do not possess neurons, a nervous system, or discrete adult sense organs (except for the oscula, see above), and nothing resembling the synaptic connections (or gap junctions) of most other Metazoa is known in these animals. Neuronal synapses, which provide for chemically mediated and directional nerve impulse transmission, do not occur in sponges (these occur in every metazoan phylum except Porifera and Placozoa).

Despite the absence of a nervous system, sponges are capable of responding to a variety of environmental stimuli by closure of the ostia or oscula, canal constriction, backflow, body contractions that flush the aquiferous system ("sneezing"), and reorganization of flagellated chambers. Acetylcholinesterase, catecholamines, and serotonin have all been shown to be present in sponges, and these probably play roles in coordinating "tissue" contractions, although electrophysiological evidence of a conducting mechanism is still lacking. Sponge larvae show both positive and negative phototaxis, depending on whether they are in their planktonic or settling phase. In larvae of the demosponge *Reniera*, there is a posterior ring of columnar monociliated epithelial cells with pigment-filled protrusions thought to be photoreceptors. In addition, the ability to conduct electrical impulses (when stimulated by an electrical probe) has been shown to exist in some Hexactinellida, where the absence of cellular membranes within the syncytium presumably allows action currents to spread in any direction from sites of depolarization. When the action currents reach choanocytes within the trabecular network, choanocyte activity is suppressed. In all sponges, the "default" behavior seems to be active pumping by the choanocytes to keep the aquiferous system functioning; and the usual effect of environmental stimuli is to reduce or stop the flow of water through the aquiferous system. For example, when suspended particulates become too large or too concentrated, sponges will respond by closing the incurrent openings and immobilizing the choanocyte flagella. Indeed, sponges have long been known to contract their ostia and oscula, and portions of their canal system, although the rates of propagation are very slow for most but not all. Lack of flow detected by sensory ciliated cells in the osculum can trigger a sneeze response, forcing water and particles to be expelled out of the sponge body. Direct physical stimulation will also elicit pumping pauses, which is easily observed by simply running one's finger across a sponge surface and observing the dermal pore or oscular contractions with a hand lens or low-power microscope. In addition, the mesohyl of some species has been shown to react to mechanical stimulation by stiffening.

Choanocyte pumping activity also varies with certain endogenous factors. For example, during a major growth phase, such as canal or chamber reorganization, choanocyte-pumping activity typically decreases. Periods of reproductive activity also cause a substantial decrease in water pumping, in part because many choanocytes are expended in the reproduction process (see the Reproduction and Development section). Even under normal conditions, variations in pumping rates occur. Some sponges cease pumping activity periodically, for a few minutes or for hours at a time; others cease activity for several days at a time—reasons for these changes in activity are not always apparent.

The switch from full pumping activity to complete cessation requires at least several minutes; considering the organism, however, this is a fairly fast response time. The spread of stimulation and consequent response in most sponges appears to be by simple mechanical action (stimulation from one cell to the adjacent cells) and perhaps also by diffusion of certain chemical messengers (hormones, or other kinds of signaling molecules) released by cells. The process by which cells communicate with other cells by secreting specific chemicals released into the surrounding extracellular matrix is called **paracrine signaling**, or a **paracrine system**, and some workers consider sponges to use this kind of cell–cell signaling.

The contractile myocytes of sponges act as independent effectors; they are organized into a network formed by contacts between filopodial extensions of adjacent myocytes and pinacocytes. Response time of myocytes is relatively slow. Latency periods average 0.01 to 0.04 sec, and conduction velocities are typically less than 0.04 cm/sec (except in the hexactinellids, where velocities of 0.30 cm/sec have been recorded).[8] Conduction is unpolarized and diffuse, and it may rely on both hormones (or other signaling molecules) and direct mechanical action of one cell on the next. Considerable research once focused on the myocytes in attempts to shed light on the possible presence of a sponge nervous system analogous to or homologous with that in other Metazoa. But, in spite of these efforts, there has been no verification of such a system.

Reproduction and Development

All sponges are capable of sexual reproduction, which is generally their primary reproductive strategy, but several types of asexual processes are also common. Many of the details of these processes are unknown, however, largely because sponges lack distinct or localized gonads (gametes and embryos can generally occur throughout the mesohyl). All hexactinellids, homoscleromorphs, and calcareous sponges are probably viviparous, as are most demosponges.

[8]It has been suggested that, in hexactinellids, the syncytium serves as an electrical conduction pathway, propagating impulses along its membranes that trigger flagellar arrests in the flagellated chambers.

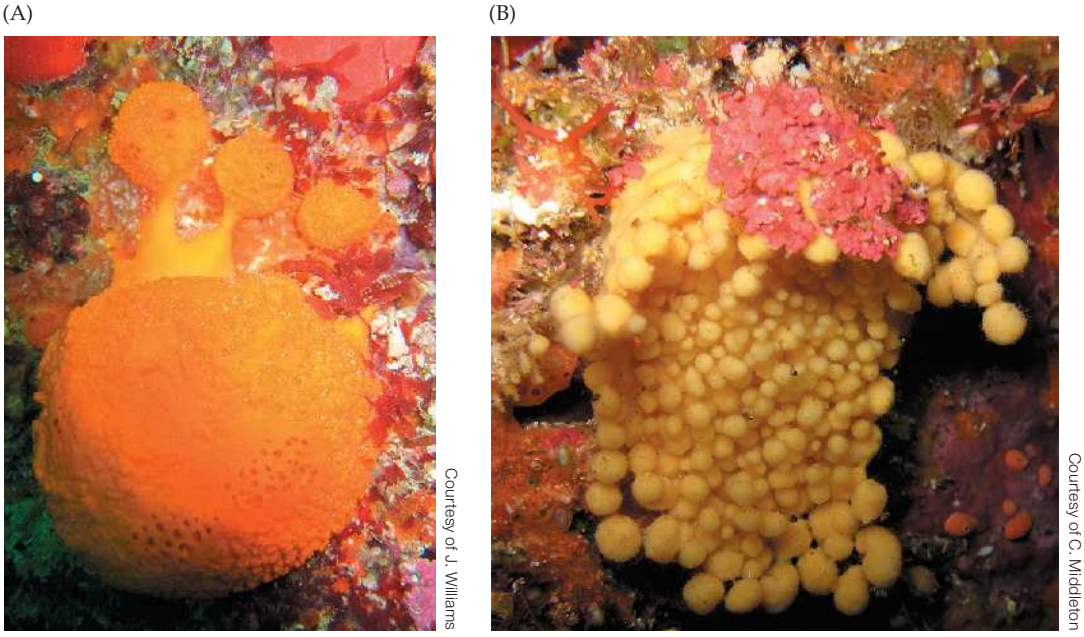

FIGURE 5.14 Budding in three demosponge species from New Zealand. (A) *Tethya burtoni*. (B) *Stelletta* sp. (C) *Tethya bergquistae*.

Asexual reproduction Probably all sponges are capable of regenerating viable adults from fragments. Many species "pinch off" buds of various types (Figure 5.14) by a process of cellular reorganization, whereas in others (especially branching species) pieces of the sponge body are simply broken off by storm surges. Either way, the dislodged pieces fall off and regenerate into new individuals. This regenerative ability was once commonly used by commercial sponge farmers, who propagated their sponges by attaching "cuttings" to submerged rocks or cement blocks. Even today, in Pohnpei (Federated States of Micronesia) sponge farmers string cuttings of *Coscinoderma mathewsi* (Keratosa) on lines in lagoons, growing them into large bath sponges. Additional asexual processes of poriferans include formation of gemmules and reduction bodies, budding, and possibly formation of asexual larvae.

In freshwater sponges, small spherical structures called **gemmules** are produced at the onset of winter (Figure 5.15). These dormant, overwintering bodies are invested with a thick collagenous coating in which supportive siliceous microscleres (**gemmoscleres**) are embedded. Gemmules are highly resistant to both freezing and drying. The gemmules of some species can withstand exposure to –70°C for up to an hour, whereas others experience mortality at –10°C. Experiments suggest that gemmules of at least some species can also withstand seasonal anoxic conditions. Fossil gemmules have been found as far back as the Cretaceous, and these ancient forms are very similar to modern ones. Gemmule morphology is highly specific and is used diagnostically at the family, genus, and even species levels. Three of the six freshwater sponge families do not produce gemmules: Lubomirskiidae and Metschinkowiidae (both known only from the Caspian Sea and Lake Baikal) and Malawispongiidae (from the ancient lakes of Africa's Great Rift Valley, through the Middle East, and to Sulawesi Island in the Indian Ocean).

The formation and eventual growth of gemmules are remarkable examples of poriferan cell totipotency. As winter approaches, archaeocytes aggregate in the mesohyl and undergo rapid mitosis. "Nurse cells," called trophocytes, stream to the archaeocyte mass and are engulfed by phagocytosis. The result is a mass of archaeocytes containing food reserves stored in elaborate vitelline platelets. This entire mass eventually becomes surrounded by a three-layered spongin

covering. Developing gemmoscleres, **amphidisc spicules** (spicules having a stellate disk at each end) in most species, are transported by their parent cells to the growing gemmule and incorporated into the spongin envelope. The final bit of the gemmule to be enclosed by the spongin case is covered only by a single layer of spongin that is devoid of spicules; this single-layered patch is the micropyle. Thus formed, hibernation of the gemmule commences, while the parent sponge usually dies and disintegrates—such species can be thought of as "annuals."

When environmental conditions are again favorable, the micropyle opens and the first archaeocytes begin to flow out (Figure 5.15C). They immediately flow onto the substratum, whereupon they begin to construct a framework of new pinacoderm and choanoderm. The second wave of archaeocytes to leave the gemmule colonizes this framework. In the course of gemmule "hatching," and in an impressive example of cellular totipotency, archaeocytes quickly give rise to every cell type of the adult sponge. Gemmule dormancy appears to be of two types, a quiescence and a true diapause. Quiescence is imposed by generally unfavorable conditions, including low temperatures, and it ends when suitable conditions return. Diapause, on the other hand, typical of annual species, is imposed by a combination of endogenous mechanisms and adverse environmental conditions. The breaking of a diapause state typically requires exposure to very low temperatures for a prescribed number of days. This phenomenal ability of freshwater sponges to develop from quiescent gemmules that

are easy to store in the laboratory has been and continues to be exploited by researchers to understand many biological processes that might otherwise be very difficult to reproduce in the lab.

Many marine species produce asexual reproductive bodies (called **reduction bodies**) that are roughly similar to freshwater gemmules, though much simpler in design and cell wall structure, and these incorporate a variety of amebocytes. And in several genera of marine sponges (e.g., *Haliclona, Chalinula*), asexual reproductive bodies very similar to gemmules are formed, with a spongin coat containing spicules (oxeas).

Sexual processes Sponges express an extreme variability of reproductive and developmental strategies. Many are hermaphroditic; some typically produce eggs and sperm at different times, but others do both simultaneously. Sequential hermaphroditism may take the form of protogyny or protandry, and the sex change may occur only once, or an individual may repeatedly alternate between male and female. In some species, individuals appear to be permanently male or female. In still other species, some individuals are permanently gonochoristic, whereas other individuals in the same population are hermaphroditic. In all cases, cross-fertilization is probably the rule.

Embryogenesis in sponges shares many cardinal features with other Metazoa, including the uniquely metazoan process of programmed cleavage and tissue layering through the process of embryonic morphogenesis that we regard as true gastrulation. However, sponge embryogenesis also expresses great variability. In fact, the range of ontogenetic adaptation among sponges is so broad that it is difficult to generalize about their development. The same cleavage pattern and blastula type may lead to several different larval types, and the same larval types may develop from different cleavage patterns.

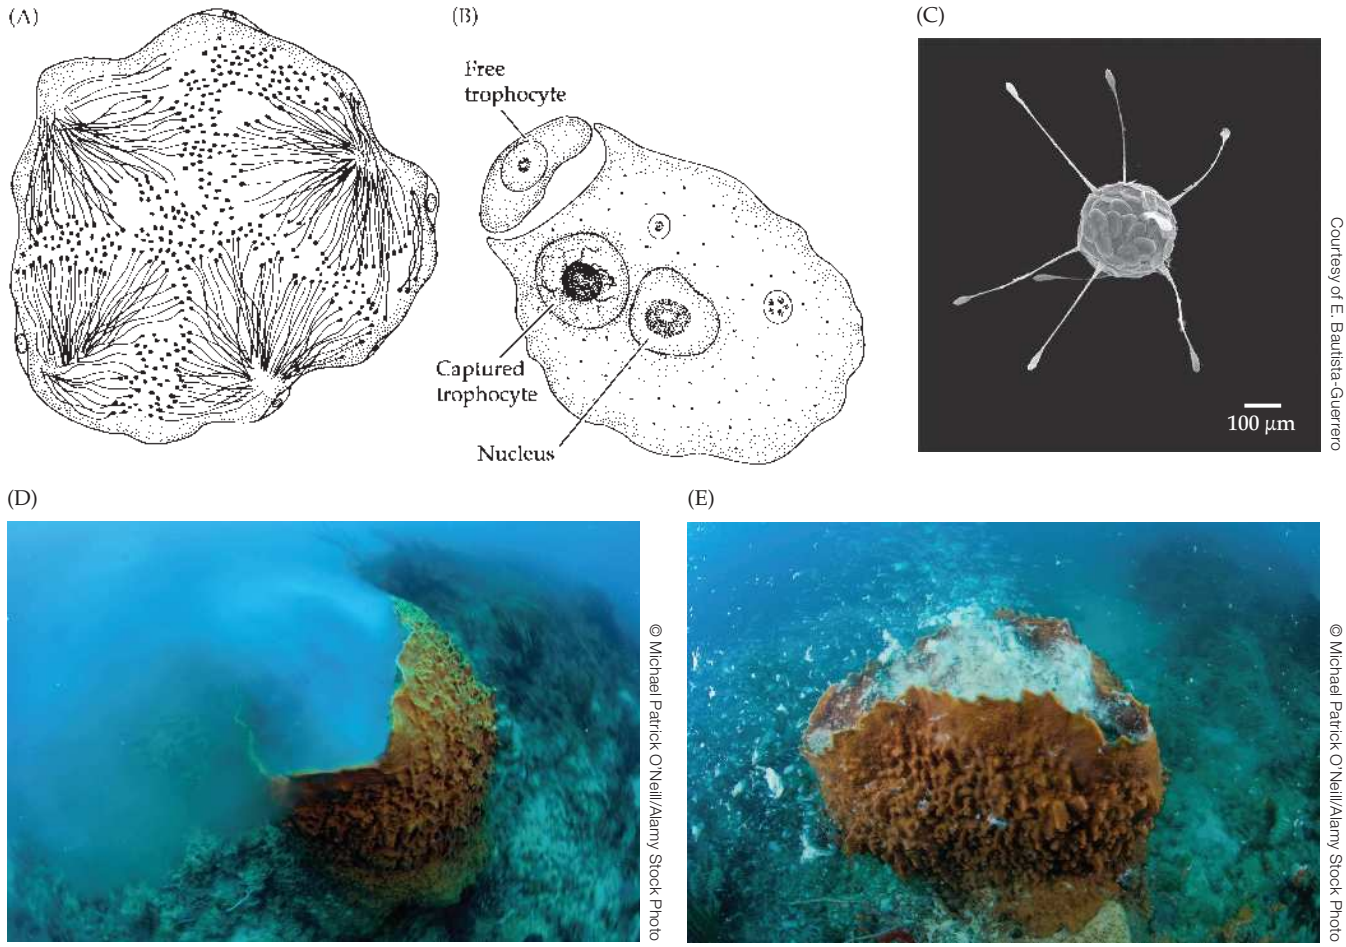
Sperm appear to arise primarily from choanocytes or archaeocytes in hexactinellids; eggs from choanocytes or archaeocytes. Spermatogenesis usually occurs in distinct **spermatic cysts** (= **sperm follicles**), which form either when all the cells of a choanocyte chamber are transformed into spermatogonia, or when transformed choanocytes migrate into the mesohyl and aggregate there (Figure 5.16A). During oogenesis, solitary oocytes typically develop in the mesohyl or within cysts surrounded by a layer of follicle cells and, sometimes, nurse cells (**trophocytes**) (Figure 5.16B).

In Demospongiae and Calcarea, mature sperm and (in the case of demosponge oviparity) oocytes are released into the environment through the aquiferous system. The rapid release of sperm from sponge oscula can be highly visible and quite dramatic in large specimens, and such individuals are often referred to as "smoking sponges" (Figure 5.16D). Sperm release may be synchronized in a local population or restricted to certain individuals. Fertilization takes place in the water (oviparity) leading to planktonic larvae, or within the female sponge itself (viviparity). In the viviparous coral-boring sponge *Cliona vermifera*, each zygote inside the sponge body becomes encapsulated; these are eventually released into the water in a series of rapid pulsations of the aquiferous system. In viviparous species, sperm (probably from a different individual) are taken into the aquiferous system and then must cross the cellular barrier of the choanoderm, enter the mesohyl, locate the oocytes, penetrate the follicular barrier, and finally fertilize the egg. In all studied species of the subclass Calcaronea, and some homocleromorphs, this impressive feat involves sperm capture by choanocytes and enclosure in an intracellular vesicle (somewhat like the formation of a "benign food vacuole"). The choanocyte then loses its collar and flagellum and migrates through the mesohyl as an ameboid cell, transporting the sperm to the oocyte (Figure 5.17A). The migratory choanocyte is called a **carrier cell**, or **transfer choanocyte** (Figure 5.17B). Choanocytes no doubt regularly consume and digest the unlucky sperm of different species of sponges and other benthic invertebrates, but by some as yet undescribed recognition mechanism, they respond with a remarkably different behavior to sperm of their own kind. Presumably this process is directed by cell surface proteins/glycoproteins. In the demosponge group Poecilosclerida, another remarkable fertilization mechanism has been proposed for *Crambe crambe*, in which a highly modified sperm cell with an elongate and highly bent body is thought to pierce the female epithelium and swim through the collagenous mesohyl hunting the oocytes. Also in Poecilosclerida, the carnivorous cladorhizids had to adapt their reproduction to the absence of an active aquiferous system. Sperm is therefore encysted in complex structures resembling floating planktonic larvae that are later captured by the mother sponge, whereupon the sperm are released and also swim through the mesohyl looking for the oocytes.

In viviparous species, embryos are typically released as mature swimming larvae, either via the excurrent plumbing of the aquiferous system or

FIGURE 5.16 Sexual reproduction in Demospongiae. ▶ (A) Sperm follicle (in section) containing mature spermatozoa. (B) An oocyte (in section) of *Ephydatia fluviatilis* is phagocytizing a trophocyte. Inside the oocyte is a trophocyte that was recently ingested. (C) The unusual armored "hoplitomella larva" typical of boring sponges in the genus *Thoosa*. The armoring consists of flat plates that are actually highly modified spicules (called "discotrienaenes"). The long fibers emerging from the larva are also modified spicules that presumably aid in flotation. (D) Sperm release from *Xestospongia muta*, Florida. (E) Oocyte release in *Xestospongia muta*, Florida.

for more ebook/ testbank/ solution manuals requests: email 9601267346@qq.com



through a rupture in the parent's body wall. Larvae may settle directly, they may swim about for several hours or a few days before settling, or they may simply move about the substratum until ready to attach. In all sponge species that have been studied, the larvae are lecithotrophic. In general, littoral sponges tend to produce planktonic larvae, whereas the larvae of subtidal species tend to settle directly or move about on the ocean floor for a few days before beginning to grow into a new adult individual.

Until very recently, cases of hybridization across different sponge species were unknown, although long suspected. Even though gamete recognition proteins are surely part of the barriers that sponges have in order to prevent cross-fertilization by different species, in very closely related species such

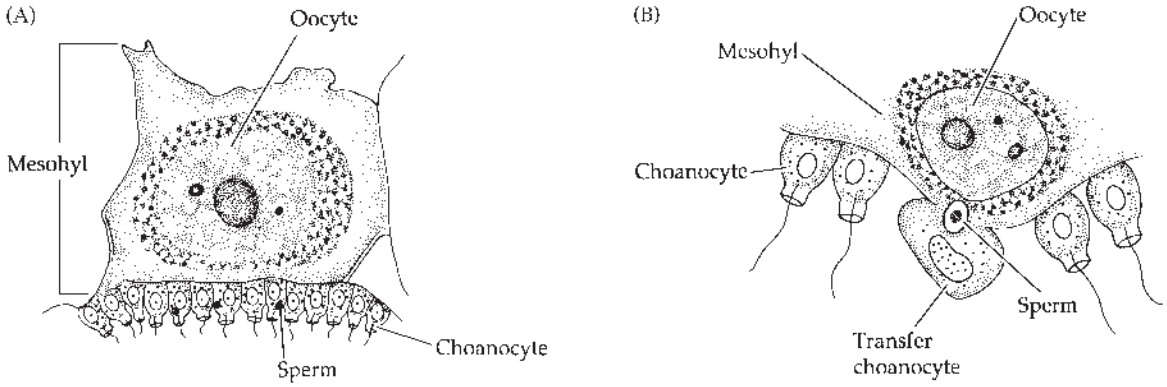


FIGURE 5.17 Fertilization in the calcareous sponge. (A) Sperm are trapped by choanocytes; an egg is lying in the mesohyl adjacent to the choanoderm. (B) A transfer choanocyte gives up its sperm to the egg; note that the egg lies next to the choanoderm and that the choanocyte has lost its flagellum.

barriers perhaps are not powerful enough to avert fusion of gametes. Such was the case of the sister species *Ircinia variabilis* and *I. fasciculata*, where asymmetric gene flow during hybridization was detected predominantly from *I. fasciculata* to *I. variabilis* using several microsatellite markers. Such a phenomenon is unlikely to be an isolated case, and with the advent of high-throughput sequencing, the coming years will probably see a massive flow of evidence proving hybridization across many groups of Porifera.

Embryogenesis and larvae Until fairly recently, larval development in sponges was surrounded by a great deal of mystery, partly because it had not been well studied and partly because huge variation exists. The broad array of blastulation/gastrulation processes and larval types seen in sponges is mind boggling, and many different, but distinct, larval types have been described. In fact, a number of embryogenic pathways occur in sponges that have not been observed in any other Metazoa (e.g., multipolar egression in Homoscleromorpha, polarized delamination in some demosponges). Since the 1990s, significant new work has altered our view of development in this phylum, although many questions still remain. The diversity of sponge developmental pathways is remarkable, and in some instances the same cleavage pattern and blastula type may be characteristic of several different larval types. On the other hand, the same larval type may arise from very different cleavage patterns. For example, the parenchymella larva of *Reniera* (Demospongiae: Haplosclerida) develops as a result of chaotic (seemingly unpatterned) cleavage and multipolar delamination, whereas the parenchymella larva of *Halisarca* (Demospongiae: Halisarcida) arises by polyaxial cleavage and multipolar ingression.

Much of the confusion surrounding sponge embryogenesis has centered on the question of when gastrulation occurs. Many older studies had reported that, during larval development, the external ciliated cells lost their cilia and migrated internally, whereupon they differentiated into adult choanocytes. These studies suggested that larvae formed in this way represented the blastula stage, with later gastrulation coinciding with larval metamorphosis. Such embryonic processes, producing blastular larvae, would make sponges unique among metazoans. However, recent work suggests that this report of migration/inversion of cell layers during larval development was probably a misinterpretation in most if not all cases, and in fact sponge larvae probably represent post-gastrulation-stage individuals (as with most other metazoan larvae). Cell migrations such as these do occur in some poriferans, but only *after* embryogenesis has formed a fully differentiated bilayered or trilayered larva, and such cell movements are thus not related to gastrulation. It now seems that most, if not all, sponge larvae derive from cellular reorganization that can be equated (though not necessarily with step-by-step homologies) with gastrulation processes seen in other metazoans. Thus, gastrulation precedes the larval stage, and probably no sponge larvae represent a blastula stage.[9]

Specialists have long wondered what the original, or ancestral, cleavage pattern in sponges (and

[9]The question of whether or not, and when, gastrulation occurs in sponges has long been debated. In fact, it depends on how one defines "gastrulation." Some workers define gastrulation simply as the epithelialization of embryos, thus clearly indicating sponges undergo gastrulation. Other workers define it as the embryogenic process through which metazoan ectoderm and endoderm, and a gut, are derived; but, of course, sponges have no guts and their inner and outer cell layers appear not to be homologous with the epithelia of higher metazoans, and on this basis one could argue that gastrulation does not occur in Porifera. Spongologists following this line of logic refer to "embryonic morphogenesis" rather than "gastrulation." Still others have defined poriferan gastrulation as the process of metamorphosis from larva to adult, when the choanocyte chambers are formed. In this book, we define gastrulation (in the general sense) as the reorganization of cells of the blastula to form multiple embryonic germ layers—the tissues upon which all subsequent development depends. Gastrulation, in most cases, creates the separation of those cells that must interact directly with the environment, and those cells that process materials taken in from the environment. Thus, gastrulation is a keystone, defining feature of the Metazoa. By our definition then, gastrulation in sponges takes place during formation of the larva, when the first germ layers are laid down, regardless of the process. It is worth noting, however, that the absence of solid cell–cell adhesion, and the ability of sponge cells to become mobile, might argue against true gastrulation in sponges because there is not necessarily conservation of cells in specific germ layers.

Interestingly, the term "gastrulation" derives from the name given by Ernst Haeckel (in 1872) to a stage in the development of calcareous sponges; in his **gastrula** stage, a ciliated egg-shaped larva settled to the benthos and, according to Haeckel, formed a "mouth and a gut." Haeckel claimed that the gastrula stage could be found in the development of all animals and thus represents the recapitulation of the ancestral metazoan, a hypothetical ancestor he called the **gastraea**—a diploblastic animal with a ciliated gut. This recapitulation, he argued, was proof that the Metazoa are monophyletic. Until recently, only one other observation of Haeckel's "gastrula" stage in calcareous sponges had been made, by the German philosopher and biologist Ernst Hammer, in 1908. And yet, "gastrulation by invagination" has been widely conceived, for over 100 years, to be the ancestral mode of germ layer formation in animals. The conundrum, of course, is that we now know sponges don't form a typical metazoan gut, so the transient cavity formed by invagination during settlement cannot represent a future gut. The outstanding sponge biologist Sally Leys has recently shown that what Haeckel (and later Hammer) witnessed was a very brief transitory stage in which the anterior cells of a settled calcareous sponge larva invaginate into the posterior half of the larva. However, the "invagination hole" closes completely and it is not until some days later that the sponge forms an osculum (not a gut!) at its apical pole. Hence, there is no reason to assume that this transitory "gastrula" stage is a precursor for formation of a gut via invagination in higher animals. Further, it is the earlier formation of the two cellular regions of the larva that comprises the actual gastrulation event (whereas metamorphosis upon settlement involves the reorganization of these already differentiated regions).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Metazoa) might be—most researchers would probably vote for radial cleavage, and indeed this form of cleavage is seen in many demosponges, although it is not known from any other sponge class. At least three other forms of holoblastic cleavage have been described: chaotic (also known as "anarchic") cleavage, table palintomy, and polyaxial cleavage. **Chaotic cleavage** (seemingly random, or unpatterned) is characteristic of many demosponges. In **table palintomy**, the cleavage furrows pass obliquely relative to the egg's animal–vegetal axis; this form of cleavage occurs in some calcareous sponges (Calcaronea). It is also reminiscent of the green algal genus *Volvox* and several other colonial protists. However, the Calcaronea also undergo an utterly unique process of inversion of the blastula, and this has led some workers to suggest that palintomy is an aberrant cleavage process. **Polyaxial cleavage** is characteristic of the genus *Halisarca* and possibly also the Calcinea (Calcarea). It is characterized by cleavage furrows that form perpendicular to the surface of the embryo during the transition from the 8- to the 16-cell stage, with axes of symmetry that radiate at certain angles from the center of the embryo; however, after the 16-cell stage, division becomes chaotic.

Although sponge embryogenesis is highly variable, all species go through an ordered sequence of blastomere divisions and movements leading to morphogenesis of larval tissue structures (which we consider to be gastrulation) and formation of a larval axis that is often referred to as an anterior–posterior axis. Spongiologists have so far recognized at least seven types of sexual development in sponges, though continued research may reveal even more. These seven types are recognized by their resultant larval forms: (1) trichimella (Hexactinellida), (2) calciblastula (Calcarea: Calcinea), (3) amphiblastula (Calcarea: Calcaronea), (4) cinctoblastula (Homoscleromorpha), (5) disphaerula (Demospongiae: Halisarcidae), (6) direct development (Demospongiae, Tetractinellida, *Tetilla*), and (7) parenchymella (most Demospongiae). These seven developmental pathways are depicted in Figure 5.18 and described below. The anterior flagellated end of swimming sponge larvae (e.g., amphiblastula, cinctoblastula, parenchymella; Figure 5.19) putatively corresponds to the animal pole of other metazoan larvae, and it is this larval region that gives rise to the internal choanoderm, while ameboid cells at the posterior end generate the outer layer (pinacoderm) of the adult sponge.

Homologues of metazoan developmental genes are just beginning to be described from Porifera, but many more should be revealed soon with the recent sequencing of "complete genomes" for two heteroscleromorph demosponges, *Amphimedon queenslandica* and *Ephydatia muelleri*. Already, a diversity of metazoan homeobox genes have been identified in sponges, and in *A. queenslandica* a broad range of transcription factor gene classes, many of which appear to be metazoan specific, are expressed during development. However, the possible homologies of adult sponge tissues with metazoan endoderm and ectoderm remain quite uncertain, and for this reason the terms "gastrodermis" and "epidermis" are used for sponges to avoid implications of embryological homology (and the inner mesohyl layer certainly does not appear to be homologous with the mesoderm of triploblastic Metazoa). This inability to directly homologize sponge tissues with those of other Metazoa is one of the reasons some workers reject use of the term "gastrulation" for Porifera. With the exception of the homoscleromorphs, typical epithelial anatomy (with underlying basal lamina) appears to be lacking in sponges. The ability of pinacocytes to migrate into the mesohyl and convert to other cell types has also argued against considering this layer to be true ectodermally derived epithelium (the motility of pinacocytes has been ascribed to the general absence of specialized desmosomal junctions among these cells).

Because there is so much variation in sponge developmental processes, each class is reviewed separately here.

Calcarea So far as is known, all calcareous sponges are viviparous. In the subclass Calcinea, oocytes develop within the mesohyl and grow in size (by phagocytizing neighboring amebocytes). Embryos also develop in the mesohyl, and cleavage is total and equal to produce a hollow blastula larva (coeloblastula). The coeloblastula of some species has two types of cells: ciliated outer cells, and one or two posterior granular cells. After larval release, and just prior to larval attachment to the substrate, in some species, some cells lose their cilia and ingress into the blastocoel via ingression.

In the subclass Calcaronea, oocytes differentiate from choanocytes and move into the mesohyl. After a period of growth, they migrate to the periphery of the sponge. Cleavage is total and equal, and the first three divisions are meridional. The fourth division (at least in *Leucosolenia*) is oblique, almost exactly like the cleavage in the colonial green alga *Volvox*—a type of cleavage referred to as table palintomy (see above). The resulting embryo is a cup-shaped blastula, with a small opening at the side closest to the choanoderm. While most of the cells continue to cleave in the same manner, forming a single-layered epithelium, a few that lie directly under the choanoderm do not; these remain much larger than the other cells, with their cytoplasm filled with large yolk granules. The most unusual feature of the calcaronean embryo is that cilia, which

differentiate on the micromeres, project into the center of the blastocoel (inverted, compared with those in all other sponge embryos); this stage is called a **stomoblastula** (Figure 5.20B–D). To reach the final orientation, the embryo actually turns itself inside out. To do this, the ciliated blastomeres move upwards and through the opening as a "single epithelium," into the choanocyte chamber (much as a bag is turned inside out). The resulting larva is an **amphiblastula** (Figure 5.20E), composed of anterior ciliated cells, posterior granular cells, and inner nutritive amebocytes.

The free-swimming amphiblastula larva of *Sycon* (class Calcaronea) exits the parent sponge via the osculum and settles within 12 hours, attaching by its cilia, which are thought to be adhesive (probably via glycoproteins on the cell surface). In some cases, the larva settles on its anterior end, on the hole left from the earlier invagination event. The hole is thus unrelated to the future osculum (nor is it a primitive "mouth" of any kind); it is, in fact, engulfed by the newly forming epithelium of the metamorphosing larva. Thus, the transient cavity that is formed by invagination is not the future osculum of the sponge, as Ernst Haeckel long ago intimated, and this invagination does not represent gastrulation. Once settled, the larva quickly undergoes metamorphosis into a juvenile (sexually immature) sponge.[10] During metamorphosis, the anterior cells lose their cilia and migrate in to form an inner cell mass; some of these cells differentiate into choanocytes, while others remain ameboid. Metamorphosis of this larva seems to involve a rapid proliferation of the "macromeres" to form pinacoderm that overgrows the flagellated hemisphere. The flagellated cells pocket inward to form a chamber lined with cells destined to become choanocytes (Figure 5.20F). An osculum breaks through, and the tiny asconoid-like sponge becomes capable of circulating water and feeding. This initial functional stage is called an **olynthus** (Figure 5.4A). After further growth, it will become an asconoid, syconoid, or leuconoid adult, depending upon the species.

Hexactinellida Because reproductive individuals in this class are rarely encountered, and most species live in deep water, almost all of our knowledge on

[10]This is the stage that Ernst Haeckel focused upon as the root of gastrulation. Haeckel, however, mistook the amphiblastula for a bilayered planula larva and claimed a number of observations that have never been repeated. It is likely that the microscopical tools that Haeckel had were simply insufficient to resolve the rapidly unfolding changes during embryogenesis and metamorphosis in *Sycon*.

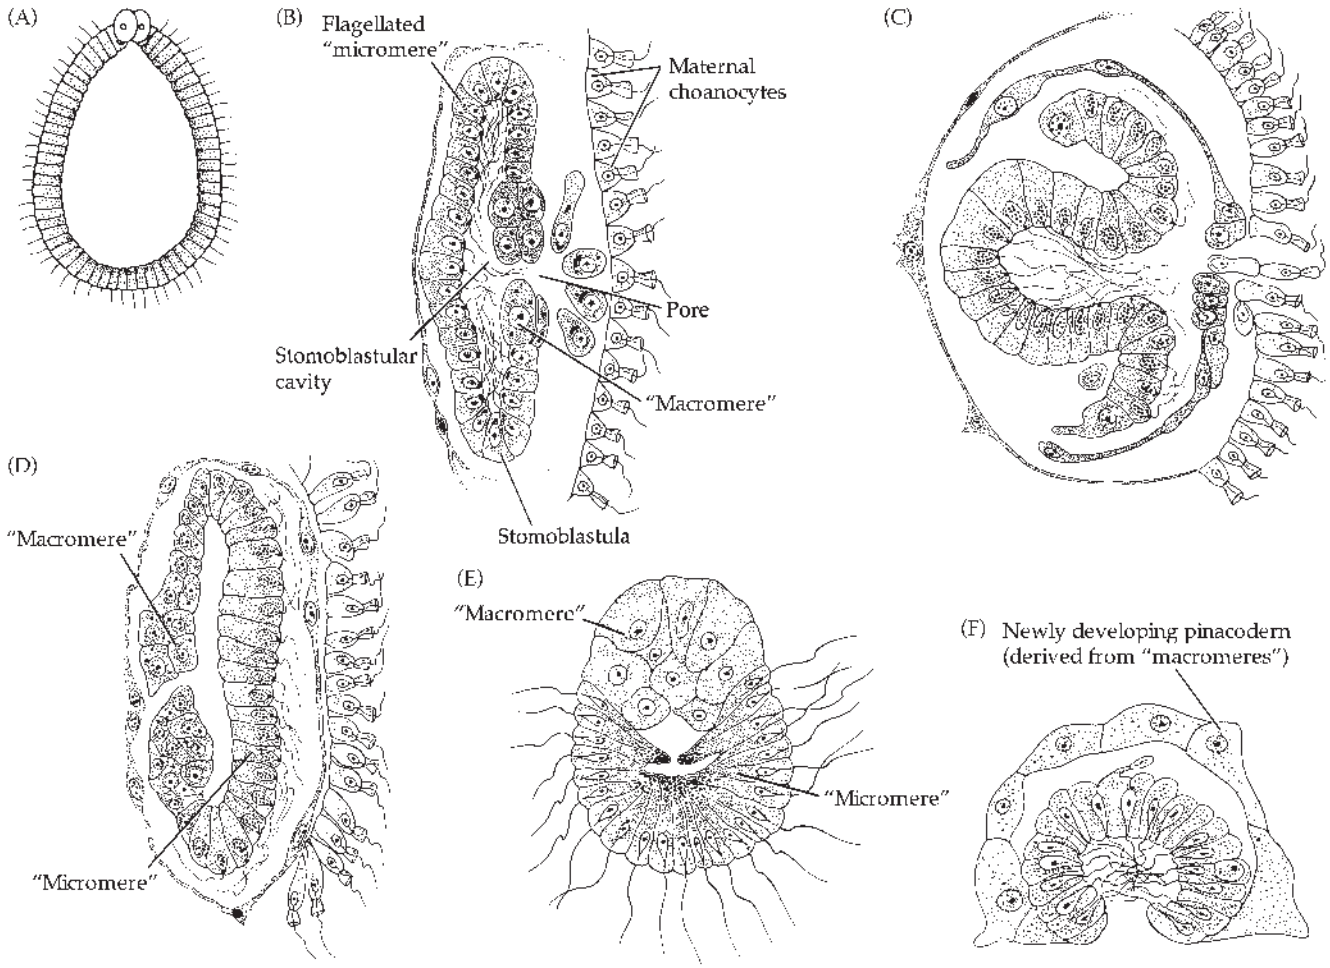

FIGURE 5.20 "Coeloblastula" and amphiblastula larvae (in section). (A) Typical "coeloblastula" larva with its posterior "macromeres." (B–D) During the remarkable process of inversion in *Sycon*, the stomoblastula turns itself inside out to form an amphiblastula larva with externally directed flagella. (E) A typical amphiblastula larva (*Sycon*). (F) Settled young sponge (*Sycon*) after invagination of flagellated cells.

development comes from a few small cave-dwelling species that are accessible by scuba. Although based upon studies of only a few species, a general overview of glass sponge development is as follows. Hexactinellids are probably all viviparous. Gametes arise from groups of archaeocytes that are suspended within the trabecular reticulum (since choanocytes are anucleate). Each archaeocyte cluster is called a **congery**, and all the cells are connected by cytoplasmic bridges (although mature oocytes are independent cells). It is not yet known how sperm find oocytes or how fertilization occurs. Cleavage to the 32-cell stage is total, equal, and asynchronous. The first cleavage is generally meridional, and the second either equatorial or rotational. By the 16- and 32-cell stages, the embryo is a hollow blastula. The following cleavages are unequal, producing smaller micromeres that lie on the outside and larger yolk-rich macromeres on the inside. The macromeres divide unequally, gradually filling the center of the blastocoel, and eventually they envelop the micromeres with massive filopodia. Uniquely, these cells then fuse to form a single multinucleated giant tissue, the new trabecular syncytium, which completely envelops the micromeres. In this way, the embryo gains its outer epithelium. The formation of micromeres was originally considered to represent gastrulation by cellular delamination. However, the epithelialization of the larva—the enveloping of the micromeres by the incipient trabecular reticulum—is probably better viewed as the true gastrulation event. The fully differentiated hexactinellid larva is a **trichimella** (Figure 5.18). The major tissue of the larva is the syncytial trabecular reticulum, continuous throughout the larva, including its surface "epithelium." After swimming for one to several days, the larva settles on its anterior, lipid-filled pole and undergoes metamorphosis. The flagellated cells of the trichimella are multiciliated, a condition unique among sponges.

Demospongiae The class Demospongiae is large and diverse—without an easily characterized or uniform developmental pattern. Detailed recent embryological

for more ebook/ testbank/ solution manuals requests: email to 2601267346@qq.com

studies have been accomplished for only a dozen or so of the 7,600 described species. Both viviparity and oviparity occur in this class. Development is highly varied among the orders, families, and genera and, in some cases, even within single species. Spermatocytes may develop in special cysts within the mesohyl, and in most demosponges these derive from choanocytes. Oocytes may be isolecithal or telolecithal, and they usually arise from archaeocytes in the mesohyl—although in the family Lubomirskiidae (freshwater sponges in Lake Baikal) they are thought to derive from choanocytes—and they may be accompanied by yolk-rich nurse cells, or follicular cells, that form a thick coating around them, the yolk being incorporated into the cytoplasm of the oocytes. Spawning of eggs and sperm has been linked to lunar cycles in some species, as in many other invertebrates. Fertilization is usually external, either in the water column or in the excurrent canals where eggs are released.

Cleavage appears to be complete, equal or unequal, often chaotic, and (at least in some species) produces micromeres and macromeres. Micromeres develop a cilium, and eventually both macromeres and micromeres segregate out until the ciliated micromeres cover the periphery of the embryo (a process termed multipolar delamination). At this point, the embryo may be a solid blastula (stereoblastula) or a coeloblastula (although the central cavity may be filled with bacteriocytes and small granular cells of the follicle layer). Many species appear to produce parenchymella larvae that are polarized and possess a ciliated outer layer. Settlement seems to occur quickly, and in some species the eggs are released in a mucus mass and a planktonic larval stage is absent (larvae develop upon the substratum near the parent sponge).

Among the Demospongiae, the genus *Halisarca* stands out in several ways. It completely lacks a skeleton and has mixed developmental pathways (that have been studied for over 100 years). Most or all species are gonochoristic and viviparous. Spermatocytes originate from choanocytes. Oocytes also derive from choanocytes, and during vitellogenesis symbiotic microbes characteristic of the mesohyl of adults are incorporated into the oocyte. Cleavage is total and equal, producing a hollow blastula. In many cases, cells invade the blastocoel by both multipolar and unipolar ingression. Cilia appear on the external cells of the 32- to 64-cell-stage blastula, while internal cells differentiate to become archaeocytes. At this point, things get strange, because three very different kinds of larvae can now develop, even within the same individual parent sponge. The first is a coeloblastula, with a single layer of surface cells surrounding a small lumen. The second is a parenchymella that has an outer layer surrounding an inner cell mass of ameboid cells. The third has two layers of epithelial cells, one external and the other internal, that line a small lumen; this type of larva is called a disphaerula. All three types are polarized by external patterns of ciliation, and all swim by rotating in a left-handed direction.

Homoscleromorpha The eggs of homoscleromorphs are isolecithal, rich in yolk inclusions, and completely surrounded by a follicle formed of parental endopinacocytes and, once they are fertilized, symbiotic bacteria. Cleavage is holoblastic and equal. During the first divisions, bacteria colonize the cleavage furrows and are incorporated into the cleaving embryo. At the third division, cleavage becomes irregular and asynchronous, and it proceeds to form a solid morula of undifferentiated yolk-rich blastomeres. At about the 64-cell stage, the outer layer of the morula begins to differentiate. The blastomeres close to the surface divide more actively, while the internal cells migrate to the periphery of the embryo to gradually form a monolayered larva with a central cavity that contains symbiotic bacteria and maternally secreted cells. The resulting embryo is a hollow coeloblastula, and as the outer layer differentiates, the cells grow cilia. So far as is known, the centrifugal migration of cells from the center to the periphery of the morula, to form the coeloblastula, is unique not only within Porifera but for all of Metazoa. This unusual process has been termed **multipolar egression**. The ciliated cells of the outermost layer become elongate (columnar) and are closely linked by desmosome-like junctions.

Loose collagen fibrils fill most of the internal cavity as the coeloblastula matures into a larva. However, immediately below the outermost cell layer there develops a tough extracellular matrix of consolidated collagen fibrils, and beneath that there is a second layer of more loosely consolidated collagen fibrils. These two layers of collagen constitute a basement membrane similar to the one found below the pinacoderm and choanoderm of adult homoscleromorphs. (A similar network of extracellular matrix has been described from beneath the larval epithelium of one demosponge larva.) The outermost cell layer of homoscleromorph larvae is a true epithelium, homologous with that seen in adult sponges and in other Metazoa, its cells being columnar and producing a basement membrane/basal lamina.

As development continues, the central cavity is progressively filled by collagen fibrils (along with the symbiotic bacteria) and the larval epithelium becomes regionally differentiated, giving the larva a polarity that most regard as truly anterior–posterior. The homoscleromorph larva was originally called an "amphiblastula" because it was thought to possess two fairly distinct regions, one ciliated and the other not. However, morphogenesis in sponges of this group is not at all like that of sponges in the Calcaronea (a group for which the amphiblastula larva is characteristic), and the larvae are in fact completely ciliated. Thus it was suggested that the homoscleromorph larva be called a **cinctoblastula**, a

term which more accurately describes its distinctive feature of paracrystalline intranuclear inclusions that form a belt around the posterior end. The free-swimming cinctoblastula larva is ovoid or pear shaped, wider at the anterior end than the posterior pole, and the entire surface is ciliated. All larvae that have been observed swim with a left-handed rotation.

Some Additional Aspects of Sponge Biology

Some basic sponge ecology has been presented in the previous sections of this chapter. However, because sponges play such important roles in so many marine habitats, and because they are intrinsically interesting in their phylogenetic "primitiveness," we add here some additional aspects of their natural history.

Distribution and Ecology

Certain distributional patterns are evident among the four classes of sponges. Calcareous sponges (and coralline demosponges) are far more abundant in shallow waters (less than 200 m), although they are not uncommon at slope depths, and a few species (particularly in the genus *Sycon*; Figure 5.1B) have even been reported from depths to 3,800 m. Hexactinellids, which were common in shallow seas of past eras, are now largely restricted to depths below 200 m, except in extremely cold environments (such as western Canada and Alaska, New Zealand, and Antarctica), where some species occur in shallow waters. Demosponges live at all depths, whereas homoscleromorphs occur from the continental shelf to around 1,000 m depth. Calcareous and homoscleromorph sponges may be restricted largely to shallow waters because they require a firm substratum for attachment. On the other hand, many demosponges and hexactinellids grow on soft sediments, attaching by means of rootlike spicule tufts or mats. The coralline sponges, once a predominant group on shallow tropical reefs, are now largely restricted to shaded crevices and caves, to subreef depths, or to warm-temperate waters where their potential competitors (the hermatypic corals) cannot grow (Figure 5.1L). They are thought to be relicts of major reef-constructing sponge clades of Mesozoic and Paleozoic seas.

Although sponges are very sensitive to suspended sediment in their environment, they seem to be quite resistant to hydrocarbon and heavy metal contamination. Many species can actually accumulate these contaminants without apparent harm, and these may be seen, for example, in the ferric granules on the spongin skeleton of fibrous bath sponges from intertidal regions. The capacity of certain species to accumulate metals at far higher levels than that of the ambient environment has been suggested as a possible defense mechanism (antipredation, antifouling). Detergents also do not appear to affect many sponges and, in fact, may even serve as a source of nutrition for these amazingly adaptable animals.

Sponges are the dominant animals in a great many benthic marine habitats. Most rocky littoral regions harbor enormous numbers of sponges, and they often occur in vast numbers (and large sizes) around Antarctica. Although many animals prey on sponges, the amount of serious damage they do is usually slight. Some tropical fishes (e.g., some angelfish) and turtles (e.g., hawksbill turtles) crop certain kinds of sponges, a number of sea stars and shelled gastropods are sponge predators, and smaller predators (mainly heterobranch gastropods that closely match the prey sponge's color) consume limited amounts of living sponge material in both warm and temperate seas. Overall, however, sponges appear to be very stable and long-lived animals, perhaps in part due to their spicules and toxic or distasteful compounds that discourage would-be predators.

Anthropogenic pressures affect sponges in many ways, including by reducing their habitat, warming seawater to temperatures that allow sponge pathogens to thrive, and reducing sponge populations by overfishing (in the North Atlantic, fishing-ground sponge bycatch can sometimes be many tons). Studies of the impact of global warming on temperate and Antarctic sponges have found high thermal tolerances in their transcriptional (molecular) responses and remarkable acclimation patterns after relatively short exposures to high temperatures. Perhaps their relatively high tolerance to global warming, compared with that of corals, is one thing giving tropical sponges an advantage in the reef ecosystems of the Caribbean, where they are now largely dominant. We may be approaching a scenario where we must call them sponge reefs!

Biochemical Agents

Seashore explorers and scuba divers quickly notice that sponges are just about everywhere. Most grow on open rock or occasionally mud surfaces, where they are obviously exposed to potential predation. Clearly, some mechanism(s) must be working to prevent these animals from being cropped excessively by predators. The primary defense mechanisms in sponges are mechanical (skeletal structures) and biochemical. Studies have also shown that sponges manufacture a surprisingly broad spectrum of biotoxins, some of which are quite potent. A few, such as the heteroscleromorphs, *Tedania* and *Neofibularia*, can cause painful skin rashes in humans. Whether these toxins are produced by the sponges or their symbiotic bacteria is still a topic of much research.

Research in sponge biochemistry has also revealed the widespread occurrence of antimicrobial agents in sponges. Sponges appear to use "chemical warfare," not only to reduce predation and prevent infections,

for more ebook/ testbank/ solution manuals requests: email to 2601267346@qq.com

but also to compete for space with other invertebrates such as bryozoans, ascidians, and even other sponges. Different species have evolved chemicals (allelochemicals) that may be species-specific deterrents or actually lethal weapons for use against competing sessile and encrusting organisms. For example, the coral-inhabiting sponge *Siphonodictyon* releases a toxic chemical into the mucus exuded from its oscula, thus preventing potential crowding by maintaining a zone of dead coral polyps around each osculum (Figure 5.21).

Many of the chemicals produced by sponges and other marine invertebrates are being closely studied by natural product chemists and biologists interested in their potential as pharmaceutical agents. Compounds with respiratory, cardiovascular, gastrointestinal, anti-inflammatory, antitumor, cytotoxic, antiviral, antihelminthic, and antibiotic activities have been identified from many marine sponges. One study found that 87% of the temperate sponges and 58% of the tropical species examined in New Zealand produced extracts with specific antibacterial activity. One New Zealand sponge (*Halichondria moorei*: Heteroscleromorpha) has long been used by native Maoris to promote wound healing and was recently discovered to contain remarkably high concentrations (10% of the sponge dry weight) of the potent anti-inflammatory agent potassium fluorosilicate. In the 1950s, compounds belonging to a class of chemicals called arabinosides, which are active against viruses, were found in the tropical sponge *Tectitethya crypta* (Heteroscleromorpha). This led to the development of a number of important drugs that are in use today, including cytarabine, sold under the trade names Ara-C and Cytosar-U. Cytosar-U was approved for treatment of certain leukemias in 1969, making it the first such approved marine-derived drug for use in cancer chemotherapy. Other drugs derived from natural products in *T. crypta* include AZT (zidovudine), manufactured under the trade name Retrovir by the drug company GlaxoSmithKline, which was the first drug licensed for the treatment of HIV infection, and Ara-A, an antiviral compound often prescribed for treating herpes.

Some sponges, including the western Pacific species *Luffariella variabilis*, produce a remarkable terpenoid compound called manoalide that not only is an extremely powerful antibacterial compound, but also acts as both an analgesic and anti-inflammatory agent. Sponges of the genera *Halichondria* and *Pandaros* are known to produce potent antitumor compounds belonging to a group of chemicals called halichondrins. For example, eribulin mesylate (sold under the trade name Halaven), a powerful treatment for metastatic breast cancer, is a synthetic analogue of halichondrin B, a product isolated from the marine sponge *Halichondria okadai*.

FIGURE 5.21 ***Siphonodictyon coralliphagum* infests the hermatypic coral *Siderastrea siderea* on a Caribbean reef.** Note the "dead zone" between the oscular chimneys of the sponge and the coral polyps.

Growth Rates

Little is known regarding growth rates in sponges, but rates appear to vary widely among species. Some species are annuals (especially small-bodied calcareous sponges of colder waters); hence, they grow from larvae or reduction bodies to reproductive adulthood in a matter of months. Most, however, appear to be perennials and often grow so slowly that almost no change can be seen from one year to the next; this growth pattern is especially true of tropical and polar demosponges. Until recently, age approximations of perennial species ranged from 20 to 100 years. However, research on the Caribbean giant barrel sponge *Xestospongia muta*, which can exceed 2 m in height, suggests that this species might be capable of living more than 2,000 years. Radiocarbon dating of several hexactinellid *Rossella* species from Antarctica recently revealed growth rates of about 3 mm per year, aging the sponges at about 440 years old. Even more impressive, the western Pacific species *Monorhaphis chuni* has giant SiO_2 spicules that can reach lengths of nearly 3 m, representing the largest biogenic silica structures in the animal kingdom; the life-span of the spicule is estimated to be 11,000 (±3,000) years, making this the longest-lived animal species on Earth!

Some sponges are capable of very rapid growth, and they regularly overgrow neighboring flora and fauna. For example, the tropical encrusting sponge *Terpios* (Heteroscleromorpha) is known to overgrow both living and nonliving substrata. In Guam, this sponge grows at rates averaging 23 mm per month, over almost every live coral species in the area as well as over hydrocorals, mollusc shells, and many algae. Experiments have shown that *Terpios* is toxic to living corals and, presumably, to many other animals. However, in most cases of observed sponge overgrowth of living corals, the corals have been stressed (by temperature, sediment, pollution) or damaged and presumably weakened.

Still another physiological trick of some sponges is the ability to rapidly produce copious amounts of

mucus when disturbed. On the west coast of North America, the beautiful red-orange *Antho* (*Plocamia*) *karykina* (Heteroscleromorpha) covers itself with a thick layer of mucus when injured or disturbed. Yet the little red sea slug *Rostanga pulchra* has evolved the ability to live and feed inconspicuously on this and other red-colored sponges, and it even lays its camouflaged red egg masses on the sponge's exposed surface without eliciting the mucous reaction.

Symbioses

Symbiosis is common among sponges of all kinds. It would be difficult to find a marine sponge that is not utilized by at least some smaller invertebrates and often by fishes (e.g., gobies and blennies) as refuge. The porous nature of sponges makes them ideally suited for habitation by opportunistic crustaceans, ophiuroids, molluscs (e.g., scallops, mussels), and various worms. A single specimen of *Spheciospongia vesparium* from Florida marine waters was found to have over 16,000 alpheid shrimps living in it, a study from the Gulf of California found nearly 100 different species of plants and animals on and in a 15 × 15 cm *Geodia hentscheli*, and an examination of eight sponge species off the coast of South Carolina and Georgia (at depths of 18 to 875 m) recorded 236 symbiotic invertebrate species. The last study concluded that sponge-symbiont assemblages can constitute legitimate ecological communities harboring complete food webs as well as gravid and juvenile individuals. Even freshwater sponges host abundant symbionts, and many freshwater invertebrate taxa have been recorded with sponges (e.g., Hydrozoa, Nematoda, Annelida, Gastropoda, Bivalvia, Isopoda, Amphipoda, Ostracoda, Copepoda, Hydrachnidia, Bryozoa).

Most symbionts of sponges use their hosts only for space and protection, but some rely on the sponge's water current for a supply of suspended food particles. A classic example of this phenomenon is the male-female pair of shrimp (*Spongicola*) that inhabit the globally distributed, deep-water hexactinellid sponges known as Venus's flower baskets (*Euplectella*; Figure 5.1O,P). The two shrimp enter the sponge when they are young, only to become trapped in their host's glasslike case as they grow too large to escape. Here they spend their lives as "prisoners of love." Appropriately, this sponge (with its guests) is a traditional wedding gift in Japan—a symbol of the lifetime bond between two partners. Also in Japan's waters, the sponge *Spongia* sp. uses the powerful water current produced by the filtration system of its endosymbiotic oyster, *Vulsella vulsella*, to enhance the incurrent flow for its own filtration.

Other symbiotic relationships with sponges are also common. Some snails and clams characteristically have specific sponges encrusting their shells, and many species of crabs (hermits and brachyurans) collect certain sponges and cultivate them on their shell or carapace (Figure 5.1M). Demosponges, such as *Suberites*, are commonly involved in these commensalistic relationships. The sponge serves primarily as protective camouflage for its host, and it perhaps benefits by being carried about to new areas. The sponge also no doubt feeds off small bits of organic material dislodged during the feeding activities of its host. Evidence suggests that scallops and oysters with their shells overgrown by sponges (frequently *Halichondria panicea*) experience reduced predation from starfish. Certain dromiid crabs carry sponges on their carapace, probably also as a predator avoidance adaptation, and numerous species of decorator crabs stick pieces of sponge on their carapace as camouflage. A particularly odd symbiosis occurs in the Mediterranean Sea, where most colonies of the bryozoan *Smittina cervicornis* are overgrown by the thinly encrusting sponge *Halisarca harmelini*; somehow, the feeding currents actually appear to be strengthened for both partners by this collaboration. On the other hand, the Indonesian sponge *Mycale vansoesti* seems to rely on a coralline alga (*Amphiroa* sp.) as its skeleton; the alga completely infuses the sponge and holds it erect, the sponge itself having almost no spicular skeleton of its own.

Other spectacular examples of poriferan symbioses are sponge–Bacteria/Archaea and sponge-algae associations, some of which appear to be mutualistic, whereas others are not. For example, a typical member of the demosponge order Verongida contains a mesohyl bacterial population accounting for some 38% of its body's volume, far exceeding the actual sponge-cell volume of only 21%. In other cases, like deep-sea sponges of the genus *Geodia*, the bacterial volume can probably account for more than 70% of the sponge volume (Figure 5.22). Presumably, the sponge matrix provides a rich medium for bacterial growth, and the host benefits by being able to conveniently phagocytize the bacteria or their by-products for food. Similar relationships are common between poriferans and various Cyanobacteria. The Indian Ocean demosponge *Tethya orphei*, and other haplosclerid sponge species, have been shown to harbor an ectosome permeated by filamentous cyanobacteria (probably *Hormoscilla spongeliae*). Vertical transmission of symbiotic bacteria (from the parent sponge to the next generation) is a specific trait of poriferan development. The bacteria are transmitted to the buds or gemmules when the sponge reproduces asexually. During sexual reproduction the bacteria are transmitted through eggs (in oviparous species) or through larvae (in viviparous forms). However, although highly prevalent, vertically transmitted symbionts have now been revealed to be an inconsistent and relatively random proportion of the mother microbiome. In *Tethya seychellensis*, the green alga *Ostreobium* sp. grows exclusively along the siliceous spicule bundles in order to capture sunlight via these natural optical fibers, and other evidence from *T. aurantium* also suggests that siliceous spicules act like fiber

FIGURE 5.22 Sponge cell surrounded by symbiotic bacteria in the mesohyl of *Geodia barretti*.

optics, channeling light to photosynthetic microbes living deep inside their bodies. Recent evidence suggests that some products of normal cyanobacterial metabolism (e.g., glycerol and certain organic phosphates) are translocated directly to the sponge for nutrition. In many sponges, both bacteria and Cyanobacteria co-occur, the former in deeper cellular regions, the latter closer to the surface where light is available. On the far-offshore regions of the Great Barrier Reef, 80% of the sponge individuals harbor commensal Cyanobacteria. In one remarkable study, C. R. Wilkinson (1983) showed that six of the ten most common sponge species on the fore-reef slope of Davies Reef (Great Barrier Reef) are actually net primary producers, with three times more oxygen produced by photosynthesis (by their symbionts) than consumed by respiration. Such relationships also exist with certain dinoflagellates, filamentous green algae, and red algae.

Recent studies of the Caribbean giant barrel sponge (*Xestospongia muta*) have provided evidence of two very different cyanobacterial symbionts in the *Synechococcus* group, both of which are implicated in "sponge bleaching" events in this species (similar to coral bleaching). There is no evidence that either species of *Synechococcus* maintains a mutualistic relationship with *Xestospongia muta*. One species seems to be a commensal, benefiting from the relationship but doing nothing positive or negative to the sponge. This species dies back on a cyclical basis (as do about 25% of the sponges off southern Florida), probably in association with abnormally warm seawater temperatures, and the cyanobacterial death causes a temporary bleaching (whitening) of the host sponge, but it does not kill it. The other species of *Synechococcus*, which also dies back with warmer than normal waters (and perhaps under other conditions), may be a pathogen, and it kills its host sponge as it dies. Similar deaths, which are often associated with a distinctive orange "death band" that moves across the sponge body, have been recorded for several species of *Aplysina* in the Caribbean.

In some areas of the Caribbean and Great Barrier Reef, sponges are second only to corals in overall biomass, and they appear to owe their rapid growth to the presence of large populations of symbiotic Cyanobacteria. Most freshwater spongillids maintain similar relationships with zoochlorellae (symbiotic green algae, or Chlorophyta). These sponges grow larger and more rapidly than specimens of the same species that are kept in dark conditions. Some marine sponges (e.g., the boring sponges *Cliona* and *Spheciospongia*) harbor commensal zooxanthellae (e.g., *Symbiodinium*) similar to those of corals that confer on them advantages to enhance their growth.

Many species of sponges prefer to grow on the roots of mangrove trees in littoral habitats, and experiments have shown that sponge-infested roots elongate much faster than those without sponges. Stable isotope studies have suggested transfer of dissolved inorganic nitrogen from sponge to mangrove, and transfer of carbon from mangrove to sponge! However, this unusual sponge-plant symbiosis is not well understood.

One of the most intriguing examples of poriferan symbiosis is the rare case of intimate association between two different sponge species. In North America, for example, *Halichondria poa* is almost always overgrown by *Hymeniacidon perlevis*, while in Europe *Haliclona cratera* almost always overgrows *Ircinia oros*. And in the Gulf of California (Mexico), *Haliclona sonorensis* overgrows *Geodia media*. It is not known how the covered species of sponge obtains sufficient water flow to survive, or what the cost-benefit relationships are of these unusual associations.

The boring demosponges (e.g., *Cliona, Spheciospongia*) excavate complex galleries in calcareous material such as corals and mollusc shells (Figure 5.23). This phenomenon, known as bioerosion, causes significant damage to commercial oysters as well as to natural coral, bivalve, and gastropod populations. In fact, in the Caribbean the boring sponge *Cliona delitrix* has been shown to undercut entire coral heads by their excavations, resulting in a collapse of the head. The active boring process involves chemical and mechanical removal of fragments or chips of the calcareous coral or shell material by specialized archaeocytes called **etching cells**, which release acid phosphatase. The coarse silt-sized excavated chips are expelled in

the excurrent canal system and can actually contribute significantly to local sediments. Many species in the remarkable boring genus *Cliona* (family Clionaidae) have two or three different growth forms (e.g., *C. californiana* of the eastern Pacific region). The alpha stage (Figure 5.24A) is purely boring (living internally within the "host"), the beta stage (Figure 5.24B) is eruptive (having "escaped" to overgrow the surface of the calcareous substratum), and the gamma stage is "free-living" (i.e., has given up the boring stage of its life history) (Figure 5.24C,D).

Sponge bioerosion has a significant impact on coral reefs. Perhaps even more important than actual erosion

is the weakening of attachment regions of large corals. This action can result in considerable coral loss during heavy tropical storms, and it is increasing as corals are weakened by bleaching events and ocean acidification resulting from increased atmospheric CO_2. Boring sponges do not appear to gain any direct nourishment from their host coral; rather, they use it as a protective space in which to reside. If you carefully examine the shells of dead bivalves along any shoreline, you will discover that most of them are perforated with minute holes and galleries from boring sponges (Figure 5.24E). Bioeroding sponges are responsible for a major portion of the initial breakdown of such calcareous structures, and thus they set the stage for their eventual decomposition and recycling through Earth's biogeochemical cycle.

Poriferan Phylogeny

The Origin of Sponges

Being a very early branch of the tree of life, sponges are a key group in which to look for innovations that form the basis of the metazoan body plan. But sponges are an ancient group, and the important events in their origin and early evolution lie hidden in the Neoproterozic Era of the Precambrian. Both the ancient and the unique nature of the poriferan body plan are strikingly revealed by the aquiferous system, cellular pluripotency, and reproductive flexibility; and by the lack of a gut, fixed reproductive organs, nervous system, muscles, cell gap junctions, or strong adult body polarity. These features, along with the choanoflagellate-like choanocytes of sponges, suggest a poriferan ancestry not far removed from the protistan origin of the Metazoa. Generally speaking, sponges clearly stand apart from all other metazoans in their possession of such features as an aquiferous system and choanocytes with flagella bearing paired vanes (nearly identical to those of the protist phylum Choanoflagellata), although choanocyte-like cells are found, in small numbers, in some other animals (see below). Molecular phylogenetic dating estimates that Metazoa and Choanoflagellata diverged about 600 million years ago, or perhaps earlier. This early origin of Metazoa is also supported by some Poriferan fossil biomarkers. Just as this book was going to press, a paper in the journal *Nature* (Turner 2021) suggested that 890 Ma vermiform fossils from the StoneKnife Formation of northwestern Canada are possibly fossilized tissues of keratose sponges. We look forward to the follow up work on this intriguing hypothesis.

Although subtle ultrastructural differences exist, the collar cells (choanocytes) of sponges are nearly identical to the collar cells of choanoflagellates, including the unique possession of two distinct winglike projections (the vanes), which arise on either side of the flagellum, and a glycocalyx sheath on the collar that joins the microvilli. In choanoflagellates, the collars are funnel shaped, and the sheath forms an uninterrupted fibrous layer on the cell surface. In sponge choanocytes, the collars tend to be tubular, and the glycocalyx forms a mesh that both holds the microvilli together and connects adjacent collar microvilli. The vanes, in both groups, are also formed from horizontal fibers of glycocalyx that extend from the flagellum. The vanes in sponge choanocytes appear to be wider than those described from Choanoflagellata, spanning the full width of the collar with the edges of the two wings lying against the inside of the collar (and perhaps attached to it) in sponges. Differences account for very specific features that are present in choanoflagellates but not choanocytes: filopodia, cytoplasmic bridges, and glycogen reserves.

Somewhat similar collar cells (but without flagellar vanes and generally with a nonmotile cilium) have also been found in some other metazoan phyla (e.g., in the gut of certain echinoderm larvae and adults, in some corals, in the trunk epithelium of the enteropneust *Harrimania kupffferi*). The homology of these other metazoan cells to sponge choanocytes needs further study. However, it is emerging from single-cell molecular analysis that the transcriptional profiles of archaeocytes, rather than choanocytes, may be more similar to those of choanoflagellates.

But in any case, so similar are choanoflagellates and sponges that periodically through the eighteenth and nineteenth centuries the proposal came up that sponges are no more than highly organized colonial choanoflagellates. However, the presence of distinctly animal features in Porifera, including metazoan developmental genes, gastrulation during embryogenesis, spermatogenesis, adherens junctions in some species, and type IV collagen, argues against this idea. And recent molecular developmental work suggests that certain genes found in sponges and other metazoans probably played critical roles in the transition from unicellularity to multicellularity. Homologues of many typical metazoan genes have now been identified in sponges, such as those encoding proteins involved in immune responses, myosin production, developmental patterning, the formation of the extracellular matrix, reproduction, and other vital functions. Even the chitin synthase gene has been found in sponges, especially in Hexactinellida, where it could be responsible for the chitin envelope of the spicules.

The major class of transcription-factor-encoding genes that regulate animal development is called homeobox. The ANTP-class of the homeobox group includes genes in the subclasses Hox, ParaHox, and NKL, all of which are paralogues (i.e., they have arisen from a shared ancestor as a result of ancestral gene-duplication events). These genes, which are involved in multiple developmental processes, are often found in clusters, and in some animals their expression is temporally or spatially correlated to their

position within the cluster (a phenomenon known as colinearity). Until relatively recently, no homeobox genes had been found in the phylum Porifera, leading to the suspicion that this gene family did not evolve until the emergence of a line subsequent to sponges—the name "ParaHoxozoa" was given to that lineage of phyla with ParaHox subclass genes. But when the first sponge genome was sequenced (from a species of Demospongiae), a group of gene clusters was found that are known to be neighbors of Hox and ParaHox genes in higher metazoans, and later several research groups found ANTP-class homeobox genes in many other demosponges. This led to a proposal in 2012 that these developmental genes had been present in the common ancestor of all animals but had been secondarily lost in sponges—an idea called the "ghost locus" hypothesis. A test of this hypothesis came in 2014, when researchers looked closely at sponge genomes in the class Calcarea and proposed that this sponge class contained both NK and ParaHox genes remarkably similar to those of other animals. In fact, they found that the expression of these homeobox genes in the choanoderm cell layer was very similar to that seen in the endoderm of bilaterians. However, in 2019, the putative ParaHox genes of calcareous sponges were finally assigned to the NKL subclass, and therefore sponges remain out of ParaHoxozoa. But in any case, the discovery of non-Hox ANTP-class genes in calcarean sponges adds further data to the recognized molecular complexity of the entire phylum Porifera. The future will see what homoscleromorph and hexactinellid genomes add to this conundrum.

Recently, genes belonging to the cadherin family have been identified in sponges. The cadherin family of genes comprise critical mediators of metazoan cell adhesion and signaling and provide the structural basis for vital developmental processes, including tissue morphogenesis and maintenance, cell sorting, and cell polarization. Plants and fungi lack cadherins, which so far are known only from metazoans and choanoflagellates. Cadherin activity has been identified in choanoflagellates in the actin-filled microvilli that comprise the apical collar, at the basal pole of the cell, and in certain cellular bodies of unknown function. The localization of cadherins on the collar suggests that actin filaments and cadherins have been associated since before the origin of the Metazoa. In metazoan epithelial cells, recruitment of β-catenin facilitates essential interactions between classical cadherins and the actin cytoskeleton to establish and maintain cell shape and polarity.

Evolution within the Porifera

Sponges comprise such an ancient and enigmatic phylum that their phylogeny largely eluded scientists until fairly recently. Although the Porifera have nearly consistently appeared near the basal splits of metazoan molecular and morphological trees, data have been slow to resolve the relationships of sponges to the other metazoan clades (e.g., Cnidaria, Ctenophora, Placozoa, Bilateria), and as this book went to press, those relationships were still unsettled, although overall evidence still supported them as one of the earliest metazoan phyla to split off from the rest. Recent genomic-level studies strongly suggest that Placozoa arose later than sponges, placing them as sister group to Cnidaria or as sister group to Bilateria, but the placement of Ctenophora and Porifera remains contentious.

With respect to the internal relationships of sponges, only since the early twenty-first century have there been robust phylogenetic hypotheses of relationships among the four poriferan classes. Molecular clocks and sterol biomarkers place the origin of sponges sometime during the Precambrian, in the Neoproterozoic era, and imply an early Cambrian origin of the Calcarea (Figure 5.25). Although fossil sponges have been described from the Precambrian, there is no reliable evidence supporting assignment of Ediacaran specimens to sponges, and not even from isolated spicules.

Even considering some preservation biases in the fossil record, well over 1,000 fossil genera have been described, about 20% of which are still extant. The fossil record suggests that sponges might have had their ecological heyday in the Paleozoic and Mesozoic when massive tropical reefs developed, composed largely of four groups: the archaeocyathans, stromatoporids, sphinctozoans, and chaetetids. The oldest of these, the coralline Archaeocyatha (Figure 5.26), had a short life within the Cambrian (550–500 Ma). Sphinctozoans and stromatoporids also appeared in the Cambrian (about 540 Ma), while chaetetids first appeared in the Ordovician (about 480 Ma). The affinities of these four coral-like groups have been debated for 100 years, and various alliances with Cyanobacteria, red algae, bryozoans, cnidarians, and foraminiferans have been proposed. However, the discovery of living coralline sponges has led most workers to believe that the majority of species in these four groups were primitive, but true, sponges. Research suggests that the calcium-carbonate-secreting sponges utilize the same α-carbonic anhydrase genetic pathway as seen in other animals that biomineralize. And it was exploitation of this gene group that led the explosion of mineralized skeletons among the Metazoa during their rapid Cambrian radiation.

Unlike the coralline sponges, which have decreased in abundance and diversity since the Mesozoic, the Calcarea and Demospongiae appear to have increased in diversity throughout their history. The demosponges were well established by the mid-Cambrian. Several recent molecular analyses favor the hypothesis that Hexactinellida and Demospongiae are sister groups, a clade called Silicea, being the first two of the four sponge classes to appear reliably in the fossil record. The Upper Devonian extinction event brought many

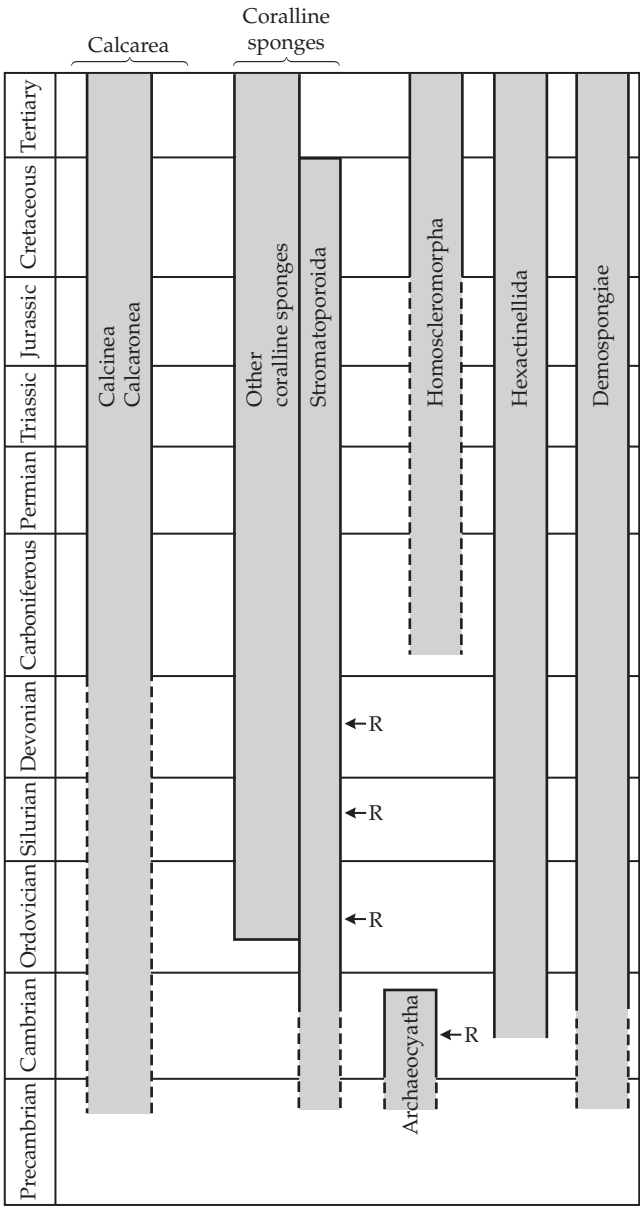

FIGURE 5.25 Fossil record of three of the extant sponge classes, the Archaeocyatha, and the other coralline sponges. Dashed lines indicate suggested occurrence, even though fossils have not yet been found. Dashed line for Homoscleromorpha indicates spicule evidence in the fossil record. "R" indicates the times when the group in question is known to have been an important marine reef builder.

demosponge clades to an end, and the modern demosponge lineages largely appeared subsequent to that event. All known orders of modern demosponges are found in Cretaceous rocks.

Hexactinellids were most diverse and abundant in the Jurassic, when they formed enormous reefs, and their fossilized remains crop up all round the world, but they declined in the Cretaceous and have largely disappeared. The oldest hexactinellid fossils, of the early Cambrian, were all thin-walled, saclike sponges with a dispersed surface spicule layer that probably could not support a thick body wall. During the Paleozoic, hexactinellids were common in shallow-water environments. Since then, however, they have become restricted largely to deeper oceanic regions. In 1987 the Geological Survey of Canada was engaged in routine surveys of the seafloor off British Columbia. Here, at around 200 m depth in ancient glacially scoured seafloor troughs, they discovered massive hexactinellid sponge reefs. Since that discovery, teams of scientists have documented the extent and composition of these living sponge reefs, which appear to be about 9,000 years old. The reefs cover roughly 700 km^2, and they are composed of fewer than a dozen hexactinellid species. They are largely identical to the massive hexactinellid-"lithistid" sponge reefs of Mesozoic times, known to paleontologists as "reef mounds" or "mud mounds," which culminated in the Late Jurassic when a 7,000-kilometer-long reef existed on the northern shelf of the Tethys Sea—the largest bioconstruction ever built on Earth.

The long fossil record of hexactinellids comprises two principal clades, the Amphidiscophora and the Hexasterophora, differing in shape and type of their microscleres. Hexactinellid synapomorphies are many, including their unique cellular and syncytial tissue organization, possession of triaxon spicules, an axial filament with a square section, and use of the enzyme glassin for building their siliceous spicules.

Until recently, two fundamentally opposing views of sponge phylogeny existed. One hypothesis suggested that the living sponge classes that produce

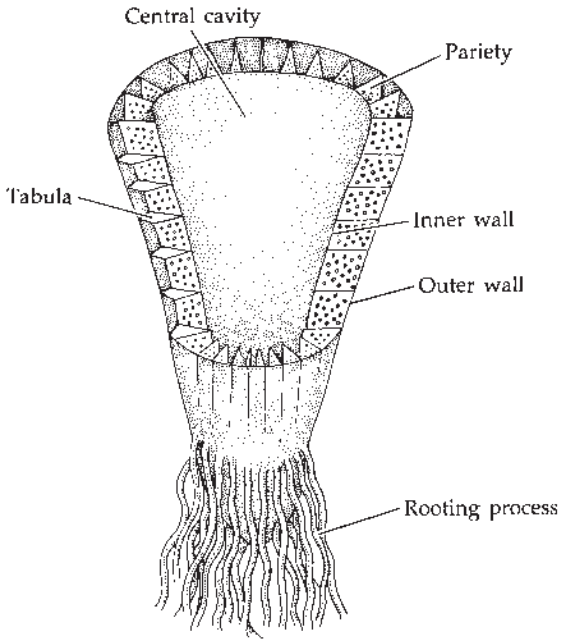

FIGURE 5.26 A typical archaeocyathan. A vertical section has been partly cut away to show the structure between the inner and outer walls (i.e., vertical parieties and horizontal tabula).

siliceous spicules comprise a monophyletic lineage (e.g., Demospongiae, Homoscleromorpha, Hexactinellida), with the Calcarea being phylogenetically more distant. The other view proposed that the classes of cellular sponges (Demospongiae, Homoscleromorpha, Calcarea) comprise a clade, with the syncytial Hexactinellida standing apart from them.

The first hypothesis was proposed in 1955 by de Laubenfels, who reduced the siliceous groups to a single class, Hyalospongiae. Subsequent authors renamed the two groups Silicea (or Silicispongia) and Calcarea (or Calcispongia). An obvious objection to this concept had been the profoundly different anatomies and spicule geometry of Hexactinellida, Demospongiae, and Homoscleromorpha. However, a very similar process of secretion of the siliceous spicules within sclerocytes around an axial filament occurs in all three groups, and that itself might be viewed as a synapomorphy of the Silicea. In addition, these three groups lack cross-striated rootlets, which are present in Calcarea and other metazoans (as well as in choanoflagellates and some other protists). Thus, *loss* of this structure may be another synapomorphy of the Silicea.

The second hypothesis of class-level relationships in Porifera suggests that the Hexactinellida stand apart from the other sponges by their unique syncytial body plan. This view recognized two groups: Symplasma (or Nuda) for hexactinellids, and Cellularia (or Gelatinosa) for demosponges (including homoscleromorphs) and calcareous sponges. One of the arguments against this view has been that hexactinellid sponges begin their lives as cellular embryos and partly cellular larvae, only later transitioning to the syncytial adult body form (by fusion of individual blastomeres), thus suggesting that Hexactinellida may have arisen from a demosponge-like ancestry.

As it turns out, neither of these views of sponge phylogeny is likely fully correct. DNA analyses since 2009 favor a version of the first hypothesis, but with the homoscleromorphs removed from the demosponges (Figure 5.27). It now appears that Demospongiae and Hexactinellida comprise a clade (Silicea), as do Calcarea and Homoscleromorpha.

The key synapomorphy of the Calcarea is their monocrystalline calcareous spicules (unique among sponges). DNA analyses also support the monophyly of the two classes of Calcarea: Calcinea and Calcaronea. An important proposed synapomorphy of the Calcinea is the basal position of nuclei in choanocytes, with no relation to the flagella. A proposed synapomorphy of the Calcaronea is the formation of the amphiblastula larva through the original process of eversion of the stomoblastula.

For many years, Homoscleromorpha was viewed as the earliest group and the most primitive looking of living Porifera (although embedded phylogenetically within the Demospongiae) owing to its seemingly simple anatomic organization. One species, *Oscarella lobularis*, was even suggested as the prototype of all sponges because of its reduced mesohyl (and appearance of having only two layers, choanoderm and pinacoderm) and lack of a mineral skeleton. For a brief period of time, some workers proposed the Homoscleromorpha be removed from the Porifera altogether and allied with the Eumetazoa (a grouping dubbed Epitheliozoa). However, just the opposite view now prevails. Recent discoveries have shown that Homoscleromorpha are not demosponges but should stand alone as a monophyletic fourth class of living sponges (closely allied to Calcarea) on the basis of DNA sequence data (18S and 28S rRNA, complete mitochondrial DNA sequence data, and more recently, a large data set of protein-coding genes) and the unique cross-striated rootlet in larval ciliated cells. In fact, homoscleromorphs have a number of distinctly metazoan-like attributes, some of which have also recently been found to be present in other sponge classes. These attributes include apical cell junctions, flagellated exopinacoderm, a well-developed basement membrane beneath both the pinacoderm and the choanoderm (in larvae and adults), acrosomes in their spermatozoa (also known from a few other sponges), and a basal apparatus of flagellated larval cells with true cross-striated rootlets (as also seen in some Calcarea and some demosponges). The fact that some of these metazoan-like features are not exclusive to Homoscleromorpha suggests that sponges are actually far more "evolved" than conventional wisdom holds and that they have undergone a massive simplification since their origin, traces of which can be seen in the Homoscleromorpha and a few other sponges.

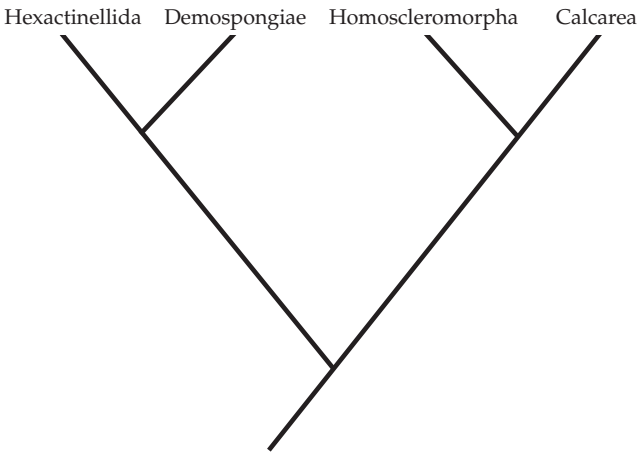

FIGURE 5.27 A modern view of poriferan phylogeny, based on phylogenomic analyses. Synapomorphies of the classes discussed in the text include the following: Hexactinellida with unique syncytial body anatomy, triaxon spicules, and a square axial filament; Homoscleromorpha never with a spongin skeleton; Calcarea with monocrystalline calcareous spicules; Demospongiae skeleton formed by monaxon and/or tetraxon spicules with an axial filament that is triangular or hexagonal, and/or spongin fibers (lost in some clades).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Overall, relationships within the Demospongiae remain uncertain, although there is growing support for the three monophyletic subclasses used herein. Several phylogenies have been published using 18S and 28S rRNA, complete mitochondrial DNA sequence data, and housekeeping genes, but still some internal relationships remain unresolved. The most robustly supported relationships among demosponge orders are those of two spicule-less orders, Dendroceratida and Dictyoceratida, which were the earliest diverging group of demosponges. These sponges are now almost entirely limited to shallow-water coastal areas, where silicon is limiting due to large diatom populations. It is interesting then to see early demosponges without spicules, suggesting that the ability to make siliceous spicules was acquired by a more recently evolved group of demosponges. This is supported by the evidence of two very different enzymatic mechanisms to condense silica in hexactinellids and demosponges, which would render spicules as nonhomologous across siliceous sponges and would point to a later acquisition of a biomineralization mechanism in Demospongiae.

Chapter Summary

This chapter introduced you to the phylum Porifera, one of the earliest-appearing (perhaps *the* earliest-appearing), extant animal phyla. Sponges are characterized by having the following: some of the simplest of tissues and a high degree of cellular pluripotency; unique flagellated cells called choanocytes, nearly identical to choanoflagellate protists; motile, planktonic ciliated larvae; internal skeletal elements composed of calcium carbonate or silicon dioxide, and/or spongin fibers; and absence of a gut, organized nervous system, or any recognizable body organs. Major research areas that will dominate investigations of sponges over the coming decade include their precise phylogenetic placement in the tree of life, their ability to produce highly bioactive compounds, the nature of their symbiotic relationships with microbes and protists, their development, and their ecological role in the chemistry of our oceans.

CHAPTER 6

Two Enigmatic Phyla

Placozoa and Ctenophora (The Comb Jellies)

In this chapter we discuss two unusual, marine, nonbilaterian animal phyla—Placozoa and Ctenophora. Although phylogenetic analyses show them to have diverged near the base of the metazoan tree of life, their precise relationships have eluded biologists for many decades and have long been at the center of phylogenetic debates. The phylum Placozoa was first discovered in 1883, and only a few species have been described. The bodies of these creatures are only a few millimeters in size, are just two cell layers thick, and lack both symmetry and organs. Once thought to be the sister group to all other animals due to their simplicity (e.g., few cell types), phylogenomics now places Placozoa as the sister group to Cnidaria or as the sister group to Cnidaria + Bilateria, with whom they constitute a clade that has been named Planulozoa. Members of the phylum Ctenophora are gelatinous and somewhat resemble jellyfish (phylum Cnidaria), although the two groups are not closely related and such resemblances largely reflect evolutionary convergences. Research on Ctenophora picked up in the late 2000s when a phylogenomic study suggested that they, and not Porifera, may be the sister group of all other Metazoa. Since then, dozens of high-profile papers have been published arguing back and forth whether sponges or ctenophores hold the honor of being the "first" Metazoa—although this is a misrepresentation because the debate is not about the first metazoan, but about the sister group relationship at the base of the animal tree of life. We consider this debate unsettled, yet it is now clear that Ctenophora are more basally placed in the metazoan tree than once thought, with the implication that complexity of tissues and a nervous system may have originated earlier than previously considered. Neither phylum (Placozoa or Ctenophora) has left a robust fossil record.

*** Paraphyletic (excludes Hexapoda)

Phylum Placozoa

Trichoplax adhaerens was discovered by F. E. Schulze in 1883 in a seawater aquarium at the Graz Zoological Institute in Austria. Specimens have subsequently been found throughout the world's tropical and subtropical seas, and two additional placozoan species were described in 2018 (*Hoilungia hongkongensis*) and 2019 (*Polyplacotoma mediterranea*). A species described in 1896, *Treptoplax reptans*, has not been seen since, and it is currently not accepted. These creatures remained a mystery until the great German protozoologist Karl Grell, director of the Zoology Institute at Tübingen, began working on them—although it remains unclear whether Grell's specimens, the source of what most people studied until recently, are conspecific with *T. adhaerens*. Molecular genetics of placozoans from around the world has suggested great genetic diversity, yet to be formalized taxonomically. Box 6A lists the major characteristics of Placozoa.

The body of *Trichoplax* is only 1 to 3 mm in diameter, although it consists of a few thousand cells, of only a few types, arranged as a simple double-layered plate (Figure 6.1) that may be polytomous (*P. mediterranea*). It lacks anterior–posterior polarity, symmetry, a mouth or gut, nervous system, muscles, or extracellular matrix, although a recent gene-expression study has suggested the existence of an oral–aboral axis that corresponds with the bottom–top of the animal. However, the cells of the upper (top) and lower (bottom) layers differ in shape, and there is a consistent orientation of the body relative to the substratum. Because the concepts of dorsal and ventral are generally taken to be characteristics of triploblastic animals, we will use the terms "upper-layer cells" and "lower-layer cells." The upper-layer cells are flattened and monociliate and epithelium-like, and they have curious extracellular structures, called **shiny spheres**, unique to placozoans. Long thought to be lipid inclusions, they appear to be easily dislodged and fall out of the cell layer. In 2007, Vicki Buchsbaum Pearse and Oliver Voight reported that gastropods, flatworms, and sabellid polychaetes recoil upon contact with placozoans, suggesting they might possess a chemical deterrent to predators. In 2009, Alexis Jackson and Leo Buss tested this hypothesis, finding that when individual *Trichoplax*

BOX 6A Characteristics of the Phylum Placozoa

1. Minute, flattened metazoans composed of ciliated upper and lower cell layers; ameboid and fibrous cells in a "gel" layer in between; adults discoidal and asymmetrical or with polytomous branching
2. With six somatic cell types
3. Cells with desmosome cell-cell connections
4. With unique shiny spheres, possibly defensive structures, in upper cell layer
5. Without a structural nervous system, muscles, or digestive system

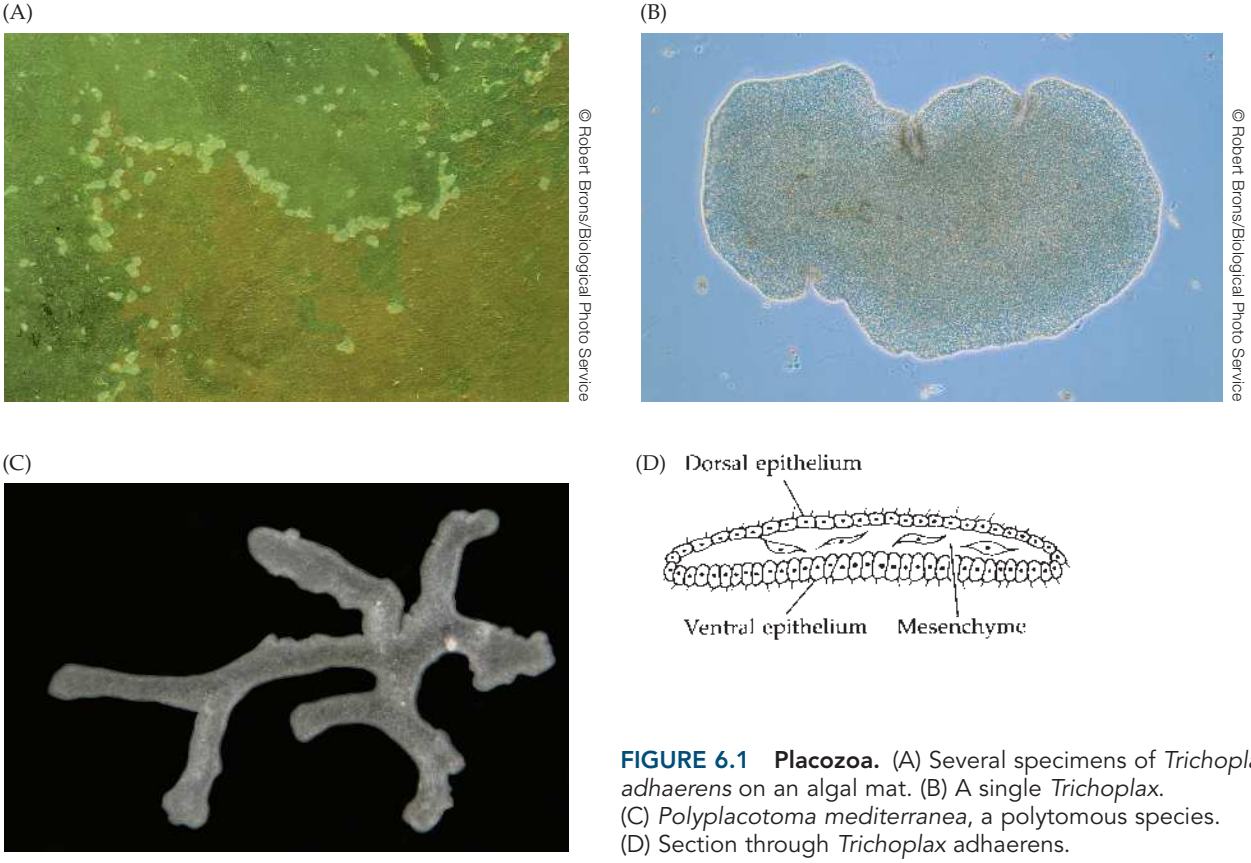

FIGURE 6.1 Placozoa. (A) Several specimens of *Trichoplax adhaerens* on an algal mat. (B) A single *Trichoplax*. (C) *Polyplacotoma mediterranea*, a polytomous species. (D) Section through *Trichoplax* adhaerens.

for more ebook/ testbank/ solution manuals requests email 9601267347@qq.com

were fed to the hydrozoan *Podocoryna carnea*, the polyps became paralyzed, suggesting that the peculiar shiny spheres might indeed be antipredator devices.

Most of the lower-layer cells are also monociliate, but they are all more columnar and lack distinct shiny spheres; "gland cells" may also occur on the lower surface. Fiber cells can be seen between the upper and lower cell layers. These internal cells have thin extensions that connect to each other in a network. Cellular material such as microtubules and microfilaments traverse the extensions from fiber cell to fiber cell. It has been suggested that this network plays a role in coordinating movement of the animal. Importantly, desmosomes, cell-cell junctions of extracellular cell adhesion proteins, have been found in placozoans, a feature not seen in Porifera but present in most other Metazoa.

The lower cell layer can be temporarily invaginated, presumably for feeding. This observation supports the notion that there are functional as well as structural differences between the two cell layers. Between these two cell layers (or epithelial sheets) is a mesenchymal layer of stellate ameboid cells embedded in a supportive gel matrix. Grell (1982) considered *Trichoplax* to be a true diploblastic metazoan and suggested that the upper and lower cell layers were true epithelia and might be homologous with ectoderm and endoderm, respectively. However, a basement membrane has not yet been identified beneath either layer, which suggests that *Trichoplax* may be closer to the Porifera in organization than it is to Cnidaria, Ctenophora, or the triploblastic Eumetazoa. No fossil placozoans have been found, but it has been suggested that the feeding tracks of the Ediacaran *Dickinsonia* are similar to those of placozoans, and an affinity between these was proposed.

Trichoplax moves by ciliary gliding along a solid surface, aided by irregular, ameba-like shape changes along the body edges. Very small, presumably young individuals can swim, while larger individuals seem to always crawl. *Trichoplax* apparently feeds by phagocytosis of organic detritus using the lower surface, which can contract to form a "feeding chamber." An elegant recent study showed that *T. adhaerens* is able to control feeding behavior and do this by responding to endomorphin-like peptides. A small number of sensory secretory cells lacking processes and synapses can evoke a wave of peptide secretion across the entire animal and even between individuals that are not in contact. These peptide secretions allow the animal to arrest ciliary beating and pause during feeding. Although there is no evidence of extracellular digestion, it is possible that *Trichoplax* secretes digestive enzymes onto its food within the lower digestive pocket. It is not known what these animals eat in nature, but lab cultures can be sustained on diets of flagellated protists (e.g., *Cryptomonas*, *Chlorella*).

Trichoplax reproduces asexually by fission of the entire body into two new individuals and also by a budding process that yields numerous multicellular flagellated "swarmers," each of which forms a new individual. It is also capable of regeneration from damage to the body, to the point that some have claimed that predation upon placozoans by rhodopemorph gastropods can contribute to asexual reproduction. Sexual reproduction is also known, followed by a developmental period of holoblastic cell division and growth. Eggs have been observed within the mesenchyme, but their origin is unknown.

With only six somatic cell types and a lack of defined symmetry or constant body axis, *Trichoplax* has the simplest body of any known metazoan. Over the years, it has been suggested that *Trichoplax* might be a secondarily reduced cnidarian (or a sister group to the Cnidaria). However, the more highly derived cnidarians (Scyphozoa, Hydrozoa, Cubozoa) all have a linear mtDNA molecule—a unique synapomorphy of that clade within Cnidaria—in contrast to the circular mtDNA of Anthozoa and all other Metazoa. *Trichoplax* also has circular mtDNA. Further, the secondary structure morphology of the mitochondrial 16S rRNA gene of *Trichoplax* differs markedly from that seen in cnidarians. Curiously, a shift from circular to linear mitochondrial genomes also occurred in a clade of calcareous sponges. But now we have more genomes than named species of placozoans available, and phylogenomic analyses have suggested two possible placements for Placozoa—either as sister group to cnidarians, or as sister group of Cnidaria + the bilaterian phyla.

Phylum Ctenophora

Ctenophores (Greek *cten*, "comb"; *phero*, "to bear")—commonly called comb jellies, sea gooseberries, or sea walnuts—are transparent, gelatinous animals. They are one of the earliest branching metazoan groups. Most of them are planktonic, living from surface waters to depths of at least 7,000 m, while a few species are benthic. Their transparency and fragile nature make them difficult to capture or observe by traditional sampling methods such as trawling with nets, and until the advent of manned submersibles and "blue water" scuba techniques, they were thought to be only modestly abundant. However, they are now known to form a major portion of the planktonic biomass in many areas of the world, and they may periodically be the predominant zooplankton in some regions. About 130 credible species have been described (90 planktonic, 40 benthic), plus there are an additional 40 species that remain uncertain, and there are many deep-sea forms yet to be discovered. Ctenophores have traditionally been illustrated with the oral side facing downward, and for this reason some people have probably confused them with cnidarian medusae.

Ctenophores have a form of radial symmetry, are probably diploblastic animals, and resemble cnidarians

The section on Ctenophora was revised by Steven Haddock.

in many—potentially superficial—respects. Some similarities include a gelatinous mesenchyme or collenchyme, the absence of a body cavity between the gut and the body wall, and a relatively simple, netlike nervous system. Zoologists, however, view these similarities as convergent features resulting from adaptations to pelagic lifestyles. Ctenophores are significantly different from cnidarians in their more extensively organized digestive system, their wholly mesenchymal musculature, and several other features (Box 6B). There remains uncertainty as to the origin of the ctenophoran mesenchyme, with developmental evidence favoring an endodermal origin. This might at first suggest developmental homology with the true mesoderm of bilaterians. However, sequencing of the genomes of *Pleurobrachia bachei* and *Mnemiopsis leidyi* have shown that many of the genes involved in mesoderm development in bilaterians appear to be absent in Ctenophora.

Ctenophores also differ fundamentally from cnidarians in that they are monomorphic throughout their life histories, are never colonial, lack any trace of an attached sessile stage, and lack cnidae. Ctenophores lack a hard skeleton, an excretory system, and a respiratory system. Most are simultaneous hermaphrodites capable of self-fertilization—an unusual quality among the Metazoa. A distinctive larval form, the **cydippid larva**, is usually produced. Ctenophores are exclusively marine. They display a wonderful variety of shapes, and they range in size from less than 1 cm in height to ribbon-shaped forms over a meter long (Figure 6.2). Some have evolved rather elaborate body forms, and a few have taken up a benthic creeping existence. They occur throughout the world oceans and at all latitudes. Battered specimens of the genus *Pleurobrachia* ("sea gooseberries") are often found washed ashore after storms, but most of the diversity is rarely seen. In their planktonic environment, ctenophores are some of the most elegant and graceful creatures in the sea, and observing them in their natural habitat is a memorable experience.

BOX 6B Characteristics of the Phylum Ctenophora

1. Diploblastic (or possibly triploblastic) Metazoa, with ectoderm and endoderm separated by a cellular mesenchyme; mesenchyme endodermal in origin
2. Biradial symmetry, with oral–aboral body axis
3. With adhesive exocytotic structures called colloblasts
4. Gastrovascular cavity (gut) as the only "body cavity"; gut with stomodeum and canals that branch complexly throughout body; gut ending in two small anal pores
5. Without discrete respiratory, excretory, or circulatory systems
6. Nervous system in the form of a nerve net or plexus, without true ganglia, but more specialized than that of cnidarians; some species with giant axons
7. With striated muscles, always formed of true mesenchymal cells
8. With eight rows of ciliary plates (combs or ctenes) at some stage in their life history; comb rows controlled by unique apical sense organ
9. Some adults and most juveniles with a pair of long tentacles, often retractable into sheaths
10. Monomorphic, without alternation of generations and without any kind of an attached sessile life stage
11. Most are hermaphroditic, and typically with a characteristic cydippid larval stage

Taxonomic History and Classification

Perhaps because many well-known ctenophores are brilliantly luminescent and are commonly seen from ships, the group has been known since ancient times. The first recognizable figures of ctenophores were drawn by a ship's doctor and naturalist in 1671. Linnaeus placed them in his group Zoophyta, along with various other "primitive" invertebrates. Cuvier classified them with medusae and anemones in Zoophytes. In the early nineteenth century, Johann Friedrich von Eschscholtz designed the first rational classification of pelagic medusae and ctenophores by creating the orders Ctenophorae (for comb jellies), Discophorae (for all the solitary cnidarian medusae), and Siphonophorae (for the colonial siphonophores and chondrophorans). Eschscholtz viewed these orders as subdivisions of the class Acalepha, regarding them as intermediate between Zoophytes and Echinodermata (on the basis of the common presence of radial symmetry). Recall that it was Leuckart who first separated the Coelenterata from the echinoderms in 1847, although his Coelenterata also included sponges and ctenophores. Raspailia Vosmaer (in 1877) was responsible for removing the sponges and Hatschek (in 1889) for removing the ctenophores as separate groups.

Until recently, two classes of ctenophores were recognized: Nuda, for species lacking tentacles (the single order Beroida), and Tentaculata, for those species with tentacles (all other orders). However, the monophyly of these two groups had been questioned even before genetic sequencing. Recent molecular analyses show that, while the Ctenophora overall are a monophyletic lineage, the presence or absence of tentacles provides some phylogenetic information but cannot constitute the basis for the main division of the phylum; Beroida (which may be monophyletic) are nested well within the phylum, suggesting an evolutionary loss of tentacles in the history of Ctenophora.

Until the taxonomy is revised, we largely follow Harbison and Madin (1982) in simply dividing the ctenophores into six orders (omitting Ganeshida) containing 18 families. Figures 6.2 and 6.3 illustrate the general anatomy of the major groups. The position of the Ctenophora among the early-diverging

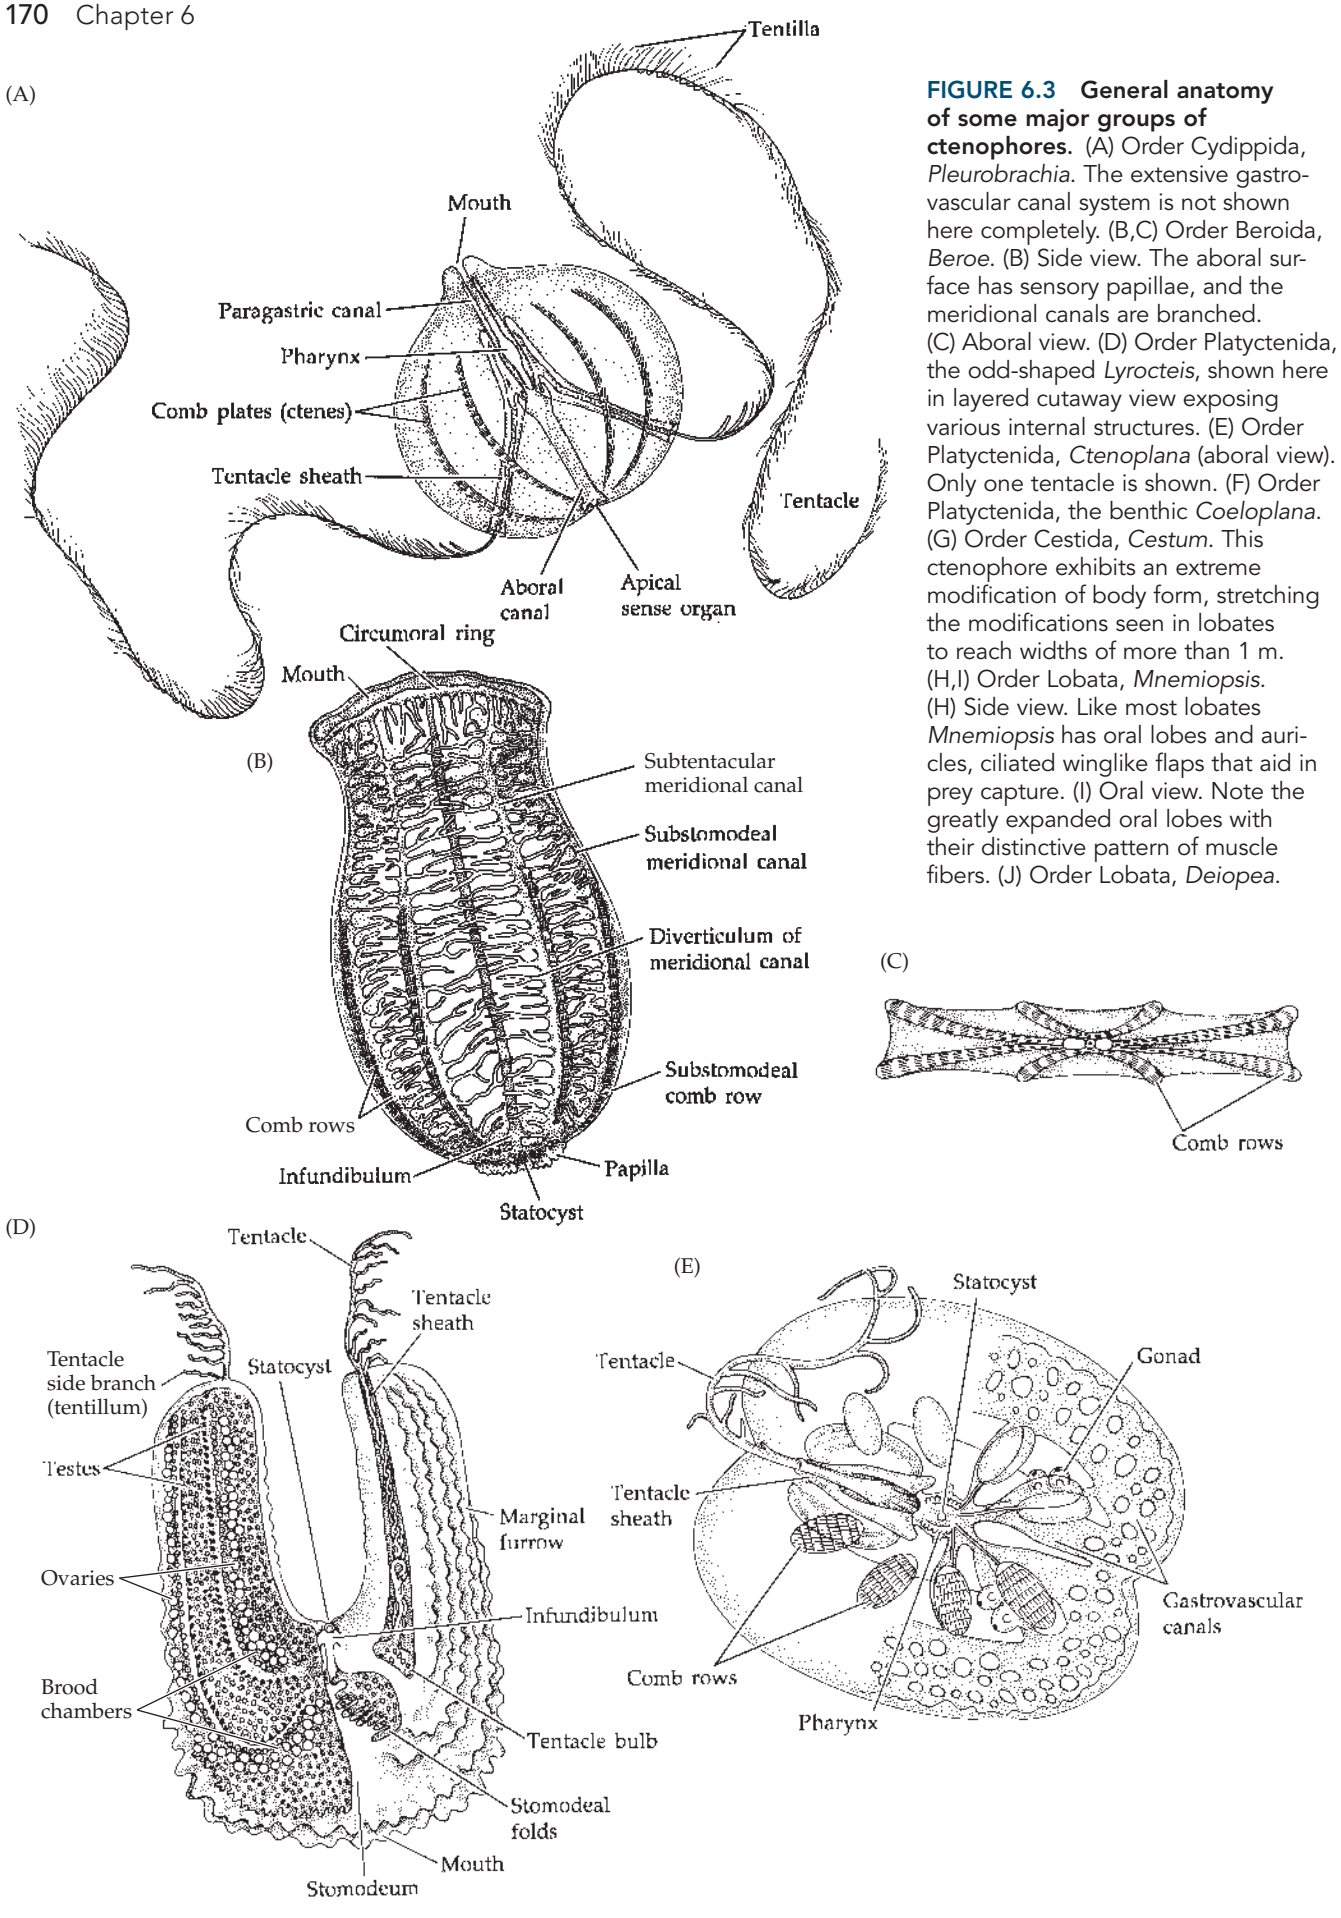

FIGURE 6.3 General anatomy of some major groups of ctenophores. (A) Order Cydippida, *Pleurobrachia*. The extensive gastrovascular canal system is not shown here completely. (B,C) Order Beroida, *Beroe*. (B) Side view. The aboral surface has sensory papillae, and the meridional canals are branched. (C) Aboral view. (D) Order Platyctenida, the odd-shaped *Lyrocteis*, shown here in layered cutaway view exposing various internal structures. (E) Order Platyctenida, *Ctenoplana* (aboral view). Only one tentacle is shown. (F) Order Platyctenida, the benthic *Coeloplana*. (G) Order Cestida, *Cestum*. This ctenophore exhibits an extreme modification of body form, stretching the modifications seen in lobates to reach widths of more than 1 m. (H,I) Order Lobata, *Mnemiopsis*. (H) Side view. Like most lobates *Mnemiopsis* has oral lobes and auricles, ciliated winglike flaps that aid in prey capture. (I) Oral view. Note the greatly expanded oral lobes with their distinctive pattern of muscle fibers. (J) Order Lobata, *Deiopea*.

Metazoa is still under debate. Some molecular phylogenetic studies have suggested they might be the sister group to all other metazoans, while others recover the traditional view of Porifera diverging first. No modern molecular studies recover a monophyletic "Coelenterata" with ctenophores as sister group to cnidarians.

CLASSIFICATION OF CTENOPHORA

ORDER CYDIPPIDA (Figures 6.2A and 6.3A). Pelagic; with well-developed comb rows; tentacles long and retractable into sheaths; body globular or ovoid, occasionally flattened in the stomodeal (= sagittal) plane; meridional canals end blindly, paragastric canals (when present) end blindly at mouth. This order is widely viewed as polyphyletic and in need of revision. (e.g., *Aulacoctena*, *Bathyctena*, *Callianira*, *Dryodora*, *Euplokamis*, *Haeckelia*, *Hormiphora*, *Lampea*, *Mertensia*, *Pleurobrachia*, *Tinerfe*)

ORDER PLATYCTENIDA (Figure 6.3D–F). Benthic or epibenthic; comb rows reduced; most species greatly flattened, with part of stomodeum everted as a creeping sole; with oral adhesive organs; often with tentacle sheaths; tentacle canals bifid; gastrovascular system complex and anastomosing; most species possess anal pores; many are ectocommensals on other organisms (e.g., corals, echinoderms). Unlike in most ctenophores, fertilization is often internal, and many platyctenids brood their embryos to the larval stage; asexual reproduction is common. (e.g., *Coeloplana*, *Ctenoplana*, *Lyrocteis*, *Tjalfiella*, *Vallicula*)

ORDER CESTIDA (Figures 6.2E,F and 6.3G). Pelagic; body extremely compressed in tentacular plane, and greatly elongated in stomodeal plane, producing a ribbonlike form more than 1 m long in some species; substomodeal comb rows elongate, extending along entire aboral edge; subtentacular meridional canals arise near subtentacular comb rows (*Cestum*) or equatorially from interradial canals (*Velamen*); paragastric canals extend along oral edge and fuse with meridional canals; oral tentacles. Two genera: *Cestum* and *Velamen*.

ORDER LOBATA (Figures 6.2D,G,H and 6.3H–J). Pelagic; body compressed in tentacular plane; with a pair of characteristic oral lobes and 4 flaplike auricles; a ciliated auricular groove extends to base of auricles from each side of each tentacle base; paragastric and subtentacular meridional canals unite orally. (e.g., *Bolinopsis*, *Deiopea*, *Eurhamphaea*, *Leucothea*, *Mnemiopsis*, *Ocyropsis*)

ORDER THALASSOCALYCIDA (Figure 6.5). Pelagic; body extremely fragile, expanded orally into medusa-like bell, to 15 cm along tentacular axis; body slightly compressed in stomodeal plane; auricles and tentacle sheaths absent; tentacles arise near mouth and bear lateral filaments; comb rows short; mouth and pharynx borne on central conical peduncle; meridional canals long, describing complex patterns in bell; all meridional canals end blindly aborally. Monotypic: *Thalassocalyce inconstans*.

ORDER BEROIDA (Figures 6.2B,C and 6.3B,C). Pelagic; body cylindrical or thimble-shaped, sometimes strongly flattened in tentacular plane; tentacles and sheaths absent; aboral end rounded (*Beroe*) or with 2 prominent keels (*Neis*); stomodeum greatly enlarged; aboral sense organ well developed; meridional canals with numerous side branches; paragastric canals simple or with side branches. Without a cydippid larva phase. Two genera: *Beroe* (worldwide in distribution) and *Neis*.

The Ctenophoran Body Plan

Although ctenophores appear simply constructed, they do possess true tissues. Between the epidermis and the gastrodermis is a well-developed middle layer, which is always a cellular mesenchyme. Within this mesenchyme true muscle cells develop, a condition that also characterizes the triploblastic Metazoa, although by different developmental pathways.

As we noted in Chapter 3, a critical essence of the ctenophoran and cnidarian body plans is radiality (in one fashion or another) we explained some of the structural constraints and advantages that derive from this symmetry. Thus, predictably, the nervous system of ctenophores is in the form of a simple, noncentralized nerve net, and the locomotor structures are arranged radially about the body. Other features that characterize the Ctenophora include retractile **tentacles** and often **tentacle sheaths**; **anal pores**; adhesive prey-capturing structures called **colloblasts** (see Figures 6.7 and 6.8); locomotor structures called **ctenes** or comb plates, arranged in **comb rows**; and an **apical sense organ** containing a statolith that regulates the activity of the comb rows. The sheathed tentacles, colloblasts, comb plates, and nature of the apical sense organ are unique features of ctenophores. Figures 6.2 and 6.3 illustrate ctenophoran anatomy.

Many ctenophores are spherical or ovoid in shape, although some species have evolved flattened shapes through compression and elongation in one of the two primary planes of body symmetry (Figures 6.2E and 6.3I). The general body plan can best be understood by first examining an idealized cydippid ctenophore (Figure 6.4). Specialists have long considered the cydippids to be ancestral within the phylum, although molecular evidence shows that the order Cydippida is polyphyletic. Fossil evidence has framed the discussion in relation to an evolutionary gain or loss of tentacles, but the evidence from extant ctenophores shows tentacles being lost and reduced (loss of tentilla) as a derived state more than once.

As in cnidarians, the principal axis is oral–aboral. The mouth is at the oral pole; the aboral pole bears the apical sense organ. Unlike pelagic cnidarians, however, ctenophores encounter their world leading with the oral end, not with the mouth trailing like a medusa. There is a long and confounding tradition of illustrating

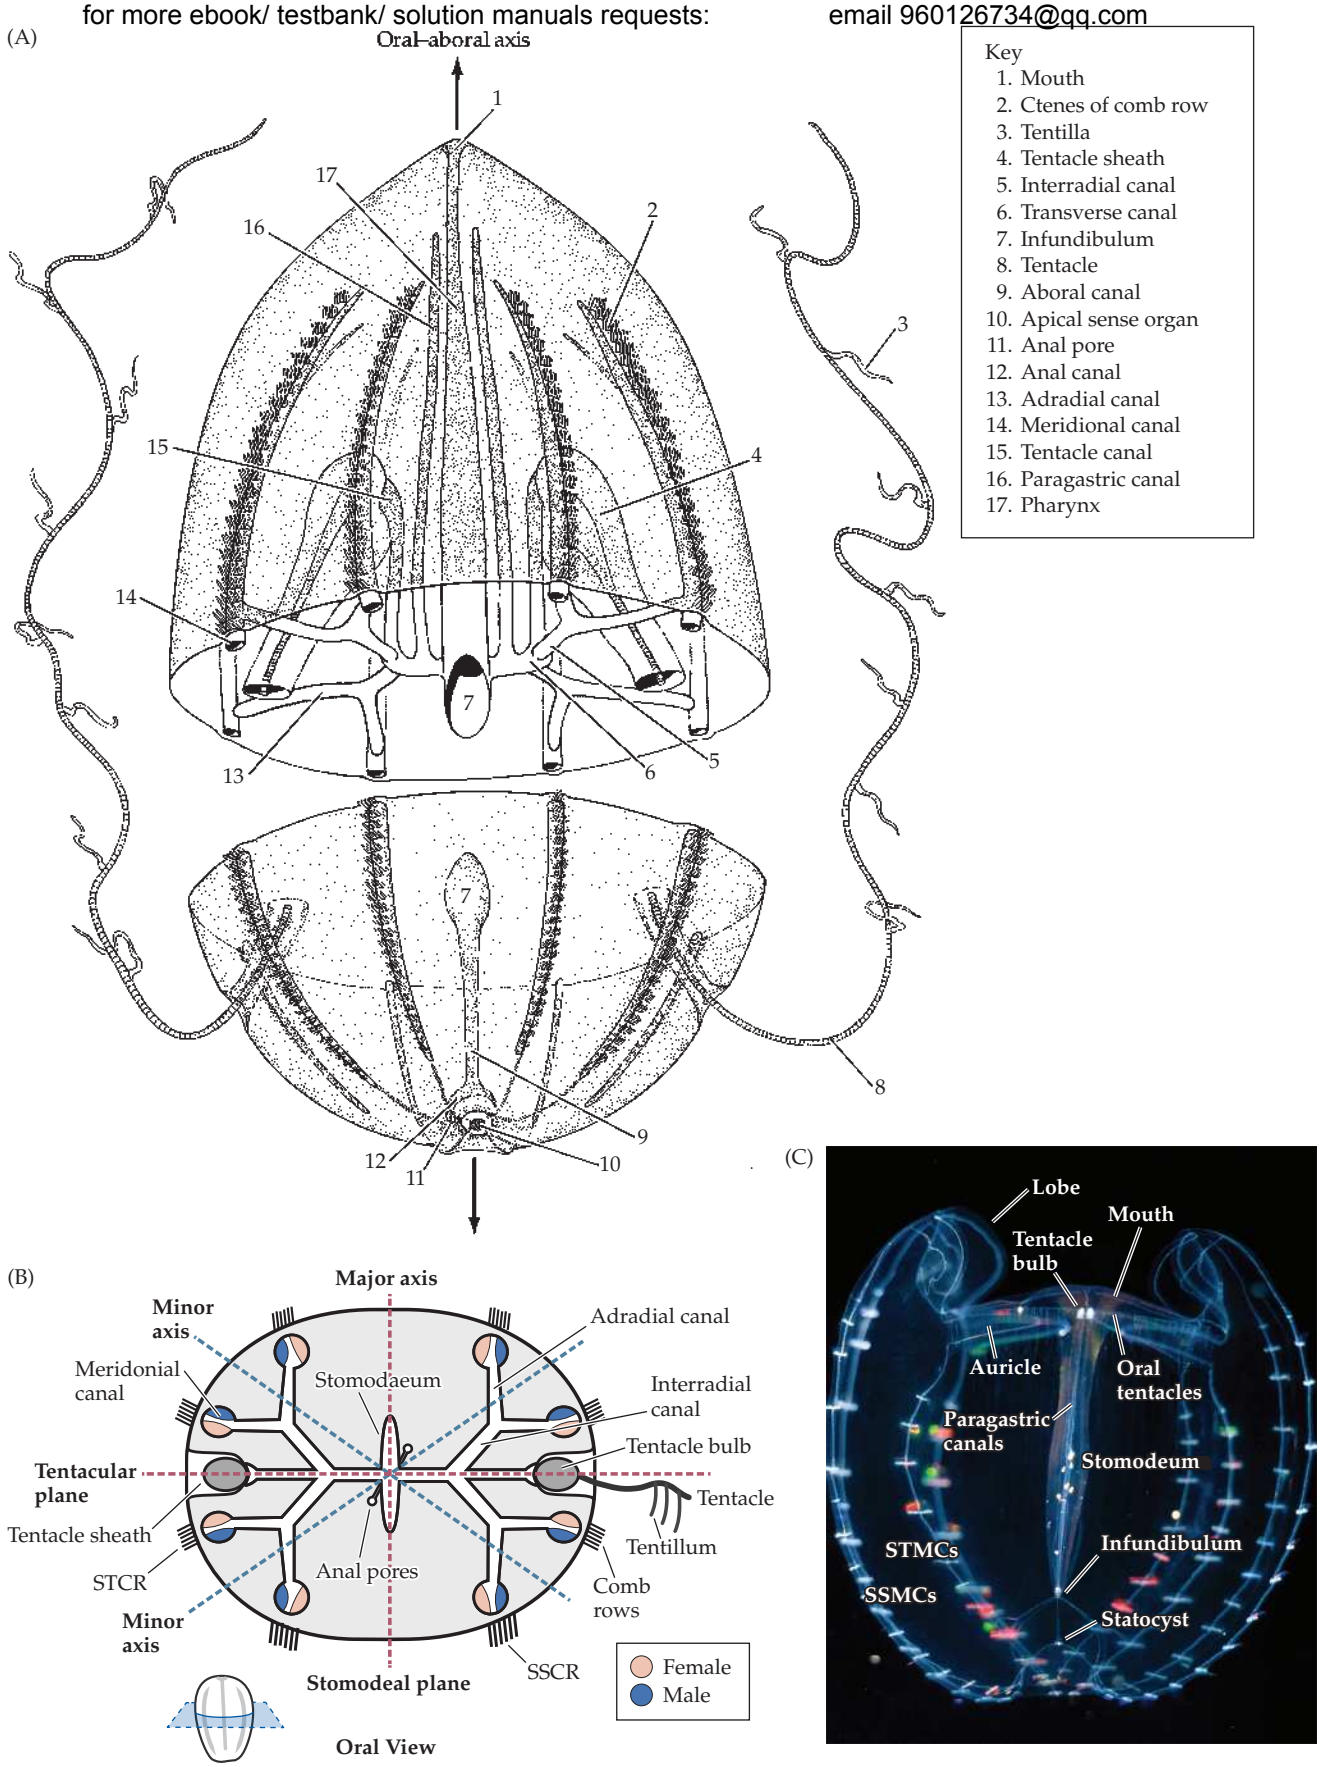

FIGURE 6.4 The ctenophoran body plan. (A) A cydippid ctenophore (cross section). (B) Ctenophoran biradiality and the planes of symmetry (oral view). (C) The lobate ctenophore, *Deiopea kaloktenota*, showing main anatomical features. SSMCs are the substomodeal meridional canals, and STMCs are the subtentacular canals, adjacent to the tentacular plane. SSCR, substomodeal comb row; STCR, subtentacular comb row.

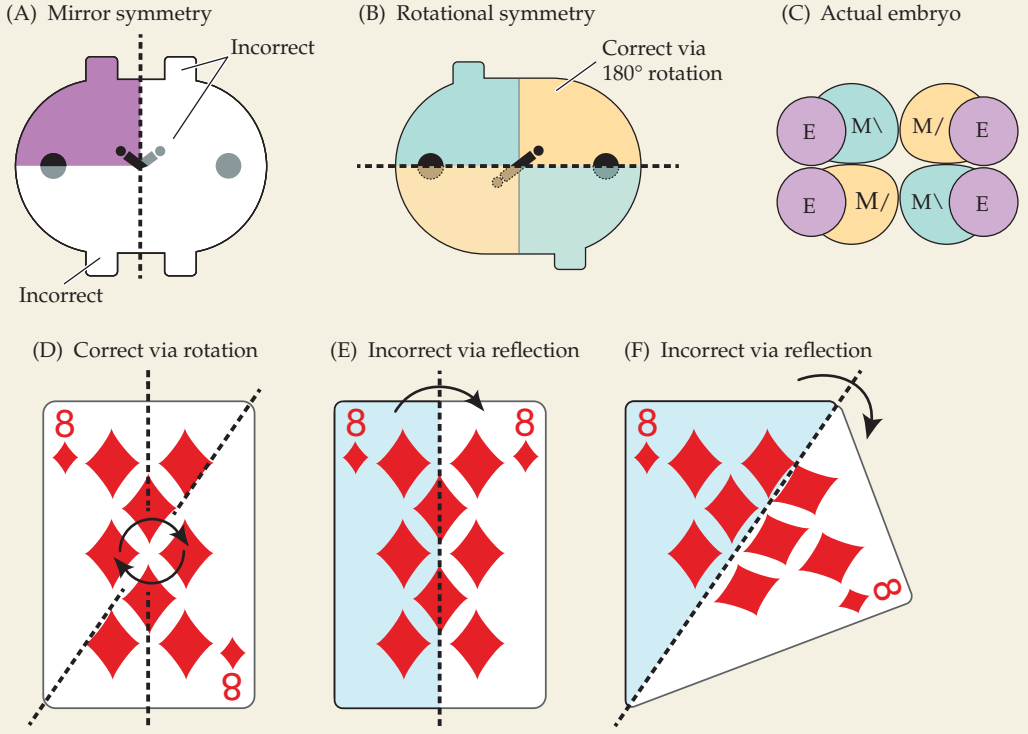
them "upside down." On the surface of the body are eight equally spaced **meridional rows** of comb plates. Each comb plate, or ctene, is composed of a transverse band of long, fused, compound cilia. On each side of the body of many species is a deep, ciliated epidermal pouch (the tentacle sheath) from whose inner wall a tentacle arises. The tentacles are typically very long and contractile and bear lateral branches called filaments, or **tentilla**. The epidermis of both the tentacles and the lateral tentilla is richly armed with colloblasts (see Figure 6.8). Most species can retract the tentacles into the sheaths with muscles. It is the tentacles and certain aspects of the internal anatomy that give ctenophores a biradial symmetry (Box 6C). The elongate **stomodeum** lies on the oral–aboral axis of the body. It is distinctly flattened in one plane of body symmetry, the **stomodeal plane**, historically called the **sagittal plane** (Figure 6.4B). Bisecting the animal along the stomodeal plane separates the two tentacular halves of the body. The second major plane of body symmetry, called the **tentacular plane**, is defined by the position of the tentacle sheaths. At roughly 45° between these major planes, the body can also be divided into minor planes of symmetry. These are useful in describing the morphology because the female gonads lie on the side of the meridional canals adjacent to the major planes, while the male gonads and bioluminescent photocytes are found next to the minor axes (Figure 6.4).

Some variations of the basic ctenophoran body plan are illustrated in Figures 6.2 and 6.3. In members of

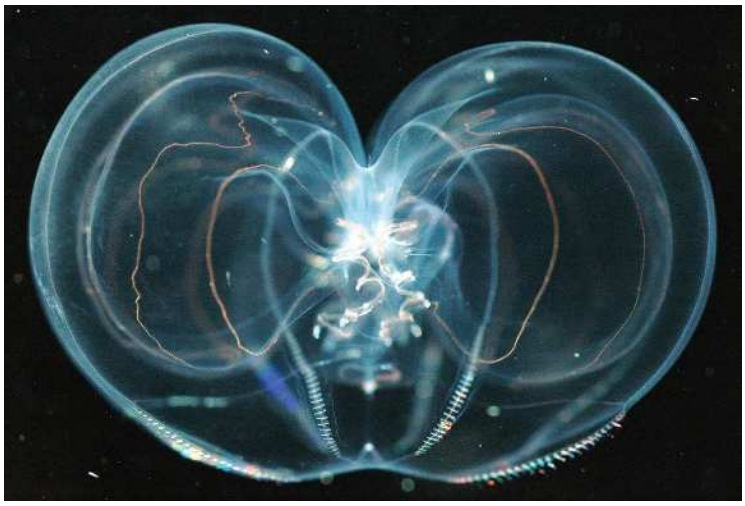
BOX 6C Ctenophore Symmetry

These "top-down" (oral) diagrammatic views of ctenophores (A,B) are shown looking down along the longitudinal axis of the body. The symmetry of ctenophores around their central axis is challenging to describe. The term "biradial symmetry" is frequently used, but by itself this does not explain the morphology. (A) At first glance it might appear that ctenophores can be described using mirror or reflectional symmetry. However, there are certain features—most conspicuously the diagonally offset anal pores—that mean you cannot get a correct representation by mirroring half or a fourth of a ctenophore across a central plane. (B) What is required to correctly reproduce a ctenophore is 180° rotation about the central axis. The half to be rotated does not have to be cut along the major horizontal or vertical axis; any slice that passes through the central point parallel to the long axis will create a suitable section for rotation. (C) Surprisingly, the diagonally offset quadrants may even be detected during the four- or eight-cell embryonic stage. Descendants of the end (E) and middle (M) micromeres form particular structures. Here, the two aqua-colored M\ cells are fated to form tissues such as the anal pores, while their counterpart brown M/ cells will form longitudinal muscles and other tissues (Martindale and Henry 1998). (D) A playing card provides a visual analogy of rotational symmetry. Any half may be rotated to reproduce the full card, but no reflections, either (E) along a major axis or (F) a diagonal, will recreate the true "morphology" of the card.



the diverse order Lobata (Figure 6.3H–J), the body is compressed in the tentacular plane, and the oral end is expanded on each side into rounded, contractile **oral lobes**. The mouth sits on an elongate region, the ends of which bear four long flaps called **auricles**. The tentacles are reduced and lack sheaths. From either side of each tentacle base, a ciliated **auricular groove** arises and extends around the perimeter of the auricles connecting with the subtentacular comb rows at the other side.

Members of the order Cestida (Figures 6.2E and 6.3G) are also compressed in the tentacular plane and extremely elongated in the stomodeal plane, giving these ctenophores a striking eel- or ribbonlike appearance—hence the common name Venus's girdle. The sheathed tentacles are reduced and shifted alongside the mouth with oral tentilla forming a fringe across the width of the body. Beroida are thimble shaped and either cylindrical or flattened in the stomodeal plane (Figures 6.2B,C and 6.3B,C) and lack tentacles and sheaths throughout their life. In the single species of Thalassocalycida (*Thalassocalyce inconstans*), the would-be lobes are fused around the mouth to form a medusa-like bell (Figure 6.5).



Courtesy of L. P. Madin/WHOI

FIGURE 6.5 ***Thalassocalyce inconstans*, in the monotypic order Thalassocalycida,** with its expanded oral lobes that form a medusa-like bell.

Members of the order Platyctenida (Figures 6.2I and 6.3D–F) look more like flatworms than their ctenophore kin. Platyctenids are benthic and small, often less than 1 cm in length; in contrast to most pelagic ctenophores, they are pigmented rather than transparent. The body is oval and markedly flattened, resembling a free-living flatworm. Despite these unusual features, early naturalists recognized them as ctenophores by the presence of an apical sense organ, comb rows, and a pair of tentacles. Detailed studies have shown that the flattened oral surface is actually an everted portion of the pharynx. The platyctenid pharynx was, in a sense, preadapted to serve a dual purpose as a creeping foot or sole by its intrinsic musculature. Many of these animals crawl about on the sea bottom and algae, while some are ectocommensals, attached like a flag on a flagpole to alcyonarian cnidarians, echinoderms, or sponges.

Support and Locomotion

Ctenophores rely primarily on their elastic mesenchyme for structural support. The watery gelatinous mesenchyme makes up most of the body mass; ctenophore dry weights are only about 4% of their live wet weights. The mesenchyme contains both elastic supportive cells and muscle cells, the general tonus of the latter being primarily responsible for maintaining body shape. Figure 6.6 shows a highly stylized cutaway section of a cydippid ctenophore and illustrates the arrangement of the supportive mesenchymal muscle fibers. Tension in the looped muscles tends to maintain the body geometry. Action of the radial muscles diminishes the radius and hence the circumference and also serves to open the pharynx. These two muscle sets are antagonistic.

Most ctenophores are pelagic. The gelatinous body and low specific gravity maintain relatively neutral buoyancy, allowing these creatures to float about with the ocean currents. Neutral buoyancy appears to be maintained by passive osmotic accommodation. Because buoyancy adjustments take time, ctenophores may temporarily accumulate at discontinuity layers in the sea, where a water mass of one density overlies a water mass of a slightly different density.

The beating of the ctenes provides most of the locomotory power that allows ctenophores to move up and down in the water column and to locate richer feeding sites or preferred environmental conditions. Some, like *Thalassocalyce* species may be motionless in the water,

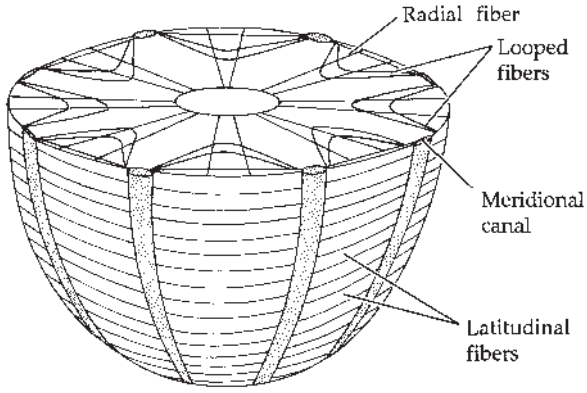


FIGURE 6.6 Stereogram of the arrangement of muscle fibers in *Pleurobrachia*, a cydippid ctenophore. The diagram depicts a transverse section through the region of the pharynx; the gastrovascular system and tentacle sheaths have been omitted for clarity.

lobates like *Leucothea* and *Eurhamphaea* cruise slowly forward to increase encounters with prey, and others like *Euplokamis* have giant ctenes that can propel them at many body lengths per second during escape swimming. Each comb row comprises many ctenes. Each ctene consists of a transverse band of hundreds of very long, partly fused cilia (to 3.5 mm in length) that beat together as a unit (see Figure 6.11D). Ctenophores are the largest animals known to use cilia for locomotion. Each cilium has a typical 9+2 microtubule structure, but each also possesses a unique set of lamellae at the 3 and 8 doublets; these lamellae protrude to link together the adjacent cilia.

Ctenophores are beautiful animals to observe in life because their beating comb rows appear iridescent over a wide range of light intensities. This feature of ctenophoran movement appears to be caused by the dense and highly regular packing of ciliary elements at the base of each comb row. Because of their size, ctenophore ctene plates move at low Reynolds numbers, where fluid flow is smoother but where water viscosity can impede ciliary movement. In contrast, the bodies of ctenophores move at higher Reynolds numbers, where viscosity is less important but water turbulence can impede or enhance animal movement through the medium.

As noted previously, mesenchymal musculature is used to maintain body shape and assist in feeding; it is involved in behaviors such as prey swallowing, pharyngeal contractions, and tentacle movements. Usually both longitudinal and circular muscles are present just beneath the epidermis. In the benthic and epifaunal platyctenids, stomodeal musculature facilitates a creeping locomotion. In the snakelike cestids, body muscles may generate graceful swimming undulations. Swimming in the lobate ctenophores is assisted by muscular flapping of their two oral lobes, especially in active species like *Ocyropsis maculata*, whose lobes appear frosty white due to the density of musculature. The lobate *Leucothea* (Figure 6.2G) can swim either by typical slow ctene propulsion or by rapid ctene propulsion; the latter is accomplished by coiling the lobes and increasing ciliary beat to produce a vortex wake, resulting in jet propulsion. Giant smooth muscle fibers—the first to be discovered in ctenophores—have been found in *Beroe*.

Feeding and Digestion

Comb jellies, so far as is known, are mostly predatory in their habits, and none are true parasites. The long tentacles of cydippids (and of the larvae of most other forms) have a muscular core with a colloblast-laden epidermal covering (Figure 6.7). The tentacles trail passively, are deployed in repeatable patterns, or are "fished" by various jigging motions. Upon contact with zooplankton prey, the adhesive granules in the colloblasts (sometimes called **lasso cells**) burst and discharge a strong adhesive

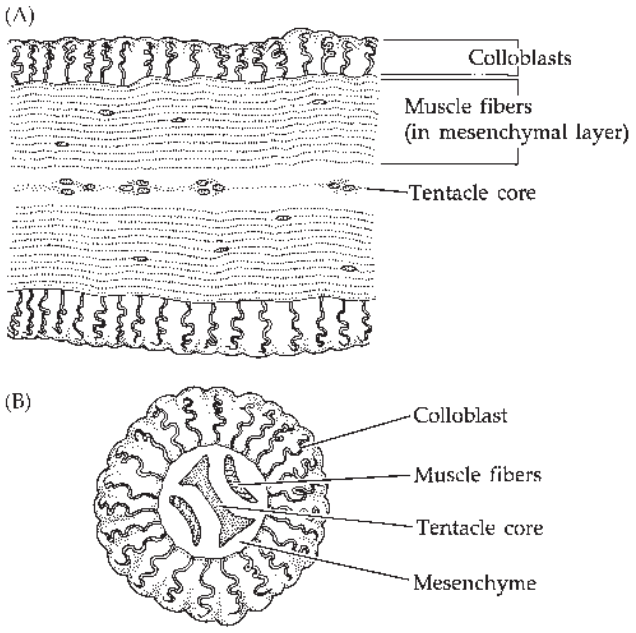

FIGURE 6.7 Ctenophore tentacle structure. (A) Longitudinal section of tentacle. (B) Cross section of a lateral filament (tentilla) of a tentacle.

material. Each multicellular colloblast develops from a single cell and consists of a hemispherical mass of secretory granules attached to the muscular core of the tentacle by a spiral filament coiled around a straight filament (Figure 6.8). The straight filament is actually the highly modified nucleus of the colloblast cell. The end of the spiral filament, which extends like a spring, adheres to the prey by the sticky material produced in the secretory granules. As the tentacles accumulate prey, they are periodically wiped across the mouth by muscular contractions or partially consumed, in some species combined with a coordinated somersaulting action of the animal that brings the mouth to the trailing tentacle. In members of the orders Lobata and Cestida, which bear very short tentacles, small zooplankton are trapped in mucus on the body or lobe surface and then carried to the mouth by ciliary currents (along the ciliated **auricular grooves** in lobate forms and ciliated **oral grooves** in cestids). Most of the benthic platyctenids also feed by capturing zooplankton in a somewhat similar fashion or using long trailing tentacles.

In some areas of the world's seas, ctenophores may be the dominant macrozooplankters and planktonic predators (e.g., *Mertensia ovum* in the Arctic region). *Mnemiopsis leidyi* is a highly effective predator and captures prey (e.g., microplankton, copepods, fish larvae) at rates comparable to predatory copepods and fish; early life stages may consume both zooplankton and phytoplankton. Many ctenophores consume crustaceans, fish larvae, and other plankton. The lobate ctenophore *Bolinopsis infundibulum* feeds primarily on copepods, which may sink to water layers near the seafloor during diapause and where *B. infundibulum*

(C) Diagram of the major structural and functional parts of a colloblast.

may form large aggregations to feed on this abundant source of carbon. The tendency of ctenophores to form aggregations near food sources or at the water's surface may contribute to their patchy distribution in nature.

Some ctenophores prey on larger animals, especially gelatinous forms. For example, as an adult the cydippid *Lampea* engulfs pelagic tunicates (salps, doliolids); but as larvae and juveniles, when they are too small to consume the whole salp, they adhere to the side with their open mouth, giving the impression of a parasite. Figure 6.9 is a series of remarkable photographs showing the cydippid ctenophore *Haeckelia* eating the tentacles of the narcomedusa *Aegina*. After consuming the tentacles one by one, *Haeckelia* retains the prey's unfired nematocysts, incorporates them into its epidermis, and uses them for its own defense. This phenomenon, known as **kleptocnidism**, occurs in several unrelated animal groups that prey on cnidarians (see Chapter 7). Because narcomedusae feed on other carnivorous jellies, this suggests that tiny 1 cm *Haeckelia* may be four trophic stages removed from the phytoplankton at the base of many marine food webs.

(B) *Haeckelia* begins to consume one of *Aegina*'s tentacles. (C) Most of the first tentacle of the medusa has been ingested. (D) Same animals, 2 minutes after feeding began. (E) *Aegina* has lost all four of its tentacles to *Haeckelia*, which goes on to incorporate the nematocysts into its own simple tentacles.

Ctenophores were center stage in an ecological drama that played out in the Black Sea near the end of the twentieth century. In the 1980s, the predatory northwest Atlantic ctenophore *Mnemiopsis leidyi* was accidentally introduced into the Black Sea from ship ballast water. The few invaders quickly underwent explosive population growth, reaching biomass levels in excess of 1 kg/m^3 by 1989, devastating the food web of the entire Black Sea basin and causing a collapse of the anchovy fishery (anchovy is one of the favored prey of *M. leidyi*). Then, in 1997, another ctenophore, *Beroe ovata*, was accidentally introduced to the Black Sea, probably also from ballast water. *Beroe ovata* readily feeds on *Mnemiopsis*, and its introduction resulted in a precipitous decline (perhaps extirpation) of *M. leidyi* in the sea, followed at last by the disappearance of *Beroe* itself. Introduced ctenophores continue to present a threat to local fisheries in many parts of the world, and their numbers are now monitored closely, particularly in the Mediterranean Sea. In recent years, *M. leidyi* has invaded the Caspian, Baltic, and Adriatic Seas, eastern Mediterranean, and parts of the North Sea and in every case has led to decreases in zooplankton abundances and diversity.

The ctenophoran mouth opens into an elongate, flattened, muscular, stomodeal pharynx. The epithelium of the pharynx is richly endowed with gland cells that produce digestive juices. Large food items are tumbled within the pharynx by ciliary action. Digestion takes place extracellularly, mostly in the pharynx. The largely digested food passes via a small chamber (the **infundibulum**, funnel, or stomach) from the pharynx into a complex system of radiating gastrovascular canals (Figures 6.3 and 6.4), eventually being evacuated through the anal pores or mouth. The details of the arrangement of the canals vary among different groups; the following description applies to the arrangement in a cydippid.

Two **paragastric** or **pharyngeal canals** recurve and lie parallel to the pharynx. Two **transverse canals** depart at right angles to the stomodeal plane and divide into three more branches. The middle branch of each triplet, the **tentacle canal**, leads to the base of the tentacle sheath. Although there is considerable diversity in ctenophore "plumbing," typically each of the other two branches (the **interradial canals**) bifurcates to form a total of four **adradial canals** on each side of the animal. These in turn connect to the eight **meridional canals**, one beneath each comb row. Depending on the morphology of the species, these canals can have diverticula or elaborations which allow them to serve lobes and internal structures that are not adjacent to the comb rows. Finally, an **aboral canal** passes from the infundibulum to the aboral pole, where it divides beneath the apical sense organ into four short canals, two ending blindly and two diagonally opposed (the anal canals) opening to the outside via small **anal pores**. These pores may open and seal intermittently, becoming undetectable when not in use. They serve as

a rudimentary anus, assisting the mouth in the voiding of indigestible material and digested waste.

Within this very complicated gastrovascular canal system, digestion is completed, nutrients are distributed through the body, and absorption takes place. Minute pores lead from the various canals into the mesenchyme (Figure 6.10). Surrounding these pores are circlets of ciliated gastrodermal cells called **cell rosettes**, which appear to regulate the flow of the digestive soup and perhaps also play a role in excretion. Except for the stomodeal pharynx, the gastrovascular system is lined by a simple epithelium of endodermal origin.

Circulation, Excretion, Gas Exchange, and Osmoregulation

There is no independent circulatory system in ctenophores; as in cnidarians, the gastrovascular canal system serves in this role by distributing nutrients to most parts of the body. The gastrovascular system probably also picks up metabolic wastes from the mesenchyme for eventual expulsion out of the mouth or anal pores. The cell rosettes may also transport wastes to the gut. Gas exchange occurs across the general body surface and across the walls of the gastrovascular system. All of these activities are augmented by diffusion through the gelatinous mesenchyme. Movement of water over the body surface is enhanced by the beating of the comb plates. Thus, the extensive canal system and the ciliary bands help to overcome the problem of long diffusion distances. In genera with larger-bodied species and smaller surface-to-volume ratios, such as *Beroe* and *Aulacoctena* (length to 20 cm), diverticula from the meridional canals penetrate the mesoglea and distribute nutrients throughout the body. It has even been shown that the gel of ctenophores may sequester oxygen and provide a reservoir that buffers the animals from intermittent exposure to hypoxia.

Nervous System and Sense Organs

Although the nervous systems of both ctenophores and cnidarians are noncentralized nerve nets, there are certain important differences. In ctenophores, nonpolar neurons form a diffuse **subepidermal plexus**. Beneath the comb rows, the neurons form an **elongate plexus** or meshes such that they produce nervelike strands. The bases of the ctenes are thus in contact with a rich array of nerve cells. A similar concentrated plexus surrounds the mouth. However, as in cnidarians, no true ganglia occur, a condition that contrasts markedly with the presence of a centralized nervous system in bilateral Metazoa (the Bilateria).

The nerve nets of ctenophores consist of polygonal nerve cords spread under the ectodermal epithelium; these nerve nets show high levels of regional specialization and concentrations associated with the apical sensory organ/polar fields and tentacle bulbs—structures without clear homologues in any other animal group. In the genus *Euplokamis,* which displays rapid swimming and bioluminescent flashes, giant axons underlying the comb rows provide rapid neural conduction.

Within the apical sense organ is a **statocyst**, in which is a **statolith** that functions in balance and orientation. The statolith contains magnesium and calcium carbonates (possibly phosphates) and is made up of clusters of concretion-bearing cells called **lithocytes**, supported by four long tufts of cilia called **balancers** (Figure 6.11). The whole structure is enclosed in a transparent **dome** that is also derived from cilia. From each balancer arises a pair of **ciliated furrows** (= **ciliated grooves**), each of which connects with one comb row. Thus, each balancer innervates the two comb rows of its particular quadrant. Tilting the animal causes the statolith to press more heavily on the downside balancers, and the resulting stimulus elicits a vigorous beating of the corresponding comb rows to right the body. Depending on the "mood" of the individual (often associated with

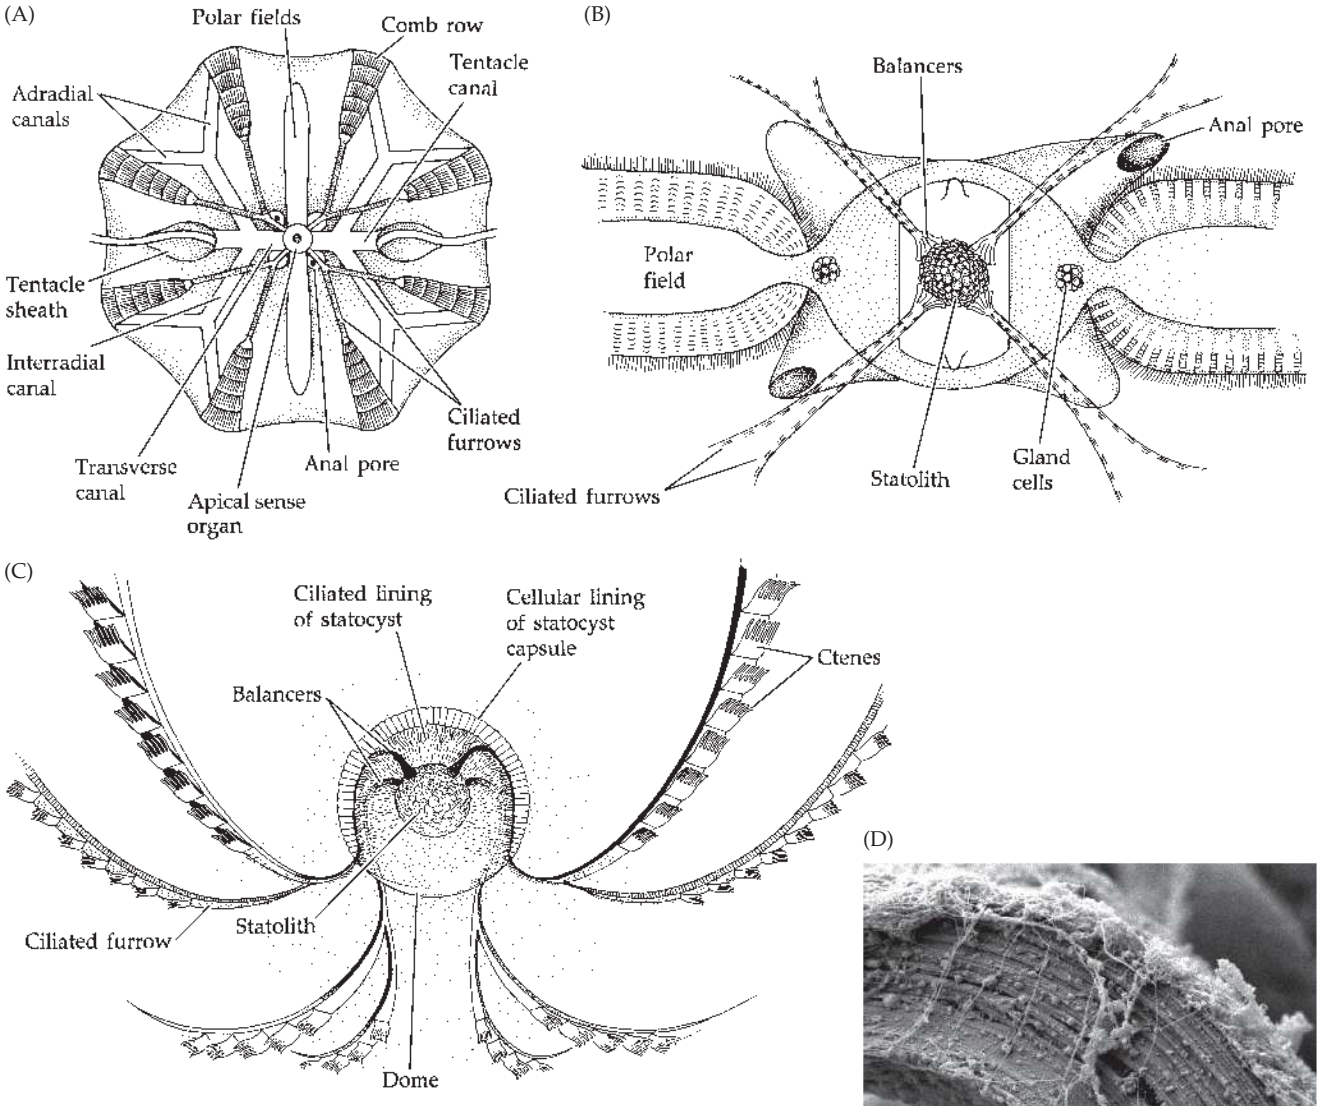

FIGURE 6.11 The ctenophore apical sense organ. (A) *Pleurobrachia* (aboral view). Note the relationship of the statocyst to the comb rows, the ciliated furrows, and the gastrovascular canals. (B) Apical sense organ of the cydippid *Hormiphora*. (C) Apical sense organ and its relationship to the eight comb rows. (D) Scanning electron micrograph showing the side view of a ctene from *Beroe forskalii*. The plate has been split along its axis to reveal the long bundles of cilia.

light-dark cycles), tilting might induce downward- or upward-directed swimming.

The two comb rows in each quadrant, connected to a single ciliated furrow, beat synchronously. If a ciliated furrow is cut, the beating of the two corresponding comb rows becomes asynchronous. The normal direction of ciliary power strokes is toward the aboral pole, so the animal is driven forward oral end first. The beat in each row, however, begins at the aboral end of the comb row and proceeds in metachronal waves toward the oral end (i.e., antiplectic metachrony). Stimulation of the oral end reverses the direction of both the wave and the power stroke. Removal of the apical sense organ or statolith results in an overall lack of coordination of the comb rows, and the injured ctenophore loses its ability to maintain a vertical position. The comb rows are very sensitive to contact; when a comb row is touched, some species partially retract it into a groove formed in the jellylike body.

In cydippids and beroids, the stimulation for any given ctene to beat is triggered mechanically by hydrodynamic forces arising from the movements of the preceding plate. However, in the lobate ctenophores, the ctenes are not coordinated in this

for more ebook/ testbank/ solution manuals reports email to 9601267347@qq.com

mechanical fashion. In these animals a narrow tract of shorter cilia—the **interplate ciliated groove**—runs between successive ctenes and is responsible for coordinating their activity. It is not known how the cilia of the groove are coordinated or how the grooves stimulate the appropriate comb row, so these actions may also be mechanical. The interplate ciliated grooves develop only as the lobate ctenophores mature to adulthood; the free-swimming larvae resemble cydippids and lack the grooves.

In most ctenophores, two oval tracts of cilia called polar fields lie on the stomodeal plane of the aboral surface (Figure 6.11B). These structures are thought to be sensory in function.

Reproduction and Development

Asexual reproduction and regeneration Many ctenophores (to a lesser extent in beroids) can regenerate virtually any lost part, including the apical sense organ. Entire quadrants and even whole halves will regenerate. Platyctenids reproduce asexually by a process that resembles pedal laceration in sea anemones; small fragments break free as the animal crawls, and each piece can regenerate into a complete adult.

Sexual reproduction and development Most ctenophores are hermaphroditic, but a few gonochoristic species are known (e.g., members of the genus *Ocyropsis*). The gonads arise on the walls of the meridional canals (Figure 6.10B), with eggs arranged on the side adjacent to the major axes and with sperm next to the minor axes. Pelagic ctenophores generally shed their gametes via the mouth into the surrounding seawater, where either self-fertilization or cross-fertilization takes place. Fertilization appears to take place within the meridional canals in *Pleurobrachia*. Special sperm ducts occur in at least some platyctenid species. The eggs are centrolecithal and formed in association with nurse cell complexes. Polyspermy is known to occur in some ctenophores. Those that free-spawn typically produce embryos that grow quickly to planktotrophic **cydippid larvae** (Figure 6.12), although species in the order Beroida lack this larval phase. Development is thus usually indirect, although growth to the adult is gradual rather than metamorphic. Some ctenophores are known to reproduce sexually before they have completed their larval development, a condition known as **dissogeny**. Precocious reproduction is known in at least two orders (Lobata: *Mnemiopsis leidyi*; Cydippida: *Pleurobrachia bachei*) and may reflect an evolutionary history favoring early reproduction, possibly because food supplies are only intermittently available or because predation rates are high. In the benthic *Coeloplana* and *Tjalfiella*, and in a few pelagic species, fertilization is internal and embryos are brooded until a cydippid larva is formed and released. This mixed life history provides a means of dispersal for these benthic, sedentary animals.

Ctenophoran cleavage cannot easily be classified as either spiral or radial (Figure 6.13). During early cleavage, the first four blastomeres arise by the usual two meridional cleavages, which mark the adult planes of symmetry. Even at this stage, corresponding quadrants are diagonally opposed, suggestive of their rotational symmetry. The third division is also nearly vertical and results in a curved plate of eight cells (with four macromeres). The next division is latitudinal and unequal, giving rise to micromeres on the concave side of the macromere plate. The micromeres continue to divide and spread by epiboly over the aboral pole and eventually over the macromeres. The latter also invaginate, so the gastrula arises through a combination of epiboly and invagination. Thus, the micromeres become ectoderm and the macromeres become endoderm. Just prior to gastrulation, the macromeres divide and produce additional micromeres on the oral side of the embryo. Whereas the aboral micromeres become ectoderm, these oral micromeres are incorporated into the endoderm and, in at least some species, give rise to photoreceptor cells. There

FIGURE 6.13 Ctenophore embryogeny: schematic diagram and fate map of ctenophore development. (A) Lateral view of the fertilized egg. The polar bodies (pb) mark the animal pole, which represents the future oral end of the animal in all illustrations. (B) At second cleavage each blastomere divides asymmetrically to give rise to an EM/ and an EM\ cell. The EM/ and EM\ cells lie in opposite, not adjacent, locations in the embryo. (C) At third cleavage, two distinct cell lineages are born, the E (end) and M (middle) blastomeres. (D) At the 16-cell stage, small micromeres arise that are given subscript numerals to indicate the order of their birth (e.g., e_1). Their sister macromeres are given ordinal numbers for ease of identification. (E) At the next round of divisions, the 1E and 1M macromeres give rise to another round of micromeres and each micromere also divides. (F) The 60-cell stage arises as all cells divide one additional time except for the 2M macromeres. (G) As gastrulation by epiboly begins, a distinct set of micromeres is born at the oral pole. These will give rise to the mesodermal derivatives. (H) The tentacle bulbs thicken prior to their invagination, the comb row cilia begin to beat, muscle and mesenchymal cells appear, and the apical organ begins to coalesce as components from all four quadrants move toward the aboral pole. (I) By approximately 24 hr, a fully functional cydippid-stage animal is formed. Cells colored in yellow give rise to ectoderm, cells colored green give rise to endoderm, and cells in red give rise to mesenchymal/mesodermal structures.

is some question about the fate of all of these oral micromeres. Metschnikoff (1885) suggested that these cells may contribute to the mesenchyme and may thus be viewed as true endomesoderm. Martindale and Henry (1999) mapped the fate of embryonic cells and showed that the mesenchyme is derived from endoderm. However, as mentioned previously, the genomes of *Mnemiopsis leidyi* and *Pleurobrachia bachei* show important genetic differences in the pathways for ctenophoran mesenchyme and the mesoderm of true triploblastic bilaterians.

As the micromeres cover the embryo to form the epidermis, four interradial bands of small, rapidly dividing cells become apparent. Eventually, each of

for more ebook/ testbank/ solution manuals visit! email 9601267347@qq.com

these thickened ectodermal bands differentiates into two of the comb rows. The aboral ectoderm differentiates into the apical sense organ and its related parts; the oral ectoderm invaginates to form the stomodeum. The gastrovascular system develops from endodermal outgrowths, and the tentacle sheaths arise as ectodermal invaginations from the points where the tentacles sprout. The embryo eventually develops into a free-swimming cydippid larva (Figures 6.12 and 6.13) that closely resembles adult ctenophores of the order Cydippida. Given the transformation, it is tempting to invoke Haeckel's "ontology recapitulates phylogeny" and conclude that Cydippida houses the most primitive lineage of extant ctenophores.

The development of ctenophores differs markedly from that of cnidarians. In the latter group, early cleavage results in an irregular mass of cells whose fates are not clearly predictable until later development, and the mesenchyme is strictly ectodermal in origin. In the ctenophores, on the other hand, development is determinate and a very precise cleavage pattern unfolds, in which the ultimate morphology is definitely mapped. For example, if the two blastomeres of a two-cell embryo are experimentally separated, the "half-embryos" develop into adults with exactly half the normal set of adult structures. Such results indicate that blastomere fate is highly determined, but they also suggest that inductive processes among embryonic cells and tissues are important in ctenophore embryogenesis, as is true in many bilaterian Metazoa. Additional data suggest that such processes can lead to more variation in cell fate than was previously suspected. Ctenophores produce a cydippid larval type having no counterpart among other metazoans.

Ctenophoran Phylogeny

Even though the ctenophores and hydrozoan cnidarians share superficial traits such as cellular mesenchyme and transparency, there are no robust affinities between ctenophores and any cnidarian group, with the exception of unipolar cleavage. The early concept of "Coelenterata" is not currently considered accurate nor particularly useful. Many of the similarities between ctenophores and cnidarian medusae are likely to be convergences reflecting adaptations to their similar lifestyles, and in fact, many gelatinous zooplankters from across metazoan diversity show superficial similarities in body form and construction. Benthic ctenophores (e.g., *Ctenoplana* and *Coeloplana*), which are flattened and creep along substrates, show some similarities with flatworms (Platyhelminthes; Chapter 17), but again this is convergence.

It is not just the affinities of ctenophores, but their phylogenetic relationships to other nonbilaterian Metazoa (Porifera, Placozoa, Cnidaria) that remain enigmatic. Some molecular phylogenies have placed the Ctenophora as sister group to the rest of the animals (including Porifera), as the earliest-diverging animal phylum. Perhaps supporting this hypothesis are phylogenomic studies that have shown the genomes of ctenophores and sponges to lack several homeobox-containing genes that are present within the genomes of placozoans, cnidarians, and bilaterians. Further, ctenophore genomes are unique in many respects. For example, they lack microRNA and microRNA-processing machinery, and their mitochondrial genomes are reduced. The debate between the "Porifera-first" and "Ctenophora-first" scenarios continues even in the presence of more comprehensive sampling of the diversity of each group, and better-quality data sets. However, methodological studies have shown that the choice of evolutionary model, outgroup taxa, and even inclusion of a particular handful of genes can sway the outcome. Resolving this question remains challenging because of the relatively small branch lengths separating the divergence of sponges and ctenophores, the long branches from that point to extant taxa, and the potential for saturation of the genetic signal due to great ages of origin, even with full genomes in hand.

Phylogenetic relationships within the Ctenophora have been challenged by limited gene data until recently, with phylogenomic analyses representing the main lineages of ctenophores. Molecular data show that the tentaculate condition is primitive and the atentaculate lineage (the order Beroida) arose from within the tentaculate groups. This placed the former class Nuda well nested within the former class Tentaculata. Furthermore, the Haeckeliidae, which have simple tentacles lacking side branches, has been shown to be the sister group to Beroidae, suggesting a progressive loss of tentacles. Molecular phylogenetic studies have also suggested that the cydippid family Mertensiidae might be the sister group to all other ctenophores, that Cydippida is clearly not monophyletic, and that some of the other orders are likely nested within the Lobata.

The fossil record for ctenophores faces several challenges, given the rare fossilization of these diaphanous organisms. In only a few cases can the features of a fossil be said to clearly correspond to the anatomy of extant ctenophores. Therefore, when a specimen has traits reminiscent of ctenophores but differs in other ways, it is hard to interpret whether this means early ctenophores were fundamentally different from modern ones, or whether the fossil may in fact not be a ctenophore ancestor at all. The fossils suggesting stalked ctenophores, or skeletonized meridional canals, are unlikely to actually be ctenophore progenitors. Cambrian fossils that have been ascribed to ctenophores typically lack tentacles, leading to the

"atentaculate primitive" hypothesis. If this is correct, then modern atentaculate ctenophores will have secondarily lost tentacles, because even before molecular evidence, it was considered that they are well nested within the tentaculate forms. The modern eight-comb rows appear to have stabilized in fossil forms long ago, including the first ctenophore fossil described in 1983. The enigmatic Ediacaran *Eoandromeda*, with octoradiate symmetry (generally equated with four pairs of comb plates), may have been an atentaculate ctenophore whose comb rows spiraled down the length of its cone-shaped body (Figure 6.14).

Chapter Summary

This chapter introduced you to two unusual, marine animal phyla, Placozoa and Ctenophora. Both are nonbilaterian, basally positioned clades in the animal tree of life, although their precise phylogenetic relationships remain elusive. Placozoans were first discovered in 1883, and only a few additional species have been described since. The bodies of these creatures are but a few millimeters in size, just two cell layers thick, and lack both symmetry and organs. They reproduce both sexually and asexually (by fragmentation or fission). Ctenophores are gelatinous creatures with biradial symmetry that are found floating in the open sea or on the seafloor. Although only about 130 species have been described, they can be quite common and abundant predators in the world's seas. Neither placozoans nor ctenophores have left a robust fossil record.

CHAPTER 7

Phylum Cnidaria

Anemones, Corals, Jellyfish, and Their Kin

The phylum Cnidaria is a highly diverse assemblage that includes jellyfish, sea anemones, corals, and the common laboratory *Hydra*, as well as many less familiar forms such as hydroids, sea fans, siphonophores, zoantharians, and the endoparasitic Endocnidozoa (Box 7A, Figure 7.1). There are about 13,300 described living species, all of which are predators (or highly modified parasites). Much of the striking diversity seen in this phylum results from three fundamental aspects of their natural history. First is the possession of **cnidae**—unique, tubular structures contained within cellular capsules that aid in prey capture, defense, locomotion, and attachment. No other animal group produces cnidae, and all cnidarians produce them. Second is the tendency to form colonies or assemblages of individuals by asexual reproduction; the colony can achieve dimensions and forms unattainable by single, nonmodular individuals. Third, many species of cnidarians exhibit a dimorphic life cycle that can include two entirely different morphologies: a **polypoid** form and a sexual **medusoid** form, in addition to a larval form as in many marine animals. The dimorphic life cycle has major evolutionary implications touching on nearly every aspect of cnidarian biology.[1] The polyp form of Cnidaria, planula larvae, stinging or adhesive cnidae, unique epitheliomuscular cells, and ectodermal-endodermal nerve nets are some of the key anatomical synapomorphies that define the phylum (Figure 7.44).

Cnidarians are **diploblastic** metazoans, at the tissue grade of construction. They possess radial symmetry (the body axes being in an oral–aboral plane), tentacles, an endodermally derived incomplete **gastrovascular cavity** as their only "body cavity," and a

[1] When both polyp and medusa phases are present in a species' life cycle, it is said to undergo **alternation of generations**, or as it is sometimes called, "**metagenesis**."

middle layer (called mesenchyme, or mesoglea) derived primarily from ectoderm.[2] They lack cephalization, a centralized nervous system, and discrete respiratory, circulatory, and excretory organs (Box 7B). This basic body plan is retained in both the polypoid and medusoid forms (Figure 7.2). In most, the radial symmetry is modified as biradial or tetraradial or by other degrees of radiality (animal symmetry was discussed in Chapter 3).

[2]There is a suite of terms in zoological literature that apply to non-triploblastic species that is frequently confused, misused, and generally messy. These terms include "mesenchyme," "mesoglea," "mesohyl," "collenchyme," "parenchyme," and "coenenchyme." In this book, these terms are used in the following ways. **Mesenchyme** (Greek, literally "middle juices") refers to a primitive connective tissue located between the outermost and innermost cell layers (e.g., epidermis and gastrodermis) and derived wholly or in large part from embryological ectoderm (and its derivatives). Mesenchyme generally consists of two components: a noncellular, jellylike matrix called **mesoglea**, and various cells and cell products (e.g., fibers). When no (or very little) cellular material is present, this layer is simply called mesoglea. Mesenchyme is the typical middle layer of sponges, between the pinacoderm and the choanoderm (where it is called the **mesohyl**), and of members of the diploblastic phyla Cnidaria and Ctenophora, between the endoderm (gastrodermis) and the ectoderm (epidermis). When cellular material is sparse or densely packed, mesenchyme may sometimes be designated as **collenchyme** or **parenchyme**, respectively. The term "parenchyme" is also sometimes used for the mesenchymal layer of triploblastic acoelomate animals (such as platyhelminths and xenacoelomorphans), in which the dense layer includes tissues derived from both ecto- and endomesoderm.

In some colonial cnidarians, particularly anthozoan polyps, the individuals are embedded in and arise from a mass of mesenchyme perforated with gastrovascular channels that are continuous among the members of the colony. The term coenenchyme refers to this entire matrix of common basal material, which is itself covered by a layer of epidermis.

Adding to the potential confusion, the term "mesenchyme" is used in a second, very different way by some biologists. Vertebrate embryologists sometimes use the term to refer to that part of true (endo-) mesoderm from which all connective tissues, blood vessels, blood cells, the lymphatic system, and the heart are derived. Thus, to a vertebrate embryologist, the term "mesenchymal cell" often denotes any undifferentiated cell found in the embryonic mesoderm that is capable of differentiating into such tissues. Occasionally, one also sees the term "mesenchyme" used in this way by echinoderm embryologists and non–vertebrate chordate specialists. In these latter cases, researchers are generally referring to cells that are destined to become mesodermal, and thus a better term might be "proto-" or "incipient mesodermal cells." Because of this confusion, some authors prefer to use the term "mesoglea" in lieu of "mesenchyme" when referring to the middle layers of sponges and diploblastic Metazoa. However, we adhere to the former definition of "mesenchyme" and hope that this note will lessen rather than add to the muddle.

A word of caution regarding spelling: the meanings of some of these terms can be altered by changing the terminal *e* to an *a*. The termination "-chyme" is preferred for animals, "-chyma" for plants. Thus, "mesenchyma" refers to tissue lying between the xylem and phloem in plant roots; "collenchyma" refers to certain primordial leaf tissues. "Parenchyma" is a very general botanical term used in reference to various supportive tissues. Unfortunately, the same spelling is occasionally (improperly) used by zoologists.

BOX 7A Classification of the Phylum Cnidaria

SUBPHYLUM ANTHOZOA

- Class Anthozoa. Anemones, sea pens, gorgonians, corals
  - Subclass Octocorallia. Octocorals
    - Order Helioporacea
    - Order Alcyonacea
      - Suborder Protoalcyonaria
      - Suborder Stolonifera
      - Suborder Alcyoniina
      - Suborder Scleraxonia
      - Suborder Calcaxonia
    - Order Holaxonia
    - Order Pennatulacea
  - Subclass Hexacorallia. Anemones and stony corals
    - Order Zoantharia
    - Order Actiniaria
    - Order Antipatharia
    - Order Corallimorpharia
    - Order Scleractinia
  - Subclass Ceriantharia

SUBPHYLUM ENDOCNIDOZOA Parasites of annelids, bryozoans, and aquatic vertebrates

- Class Polypodiozoa (monotypic: *Polypodium hydriforme*)
- Class Myxozoa
  - Subclass Myxosporea
    - Order Bivalvulida
    - Order Malacosporea

SUBPHYLUM MEDUSOZOA

- Class Hydrozoa. Hydroids and hydromedusae
  - Subclass Trachylina
    - Order Limnomedusae
    - Order Trachymedusae
    - Order Narcomedusae
    - Order Actinulida
  - Subclass Hydroidolina
    - Order Thecata (= Leptomedusae, Calyptoblastea)
    - Order Athecata (= Anthomedusae, Gymnoblastea)
      - Suborder Capitata
      - Suborder Aplanulata
      - Suborder Filifera
    - Order Siphonophora
      - Suborder Cystonecta
      - Suborder Codonophora
- Class Staurozoa. Stalked jellyfish
- Class Cubozoa. Sea wasps and box jellyfish
  - Order Chirodropida
  - Order Carybdeida
- Class Scyphozoa. Jellyfish
  - Order Coronatae
  - Order Semaeostomeae
  - Order Rhizostomeae

Cnidaria are marine, except for some Hydrozoa and some Endocnidozoa; only a few dozen species have been described from inland waters. Most are sessile (polyps) or planktonic (medusae) predators, although some employ suspension feeding and many species harbor symbiotic intracellular "algae" (e.g., dinoflagellates, cyanobacteria) from which they may secondarily derive energy, and one clade (Endocnidozoa) is strictly parasitic. Free-living cnidarians range in size from nearly microscopic polyps and medusae, to individual jellyfish 2 m wide and with tentacles 25 m long. Colonies, such as corals and siphonophores, may be many meters in size. The phylum probably dates back to the Precambrian but is known with greater confidence from the earliest Cambrian. Its members have played important roles in various ecological settings throughout their long history, just as they do today.

In Asia, jellyfish are routinely consumed by humans, and they have been a regular part of Chinese cuisine for centuries. About 35 species are eaten, most from the order Rhizostomeae, which tend to have more rigid bodies and produce the desired crunchiness when cooked. Recently, jellyfish fisheries (for export to Asia) have also started up in the New World, from Canada to Peru and

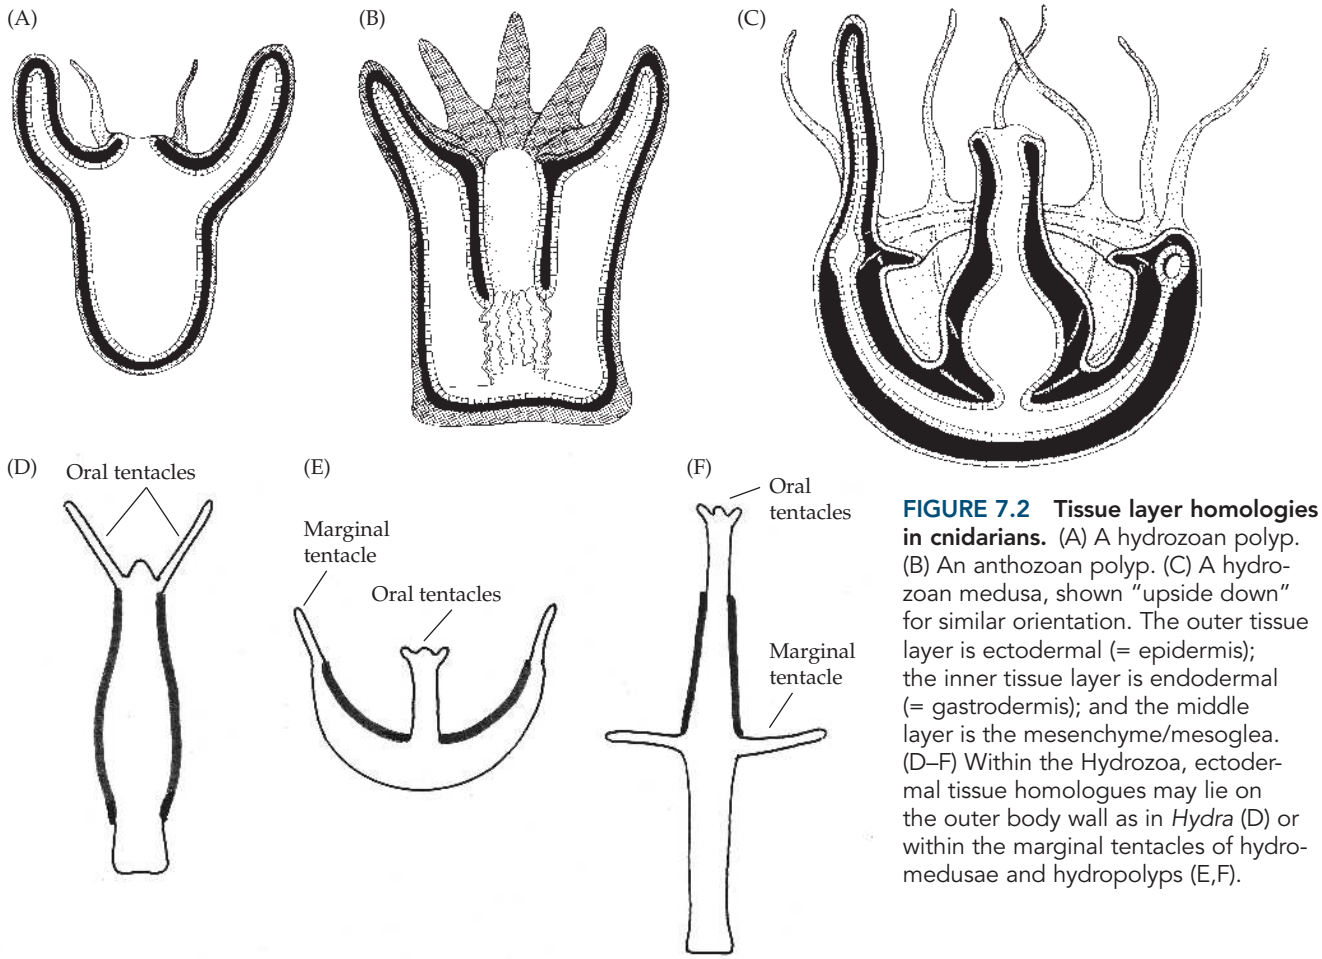

FIGURE 7.2 Tissue layer homologies in cnidarians. (A) A hydrozoan polyp. (B) An anthozoan polyp. (C) A hydrozoan medusa, shown "upside down" for similar orientation. The outer tissue layer is ectodermal (= epidermis); the inner tissue layer is endodermal (= gastrodermis); and the middle layer is the mesenchyme/mesoglea. (D–F) Within the Hydrozoa, ectodermal tissue homologues may lie on the outer body wall as in *Hydra* (D) or within the marginal tentacles of hydromedusae and hydropolyps (E,F).

Argentina. Most fisheries operations process the catch into semidried, rather than freeze-processed, products. In Asia, jellyfish are often touted as a traditional Chinese medicine that is beneficial for treating arthritis, high blood pressure, cancer, ulcers, and a myriad of other ailments. However, mild to severe allergic reactions have also been observed in humans eating jellyfish. In Russia, jellyfish have been added to cement to increase its strength. Sea turtles, penguins, ocean sunfish, and other fishes are all significant predators on jellyfish.

Cnidarians play numerous roles in folklore around the world. In Samoa, the corallimorpharian anemone

BOX 7B Characteristics of the Phylum Cnidaria

1. Diploblastic Metazoa with ectoderm and endoderm separated by a (primarily) ectodermally derived acellular mesoglea or partly cellular mesenchyme
2. With primary radial symmetry, often modified as biradial or quadriradial or with other variations on the radial theme, and an oral–aboral primary body axis
3. With unique stinging or adhesive structures called cnidae, the most common being called nematocysts, with each cnida residing in and produced by one cell, the cnidocyte
4. Musculature formed largely of myoepithelial cells (= epitheliomuscular cells and nutritive-muscular cells), derived from ectoderm and endoderm (adult epidermis and gastrodermis)
5. Alternating asexual polypoid and sexual medusoid generations, but with many variations on this basic theme (e.g., no medusoid stage in the class Anthozoa)
6. With a single "body cavity," the endodermally derived gastrovascular cavity (coelenteron), which is saclike, partitioned, or branched but with only a single opening serving as both mouth and anus
7. With no head, centralized nervous system, or discrete gas exchange, excretory, or circulatory structures
8. With a simple nerve net(s) of naked and largely nonpolar neurons as the nervous system
9. Typically with a planula larva (ciliated, motile, gastrula larva)

Rhodactis howesii, known as *mata-malu*, is served boiled as a festive holiday dish. Eaten raw, however, *mata-malu* causes death and is a traditional device in Samoan suicide. Hawaiians refer to the zoantharian *Palythoa toxica* as *limu-make-o-Hana* ("the deadly seaweed of Hana"). Hawaiians used to smear their spear tips with this cnidarian, the toxin from which is called **palytoxin**. Interestingly, palytoxin may be produced by an unidentified symbiotic bacterium, not by the cnidarian itself. It is one of the most powerful toxins known, being deadlier than that of poison arrow frogs (batrachotoxin) and paralytic shellfish toxin (saxitoxin).

Taxonomic History and Classification

As is the case with sponges, the nature of cnidarians was long debated. In reference to their stinging tentacles, Aristotle called the medusae *Acalephae* (*akalephe*) and the polyps *Cnidae* (*knide*), both names derived from terms meaning "nettle." Renaissance scholars considered them plants, and it was not until the eighteenth century that the animal nature of cnidarians was widely recognized. Eighteenth-century naturalists classified them along with the sponges and a few other groups under Linnaeus's Zoophytes, a category for organisms deemed somewhere between plants and animals. Lamarck instituted the group Radiata (or "Radiaires") for medusoid cnidarians, ctenophores, and echinoderms.

In the early nineteenth century the great Norwegian naturalist Michael Sars demonstrated that medusae and polyps were merely different forms of the same group of organisms. Sars also demonstrated that the genera *Scyphistoma*, *Strobila*, and *Ephyra* actually represented stages in the life history of certain jellyfish (scyphozoans). The names have been retained and are now used to identify these stages in the life cycle. The German zoologist Rudolph Leuckart eventually recognized the fundamental differences between the two great "radiate" groups, the Porifera/Cnidaria/Ctenophora and the Echinodermata, and in 1847 he created the name Coelenterata (Greek *koilos*, "cavity"; *enteron*, "intestine") for the former group in his recognition of the "intestine" as the sole body cavity. In 1888 the Austrian zoologist Berthold Hatschek split Leuckart's Coelenterata into the three phyla recognized today: Porifera, Cnidaria, and Ctenophora. Cnidarians and ctenophores are now universally recognized as distinct phyla, a view upheld by molecular analyses.

An important recent major advance in cnidarian systematics was confirmation that the myxozoans, formerly classified as protists, are in fact, highly derived, parasitic cnidarians. Myxozoans had been considered protists until 1899 when the Czech zoologist Antonín Štolc proposed they should be considered reduced cnidarians because of the nematocyst-like architecture of their spores. Over time, the multicellular nature of Myxozoa, and the structural and developmental similarity of their polar capsules to cnidarian nematocysts, gradually came to be recognized. And, since the early 2000s, molecular data have supported the classification of Myxozoa as cnidarians. In 2002, the enigmatic metazoan *Buddenbrockia plumatellae,* first discovered in 1850, was reinterpreted as a myxozoan. *Buddenbrockia* is a motile vermiform creature that inhabits the body cavity of freshwater bryozoans. It possesses four bands of longitudinal muscle cords, a cuticle-like body surface, no digestive tract, a cnidarian-like complement of polar capsules, and myxozoan-like infective spores (including polar capsules) that form inside the body cavity. Shortly after its rediscovery, it became clear that *Buddenbrockia plumatellae* is the same creature as *Tetracapsula bryozoides*, a known malacosporean (also described as *Myxosporidium bryozoides*), and furthermore, that another myxozoan, *Tetracapsula bryosalmonae*, was responsible for proliferative kidney disease (PKD) in salmonid fishes. The class Polypodiozoa comprises a single known species (*Polypodium hydriforme*), an intracellular parasite of acipenseriform fishes (sturgeons and paddlefishes); once thought to be allied with the class Hydrozoa, Polypodiozoa has been shown to be the sister group of Myxozoa, the two forming a clade of parasites called Endocnidozoa (Box 7A, and see below).

The Cnidaria thus comprise three major lineages: Anthozoa, a polypoid lineage lacking medusae; Medusozoa, a diverse clade including species exhibiting primarily motile medusoid forms as well as forms with both medusoid and polypoid life stages; and Endocnidozoa, a clade of highly simplified obligate endoparasites.

CLASSIFICATION OF PHYLUM CNIDARIA

SUBPHYLUM ANTHOZOA Class Anthozoa. Marine. Anemones, sea pens, soft corals, gorgonians, organ-pipe corals, and stony corals (Figure 7.1A–F).[3] Solitary or colonial; without a medusoid stage (individuals all polypoid); cnidae epidermal and gastrodermal; coelenteron divided by longitudinal (oral–aboral) mesenteries, the free edges of which form thick, cordlike mesenterial filaments; mesenchyme thick; tentacles number 8 (Octocorallia) or occur in multiples of 6 (Hexacorallia) and contain extensions of the coelenteron; stomodeal pharynx (= actinopharynx) extends from the mouth into the coelenteron and bears one or more ciliated grooves (siphonoglyphs); polyps may reproduce both sexually and asexually; gametes arise from gastrodermis. About 7,200 described living species divided into three subclasses: Octocorallia, Hexacorallia, and Ceriantharia.

[3] We use the term "anemone" in a general sense for any solitary anthozoan polyps, but we restrict the term "sea anemone" to the anemones of the order Actiniaria.

for more ebook/ testbank/ solution manuals requests email 9601267345@qq.com

SUBCLASS OCTOCORALLIA Octocorals. Polyps with 8 hollow, marginal, pinnate tentacles, and 8 complete (perfect) mesenteries, each with retractor muscle on the sulcal side (facing the single siphonoglyph); most species with free or fused calcareous sclerites embedded in mesenchyme, although sclerites lacking in some species; stolons or coenenchyme connect the polyps. Four orders are currently recognized, but considerable revision of subordinal groups is likely, particularly within the Alcyonacea.

ORDER HELIOPORACEA Helioporaceans. Colonies produce massive, rigid calcareous skeletons of aragonite crystals (not fused sclerites) similar to those of milleporid hydrozoans and stony corals; polyps monomorphic. Two families (Lithotelestidae and Helioporidae) and three genera (*Epiphaxum, Nanipora*, and *Heliopora*, "blue coral").

ORDER ALCYONACEA Soft gorgonians and organ-pipe corals. Colonies encrusting or erect, often massive; usually fleshy and flexible, although the coenenchyme is sclerite-filled; polyps monomorphic or dimorphic; fleshy distal portions of polyps usually retractable into more compact basal portion; skeletal elements composed of calcite and gorgonin. With 29 recognized families, classified in 5 heterogeneous suborders that may be little more than morphological grades.

SUBORDER PROTOALCYONARIA Deep-water octocorals with solitary polyps that reproduce exclusively by sexual means (e.g., *Ignis*, *Taiaroa*, and possibly *Haimea*).

SUBORDER STOLONIFERA Stoloniferans. Simple polyps arise separately from ribbon-like stolons that form an encrusting sheet or network; oral disc and tentacles retractable into a calyx (stiff proximal portion of polyp); mesenchyme with or without sclerites; in some (e.g., Cornulariidae) a thin, horny external skeleton may cover polyps and stolons (e.g., *Bathytelesto*, *Clavularia*, *Coelogorgia*, *Cornularia*, *Pseudogorgia, Sarcodictyon*, *Telesto*, *Tubipora*, the organ-pipe or pipe-organ "corals").

SUBORDER SCLERAXONIA Encrusting or upright, branched colonies with an inner axis (or axial-like layer) consisting mainly of fused sclerites. Includes *Corallium*, one of the precious corals used to make jewelry (also *Briareum*, *Melithaea*, *Paragorgia*, *Parisis*).

SUBORDER CALCAXONIA Gorgonians. Upright, branched or unbranched colonies with an inner axis consisting of scleroproteinous gorgonin without hollow cross-chambered central core, with large amounts of nonscleritic $CaCO_3$ as internodes or embedded in the gorgonin. Mostly found in the deep sea (e.g., *Australogorgia*, *Callogorgia*, *Chrysogorgia*, *Dendrobrachia*, *Helicogorgia*, *Isis, Plumarella*, *Plumigorgia*, *Primnoa*, *Verrucella*).

SUBORDER ALCYONIINA Soft corals. Polyps united within a mass of fleshy coenenchyme; coenenchyme usually with sclerites, but lacking an axis (e.g., *Alcyonium*, *Nidalia*, *Sarcophyton*, *Studeriotes*, *Umbellulifera*, *Xenia*).

SUBORDER HOLAXONIA Gorgonians. Upright, branched colonies with an inner axis consisting of scleroproteinous gorgonin without free spicules, with hollow cross-chambered central core, often with small amounts of embedded nonscleritic $CaCO_3$ (e.g., *Acanthogorgia*, *Eugorgia*, *Eunicea*, *Gorgonia*, *Ideogorgia*, *Muricea*, *Pseudopterogorgia, Swiftia*).

ORDER PENNATULACEA Sea pens and sea pansies. Colonies complex and polymorphic; adapted for life on soft benthic substrata; often bioluminescent; elongate primary axial polyp extends length of the colony (to 1 m) and consists of a basal bulb or peduncle for anchorage and a distal stalk, the latter giving rise to dimorphic secondary polyps; coelenteron of axial polyp with skeletal axis of calcified horny material in canals (e.g., *Anthoptilum*, *Cavernularia*, *Funiculina*, *Halipteris*, *Pennatula*, *Ptilosarcus*, *Renilla*, *Sarcoptilus, Stylatula*, *Umbellula*, *Virgularia*).

SUBCLASS HEXACORALLIA Anemones and stony corals. Solitary or colonial; naked, or with calcareous skeleton or chitinous cuticle, but never with isolated sclerites; mesenteries usually paired and in multiples of 6; mesenteries bear longitudinal retractor muscles arranged so that those of each pair either face toward each other or away from each other; mesenterial filaments typically trilobed, with two ciliated bands flanking a central one bearing cnidocytes and gland cells; one to several circles of hollow tentacles arise from endocoels (the spaces between the members of each mesentery pair) and exocoels (the spaces between 2 mesenteries of different pairs); pharynx may have 0, 1, 2, or many siphonoglyphs; cnidae very diverse; endodermal zooxanthellae may be profuse.

ORDER ACTINIARIA The sea anemones. Solitary or clonal; calcareous skeleton lacking, although some species secrete a chitinous cuticle; some harbor zooxanthellae; column often with specialized structures, such as warts or verrucae, acrorhagi, pseudotentacles, or vesicles; oral tentacles conical, digitiform, or branched, usually hexamerously arrayed in 1 or more circles; typically with 2 siphonoglyphs. A highly successful group with at least 1,000 living species in 41 families, the largest being the Actiniidae (e.g., *Actinia*, *Adamsia*, *Aiptasia*, *Alicia*, *Anemonia*, *Anthopleura*, *Calliactis*, *Diadumene*, *Edwardsia*, *Epiactis*, *Halcampa*, *Heteractis*, *Liponema*,

Metridium, *Nematostella*, *Peachia*, *Ptychodactis*, *Stichodactyla*, *Stomphia*, *Triactis*).

ORDER SCLERACTINIA (= MADREPORARIA) Stony corals. Colonial or solitary; polyp morphology almost identical to that of Actiniaria, except lacking siphonoglyphs and ciliated lobes on the mesenterial filaments; zooxanthellae present in about half the known species; colonies form delicate to massive calcareous (aragonite) exoskeletons, with platelike skeletal extensions (septa). Many species harbor symbiotic zooxanthellae of the genus *Symbiodinium*.[4] Over 1,300 extant species, in 24 families[5] (e.g., *Acropora*, *Agaricia*, *Astrangia*, *Balanophyllia*, *Dendrogyra*, *Flabellum*, *Fungia*, *Goniopora*, *Leptopsammia*, *Lophelia*, *Meandrina*, *Montipora*, *Oculina*, *Pachyseris*, *Porites*, *Psammocora*, *Siderastrea*, *Stylophora*).

ORDER ZOANTHARIA Zoantharians. Colonial polyps arise from a basal mat or stolon containing gastrodermal solenia or canals; new polyps bud from gastrodermal solenia of stolons; pharynx flattened, with one siphonoglyph; mesenteries numerous, but with weak musculature; without intrinsic skeleton, but many species incorporate sand, sponge spicules, or other debris into the thick body wall; most with a thick cuticle; zooxanthellae abundant in some species; many species epizootic (e.g., *Epizoanthus*, *Isaurus*, *Isozoanthus*, *Palythoa*, *Parazoanthus*, *Thoracactis*, *Zoanthus*).

ORDER ANTIPATHARIA Black or thorny corals. Upright, branched or whiplike colonies up to 6 m tall; calcareous axial skeleton, usually brown or black and covered by a thin coenosarc bearing small polyps, usually with 6 (but up to 24) nonretractable tentacles; with feeble mesenteries; skeleton produces thorns on its surface (e.g., *Antipathes*, *Bathypathes*, *Leiopathes*).

ORDER CORALLIMORPHARIA Corallimorpharians are solitary polyps, without a skeleton and lacking siphonoglyphs; with ciliated bands on mesenterial filaments, and muscles in the pedal disc (e.g., *Amplexidiscus*, *Corynactis*, *Rhodactis*, *Ricordea*).

SUBCLASS CERIANTHARIA Ceriantharians or tube anemones. Mesenteries complete, but with feeble musculature; with 6 primary mesenteries (as in Hexacorallia). Large, solitary, elongate polyps living in vertical tubes in soft sediments; tube constructed of interwoven specialized cnidae (ptychocysts) and mucus; aboral end lacks a pedal disc and possesses a terminal pore; long, thin tentacles arise from margin of oral disc, fewer shorter labial tentacles encircle mouth; mesenteries complete; gonads occur only on alternate mesenteries; protandric hermaphrodites. Two orders usually recognized, Penicillaria and Spirularia (e.g., *Arachnanthus*, *Botruanthus*, *Ceriantheomorphe*, *Ceriantheopsis*, *Cerianthus*, *Pachycerianthus*). Until recently, considered an order of Hexacorallia.

SUBPHYLUM ENDOCNIDOZOA Marine, brackish, and freshwater. Intracellular parasites of poikilotherm vertebrates, annelids, and bryozoans; possessing myxospores, cnidalike structures with 2 or more shell valves and polar capsules containing nematocyst-like filaments. This subphylum contains 2 clades (Polypodiozoa and Myxozoa), well supported by molecular phylogenetic analyses. About 2,200 described species.

CLASS POLYPODIOZOA Parasites of the oocytes of acipenseriform fishes. Worm shaped, without epithelial muscle cells, but with smooth muscle cells in mesoglea. Binucleate cells within fish oocytes develop into inverted planuliform larvae, which evert during host spawning into tentaculate stolons that possess cnidae and fragment when released into fresh water, dispersing as asexually reproducing medusoids whose gametes infect host fish. A single known species, *Polypodium hydriforme*.

CLASS MYXOZOA

SUBCLASS MYXOSPOREA Marine and freshwater species, usually with hard valves; life cycles include a myxosporean phase in vertebrates and an actinosporean phase within marine annelids. About 2,200 described species (Figure 7.1O).

ORDER BIVALVULIDA Possessing 2 valves per myxospore; gut and tissue parasites (e.g., *Ceratomyxa*, *Henneguya*, *Myxidium*, *Myxobolus*, *Sphaerospora*; the genus *Myxidium* appears to be polyphyletic).

[4] Coral reef ecosystems, to a great extent, owe their success to obligate mutualistic symbioses involving various invertebrates, particularly corals, and photosynthetic dinoflagellate symbionts. These single-celled algae, commonly referred to as zooxanthellae and predominantly belonging to the family Symbiodiniaceae, occur as symbionts with numerous species of Cnidaria, Porifera, Acoela, and Mollusca and with some other protists. In most cases, the algae are intracellular, residing in complex host-derived vacuoles, but in some cases (e.g., the bivalves *Tridacna* and *Hippopus*) they are intercellular. Photosynthetically fixed carbon, typically in the form of glycerol and other simple molecules, is translocated from the alga at a rate and volume often capable of meeting the host's respiratory demands. The presence of Symbiodiniaceae also facilitates the assimilation and conservation of nitrogen, a limiting resource in most coral reef ecosystems. Vertical transmission of the symbiont (the alga is passed from parent to progeny) is common, but in a majority of cases the offspring must be infected from environmental pools of the alga (horizontal transmission). The latter process potentially offers host progeny an opportunity to associate with symbiodiniacean types best adapted to local environmental conditions. Recent molecular genetic studies have revealed a half dozen or so "types" or clades within the former genus *Symbiodinium*, which has now been split into seven genera: *Symbiodinium*, *Breviolum*, *Cladocopium*, *Durusdinium*, *Effrenium*, *Fugacium*, and *Gerakladium*.

[5] The taxonomy of the Scleractinia is in a state of confusion, and many taxa, from genus and higher, appear to be nonmonophyletic. About 700 coral species live in deep water and do not form symbiotic relationships with zooxanthellae, and about two dozen of these build reef structures.

for more ebook/ testbank/ solution manuals requests email 9601267345@qq.com

ORDER MULTIVALVULIDA Possessing more than 2 valves per myxospore (e.g., *Kudoa*, *Trilospora*).

SUBCLASS MALACOSPOREA With a single order, Malacovalvulida, and a single family, Saccosporidae. Freshwater parasites of bryozoans; characterized by soft-walled spores, and spore formation within a saclike body form (e.g., *Buddenbrockia*, *Tetracapsuloides*).

SUBPHYLUM MEDUSOZOA Medusozoans. Marine and freshwater; free-swimming and sessile forms; medusae produced through lateral budding and growth of the entocodon; epidermal gonads; loss of intramesogleal muscles, associated with 4 peristomial pits; loss of primary polyp tentacles, transformed into hollow structures; gastric filaments and coronal muscles absent. Body typically tetraradial or, rarely, pentaradial. About 3,900 described living species in 4 classes.

CLASS STAUROZOA Stalked jellyfish (Figures 7.1G and 7.15E). Small, sessile individuals that develop from benthic, nonciliated planula larvae and have complex but poorly understood life cycles; the planula develops into a sessile stauropolyp, and this into a stauromedusa with a stalked adhesive disc by which individuals attach to substratum (a highly motile medusa stage does not exist); stauromedusae have 8 tentacle-bearing "arms" and lack a velum; sexual reproduction may be dominant in most species, although asexual reproduction is known in at least one (*Haliclystus antarcticus*). About 50 species, most in the Northern Hemisphere (e.g., *Calvadosia*, *Haliclystus*, *Lucernaria*). Molecular phylogenetic analyses indicate that despite considerable morphological convergence with trachyline hydrozoans, the minute Antarctic species, *Microhydrula limopsicola*, formerly identified within the Limnomedusae, is in fact a life stage within the life cycle of *Haliclystus antarcticus*.

CLASS CUBOZOA Sea wasps and box jellyfish (Figures 7.1I and 7.15A). Medusae 1–30 cm, largely colorless; polyps each produce a single medusa by complete metamorphosis (strobilation does not occur), medusa bell nearly square in cross section; rhopalia with complex visual structures; hollow interradial tentacle(s) hang from bladelike pedalia, one at each corner of umbrella; unfrilled bell margin drawn inward to form a velumlike structure (the velarium) into which diverticula of the gut extend. Cnidae of the nematocyst type only; the sting is very toxic, in some cases fatal to humans, hence the name "sea wasps." Cubozoans are strong swimmers that occur in all tropical seas (and a few temperate regions, e.g., the west coast of South Africa and Namibia) but are especially abundant in the Indo-Pacific region.

ORDER CHIRODROPIDA Pedalia branch into handlike structure with each branch giving rise to a tentacle; externally fertilizing species including known deadly genera, although toxicity is variable within this order due to differences in tentacle surface area and means of venom delivery (e.g., *Chironex*, *Chiropsalmus*, *Chiropsella*).

ORDER CARYBDEIDA Ovoviviparous species; venom can induce Irukandji syndrome, a usually not-life-threatening but physically and psychologically uncomfortable set of symptoms following envenomation. Five families: the pelagic Alatinidae (*Alatina, Keesingia*, *Manokia*), whose rhopaliar openings are T shaped; two families that lack rhopaliar horns and have rhopaliar openings that are frown shaped, the Carukiidae (*Carukia*, *Gerongia*, *Malo, Morbakka*) and the Tamoyidae (e.g., *Tamoya*), which also lack gastric filaments; the Carybdeidae (*Carybdea*), whose rhopaliar openings are heart shaped; and the Tripedaliidae (*Tripedalia*, *Copula*), which engage in courtship and "copulatory" behavior.

CLASS SCYPHOZOA Jellyfish (Figures 7.1H and 7.15B–D). Polypoid individuals (scyphistomae) are small and inconspicuous but often long-lived; polyps lacking in some species; when present, polyps produce medusae by asexual budding (strobilation); coelenteron divided by 4 longitudinal (oral–aboral) mesenteries; medusae acraspedote (without a velum), typically with a thick mesogleal (or collenchymal) layer, distinct pigmentation, filiform or capitate tentacles, and marginal notches producing lappets; sense organs occur in notches and alternate with tentacles; rhopalia with complex visual structures; gametes arise from gastrodermis; cnidae present in epidermis and gastrodermis, nematocysts only; mouth may or may not be on a manubrium; usually without a ring canal. Scyphozoans are exclusively marine; planktonic, demersal, or attached. About 200 species, divided into three orders.

ORDER CORONATAE High bell divided into upper and lower regions by a coronal groove encircling exumbrella; margin of bell deeply scalloped by gelatinous thickenings termed "pedalia," which give rise to tentacles, rhopalia, and marginal lappets; gonads present on the 4 gastrovascular septa. Small to moderate in size; primarily bathypelagic; some contain zooxanthellae (e.g., *Atolla*, *Linuche*, *Nausithoe*, *Periphylla*, *Stephanoscyphistoma*).

ORDER SEMAEOSTOMEAE Corners of mouth drawn out into 4 broad, gelatinous, frilly lobes; stomach with gastric filaments; hollow marginal tentacles contain extensions of radial canals; without coronal furrow or pedalia; gonads on folds of gastrodermis. This order contains most of the typical jellyfish of temperate and tropical seas; moderate to very large forms (some with a bell reaching several meters in diameter) (e.g., *Aurelia*, *Chrysaora*, *Cyanea*, *Pelagia*, *Phacellophora*, *Sanderia*, *Stygiomedusa*).

ORDER RHIZOSTOMEAE Lacking a central mouth; frilled edges of the four oral lobes are fused over the mouth so that many suctorial "mouths"

(ostioles) open from a complicated canal system on 8 branching armlike appendages; bell without marginal tentacles or pedalia; stomach without gastric filaments; gonads on folds of gastrodermis. Small to large jellyfish that swim vigorously using a well-developed subumbrellar musculature; primarily occur in low latitudes (e.g., *Cassiopea*, *Cephea*, *Eupilema*, *Mastigias*, *Rhizostoma*, *Stomolophus*).

CLASS HYDROZOA Hydroids, fire coral, and hydromedusae (Figures 7.1J–M and 7.8). Alternation of generations occurs in most genera (typically asexual benthic polyps alternate with sexual planktonic medusae), although one or the other generation may be suppressed or lacking; medusae produced through lateral budding of the entocodon; medusoids often retained on the polyp; polyps usually colonial, with interconnected coelenteron; often polymorphic, with individual polyps modified for various functions (e.g., gastrozooids feed, gonozooids are reproductive, dactylozooids are for defense and prey capture, etc.); exoskeleton, when present, usually of chitin or occasionally calcium carbonate (in the families Milleporidae and Stylasteridae); coelenteron of polyps and medusae lacks a pharynx and mesenteries; mesoglea acellular; tentacles solid or hollow; cnidae occur only in epidermis; gametes arise from epidermal cells; medusae mostly small and transparent, nearly always craspedote (with a velum) and with a ring canal; mouth typically borne on pendant manubrium; medusae lack rhopalia. A highly diverse group of about 3,500 described species, in 6 orders, including several dozen species from inland waters. Although the taxonomy of Hydrozoa is currently in a state of revision (and debate), there is considerable support for the existence of two monophyletic groups classified as subclasses, the Trachylina and the Hydroidolina. The Siphonophora has previously been regarded as its own subclass, but it now appears likely to be part of the subclass Hydroidolina.

SUBCLASS TRACHYLINA Trachyline medusae. Polypoid generation minute or absent; medusae produce planula larvae that usually develop directly into actinula larvae, which metamorphose into adult medusae; medusae craspedote, with tentacles often arising from exumbrellar surface, well above bell margin; medusae mostly gonochoristic; over 150 known species, in 4 orders.

ORDER LIMNOMEDUSAE (Figure 7.13A–C). Freshwater and marine hydromedusae with ecto-endodermal statocysts, hollow tentacles, and 4 (rarely 6) radial canals. The close relationship among freshwater genera suggests that freshwater species may share a common ancestor; these species are the only trachylines with true polyps, tiny structures that bud sexual medusae or asexual frustules that creep away to generate more polyps. Limnomedusae includes 6 families and numerous genera (e.g., *Astrohydra, Craspedacusta*, *Geryonia, Gonionemus*, *Limnocnida, Liriope, Monobrachium*, *Olindias*).

ORDER TRACHYMEDUSAE Exclusively marine hydromedusae, usually with 8 radial canals and solid tentacles; includes 4 families—Halicreatidae, Petasidae, Ptychogastriidae, and Rhopalonematidae. A large, possibly nonmonophyletic order with 6 families and many genera (e.g., *Aglantha*, *Botrynema, Ptychogastria*).

ORDER NARCOMEDUSAE Pelagic or bathypelagic hydromedusae lacking radial canals, with lobed umbrella margins, broad, pouched stomach, solid tentacles. Includes 7 families and numerous genera (e.g., *Aegina*, *Cunina*, *Pegantha*, the wormlike *Tetraplatia* formerly considered a coronate scyphozoan).

ORDER ACTINULIDA Two marine families, Halammohydridae (e.g., *Halammohydra*) and Otohydridae (e.g., *Otohydra*).

SUBCLASS HYDROIDOLINA (Figures 7.5 and 7.13D–F). Hydroids and their medusae, and siphonophores. Polypoid generation often predominant; polyps may have a chitinous exoskeleton; oral tentacles filiform or capitate, rarely branched or absent; colonies often polymorphic; many do not release free medusae but release gametes from sporosacs or sessile attached medusoids (= medusoid buds, or gonophores) on polypoid colony; colonies gonochoristic. A large group, with over 75 described families and over 3,220 species. Hydroids occur at all depths; the polypoid forms are very common in the littoral zone.

ORDER THECATA (= LEPTOMEDUSAE, CALYPTOBLASTEA, OR LEPTOTHECATA) A diverse group of hydroids with polyps, always colonial; hydranths and gonozooids encased in exoskeleton; free medusae usually absent, but when present flattened and with statocysts; medusae form gametes on subumbrella, beneath radial canals; gonozooids (= gonangia) with blastostyle that produces medusa buds. Monophyly of Thecata seems likely, but relationships within this order await further study. These are some of the most common species of hydrozoans in the marine littoral zone (e.g., *Abietinaria*, *Aequorea*, *Aglaophenia*, *Bonneviella*, *Campanularia*, *Cuvieria*, *Gonothyraea* [Figure 7.1K], *Lovenella*, *Obelia*, *Plumularia*, *Sertularia*).

ORDER ATHECATA (= ANTHOMEDUSAE, GYMNOBLASTEA, OR ANTHOATHECATA) Polyps solitary or colonial; hydranths and gonozooids lack exoskeleton; gonozooids produce free or sessile medusae; some groups produce gametes in transient sporosacs; free medusae tall and bell shaped, without statocysts, with or without ocelli; medusae form gametes on subumbrella or manubrium. Current research suggests this order is poly- or paraphyletic, and the three suborders here listed are provisional.

SUBORDER CAPITATA A diverse (and probably nonmonophyletic) group of hydroids

for more ebook/ testbank/ solution manuals requests email 9601263434@qq.com

possessing stenotele nematocysts and tentacles with rounded (capitate) tips at some stage in the life cycle; many have medusae with complex, cup-shaped ocelli. Current research suggests there may be two clades, Zancleida and Corynida. Zancleida includes well-known polypoid forms (e.g., *Pennaria*, the Christmas tree hydroids) and the fire corals or milleporids (known for their calcium carbonate skeleton and their potent stinging nematocysts). Milleporidae is a small family of about 13 species, all living in shallow tropical seas. Distinguished by massive or encrusting calcareous coral-like skeletons, the calcareous matrix covered by thin epidermal layer; gastrozooids with short capitate tentacles, each gastrozooid surrounded by 4–8 dactylozooid-like tentacles, each tentacle in a separate skeletal cup; gonophores housed in pits (ampullae) in skeleton; and, in the small free medusae, lack of mouth, tentacles, and velum. Like the stony corals, milleporids rely on a commensal relationship with zooxanthellae and are thus restricted to the photic zone. Zancleida also includes well-known medusoid forms, formerly known as "chondrophorans," whose colonies may consist of gastrozooids, gonozooids, and dactylozooids; or may be solitary but highly specialized polypoid individuals. Chondrophoran "zooids" are attached to a chitinous, multichambered, disclike float that may or may not have an oblique sail (e.g., *Porpita*, *Velella* [Figure 7.1M]); their "gonozooids" bear medusiform gonophores that are released and shed gametes; and most are richly supplied with zooxanthellae. The Corynida includes well-known medusoid forms such as *Coryne, Polyorchis* (Figure 7.1L), *Sarsia*, and *Slabberia*. The status and generic relationships of Corynida are unclear.

SUBORDER APLANULATA Members of this taxon lack a ciliated planula stage, hence their name; the group is well supported by molecular phylogenetic analyses. This suborder includes *Corymorpha*, *Tubularia*, *Hydra,* and *Candelabrum*. *Hydra*, while often used to exemplify the Cnidaria, is actually rather unusual in life cycle and morphology.

SUBORDER FILIFERA This heterogeneous (and probably nonmonophyletic) taxon is currently divided into around 26 families, in 4 major groups (Filifera I, II, III, and IV). Filifera I is typified by the family Eudendriidae, which is distinguished from other filiferans by the absence of desmoneme nematocysts, the presence of a styloid-shaped gonophore, and a trumpet-shaped hypostome. Filifera II is less distinct but shares a solid ring canal and macrobasic eurytele cnidae, as well as reduction in hydranth tentacles. Many species in this group live on other invertebrates (e.g., *Hydrichthella* on octocorals; *Brinckmannia* within hexactinellid sponges; *Proboscidactyla* on sabellid polychaete tubes). Filifera III is typified by the families Hydractiniidae (e.g., *Clava*, *Hydractinia*) and Stylasteridae (e.g., *Stylaster*). Members of these families have polymorphic polyps and perisarc- or skeleton-covered stolons that can be colorful. With over 300 living species in 30 genera, Stylasteridae is one of the most species-rich hydrozoan families. The stylasterid skeleton is secreted within the epidermis and covered by a thick epidermal layer; a calcareous style often rises from the base of the polyp cup, hence the name "stylasterid"; polyps may have tentacles; free medusae are not produced, but sessile medusoid gonophores are retained in shallow chambers (ampullae) of the colony; several dactylozooids surround each gastrozooid, although polyp pits are joined. Filifera IV includes the families Bougainvilliidae (e.g., *Bougainvillia*, *Dicoryne*), Cordylophoridae (e.g., *Cordylophora*), Pandeidae (e.g., *Pandea*), Rathkeidae (e.g., *Rathkea*), and Oceaniidae (e.g., *Turritopsis*, the "immortal jellyfish"), which all bear gonophores on structures other than hydranths.

ORDER SIPHONOPHORA Siphonophores comprise a diverse clade of about 190 named species of polymorphic colonies, with a number of distinct types of polyps and attached modified medusae (Figures 7.1N, 7.8F,H,I, and 7.9). Most species planktonic, but some are benthic and tethered to the sea bottom (Codonophora: Rhodaliidae) at depths up to 4,300 m. They are well known for their ability to produce bioluminescence, fluorescence, and structurally based colors (especially the nectophores). All are colonial, each zooid being homologous with a solitary animal though physiologically integrated. Zooids are specialized for a range of functions, including feeding, reproduction, protection, swimming, and flotation. Some species have numerous zooid types, for example, nectophore, gastrozooid, palpon, several types of bracts, and gonophores. Gonophores are male or female sexual medusae that produce gametes. Some species are hermaphroditic (male and female gonophores occur on the same colony), but most are gonochoristic (male and female gonophores are on different colonies). Gastrozooids are feeding polyps that have a single tentacle attached to the base of the zooid used for prey capture (with the exception of *Physalia physalis*, the Portuguese man-of-war, which has separate zooids for feeding and prey capture, and rhodaliids, which have some tentacles used to anchor to the substratum). Gastrozooids carry nematocyst batteries. Nectophores are highly specialized nonreproductive propulsive medusae of the nectosome region. Bracts are greatly reduced zooids (unique to codonophoran siphonophores)

that function for protection of the other zooids and help maintain neutral buoyancy; they usually have extensions of a gastrovascular or radial canal system. The role of palpons is not well understood, but they might function in circulation of gastrovascular content, digestion, and/or defense; each bears a single tentacle with nematocysts. All these zooid types bud from one or two restricted growth zones at the base of the nectosome, creating long chains of highly organized zooids (the siphosome region) in repeating groups called cormidia and typically containing a helmet-shaped bract, a gastrozooid, and one or more gonophores. The pneumatophore (when present) is a gas-filled float located at the "anterior" end of the colony, which helps the colony maintain its orientation in the water column and can play a role in flotation (it is not a zooid but is formed by invagination at the aboral end of the planula during early development). The term "anterior" in this case is strictly a legacy convention and does not imply an anatomical anterior–posterior axis in the colony. Siphonophores are major oceanic predators, some colonies reaching tens of meters in length (in 2020 a spectacular colony was seen off the west coast of Australia, estimated to be 50 m in length); a majority of the species is bioluminescent. Historically divided into three groups based on body structure, but molecular phylogenetic research now suggests the existence of two major clades—Cystonectae and Codonophora. The benthic, deep-sea *Dendrogramma enigmatica*, from southern Australian seabeds at 400 to 2,900 m depth (Figure 7.1N), once thought to be a medusozoan, is now believed to be the detached bracts of a benthic codonophoran siphonophore.

SUBORDER CYSTONECTA Possessing an anterior gas-filled float or pneumatophore, with a posterior, zooid-bearing siphosome (e.g., *Physalia*, *Rhizophysa*).

SUBORDER CODONOPHORA Structurally the more complex siphonophores, this suborder includes the monophyletic Calycophorae and the paraphyletic Physonectae. The former includes most siphonophore species, which possess an anterior nectosome, composed of nectophores, swimming elements that propel the colony, and a posterior zooid-bearing siphosome but no pneumatophore (e.g., *Diphyes*, *Hippopodius*, *Sphaeronectes*). "Physonectans" possess an apical (aboral) gas-filled float, or pneumatophore, that is probably not a medusa nor of medusoid origin (the float is filled mainly with carbon monoxide, and the cavity is lined by ectoderm); they are currently divided into a few clades, including Apolemiidae and Pyrostephidae (e.g., *Agalma*, *Apolemia*, *Bargmannia*, *Dendrogramma*, *Nanomia*, *Physophora*).

The Cnidarian Body Plan

Although showing marked advances over Porifera and Placozoa, cnidarians still possess only two embryonic germ layers—the ectoderm and the endoderm—which become the adult epidermis and gastrodermis, respectively. The middle mesoglea or mesenchyme in adults is derived largely from ectoderm and never produces the complex organs seen in triploblastic Metazoa (i.e., the Bilateria).

Whether or not a true basement membrane (= basal lamina) exists in cnidarians is debatable. We define a **basement membrane** as a thin sheet of extracellular matrix upon which an epithelial layer may rest; it contains collagen and other proteins, and it helps hold the epithelial cells in place. By this definition, placozoans lack a basement membrane, cnidarians and ctenophores possess one by way of the mesenchyme, and the Bilateria possess a well-developed, highly proteinaceous basement membrane. And, as we have seen, basement membranes also occur in some sponges.

The essence of the cnidarian body plan is radial symmetry (Figure 7.3). As discussed in Chapter 3, radial symmetry is associated with various architectural and strategic constraints. Cnidarians are sessile, sedentary, or pelagic, and they do not engage in the active unidirectional movement seen in bilateral, cephalized creatures. Radial symmetry demands certain anatomical arrangements, particularly of those parts that interact directly with the environment, such as feeding structures and sensory receptors. Thus, we typically find a ring of tentacles encircling the body that can collect food from any direction, and a diffuse, noncentralized nerve net with radially distributed sense organs. These and other implications of radial symmetry are explored further throughout this chapter. Although polypoid and medusoid forms are often represented as inverted forms of one another (Figure 7.2A–C), studies of gene expression in cnidarians show that the oral tentacles of polyps and the marginal tentacles of medusae may not necessarily be homologous structures (Figure 7.2D–F). As we will see, differences between polyps and medusae go well beyond how animals appear to be oriented along their oral–aboral axis.

In spite of the limitations of a diploblastic, radially symmetrical body plan, cnidarians are a highly successful and extraordinarily diverse group. Much of their success has been attributed to the possession of cnidae and the diversity of different dimorphic life histories. Although polyps and medusae are very different in appearance, they are really variations on the basic cnidarian body plan (Figure 7.2). And yet, the two stages are vastly different ecologically, and their presence in a single life history allows an individual species to exploit different environments and resources, leading a "double life."

The Body Wall

Cnidarian epithelia—the outer epidermis and the inner gastrodermis—include **myoepithelial cells** (Figures 7.4 and 7.19), which are capable of performing both epithelial and muscular functions. These columnar cells bear flattened, contractile, basal extensions called **myonemes** (Figure 7.19). In the epidermis, these cells are referred to as **epitheliomuscular cells**, and in the gastrodermis they are called **nutritive-muscular cells**. The myonemes rest against the middle mesoglea or mesenchyme, and the opposite ends of the cells form the outer body and gut surfaces. The myonemes run parallel to free surfaces and contain contractile myofibrils. Myonemes of neighboring cells are interconnected, often forming longitudinal and circular sheets capable of contracting like typical muscle layers of the triploblastic phyla.

Molecular studies of germ layer formation in anthozoans show that virtually all of the genes involved in endomesoderm formation in bilaterian embryos, including the core genes identified as components of an evolutionarily conserved endomesoderm ("kernel") gene regulatory network, are expressed in cnidarian epithelial tissue that lines the gastric cavity or the pharynx. This conservation in components of the endomesodermal gene regulatory network provides compelling evidence that the endodermal and pharyngeal tissue of cnidarians (and probably ctenophores) is homologous with that of the gut and oral ectoderm of bilaterians, and that both endoderm and mesoderm of bilaterians evolved from an ancestral endomesodermal layer. Fate mapping experiments have shown that the definitive endoderm is generated from the oral pole/animal hemisphere in both anthozoan cnidarians and ctenophore embryos. They also show that the primary opening to the cnidarian and ctenophoran gut arises from the same region of the embryo (the animal hemisphere) that forms the mouth in all bilaterians. This suggests that the oral pole of adult ctenophores and cnidarians is homologous with the anterior pole of bilaterians and that the gastrovascular opening/mouth is homologous with the mouth of bilaterians. This relationship is also supported by molecular data. Thus, the mouths of all animals appear to be homologous, with the possible exception of the chordates. (The mouth of chordates does not express the same suite of genes seen in other metazoans, and its position forms independently of a circumoral component of the nervous system shared by most other metazoans.)

Some cnidarians also possess subepidermal mesenchymal muscles, apparently derived from the contractile elements of the myoepithelial cells. In anemones, for example, cordlike sphincters are sunk below the epithelium and reside as distinct muscles wholly within the mesenchyme. In addition to epitheliomuscular cells, the epidermis contains sensory cells, cnida-bearing cells called cnidocytes, gland cells, and interstitial cells. The last are undifferentiated and capable of developing into other cell types. The gastrodermis is histologically somewhat similar to the epidermis (Figure 7.4). Along with the nutritive-muscular cells, it also contains cnidocytes (except in the Hydrozoa) and gland cells.

In medusozoans, the middle layer is a rather simple, gel-like, largely acellular mesoglea. Scyphomedusae have a very thick mesogleal layer with scattered cells. In stauromedusans, cubozoans, and hydrozoans, the mesoglea is noncellular. In anthozoans the middle layer is often a thick and richly cellular mesenchyme (see footnote 2, earlier in the chapter). Myxozoans are primarily small and cellular without clearly defined

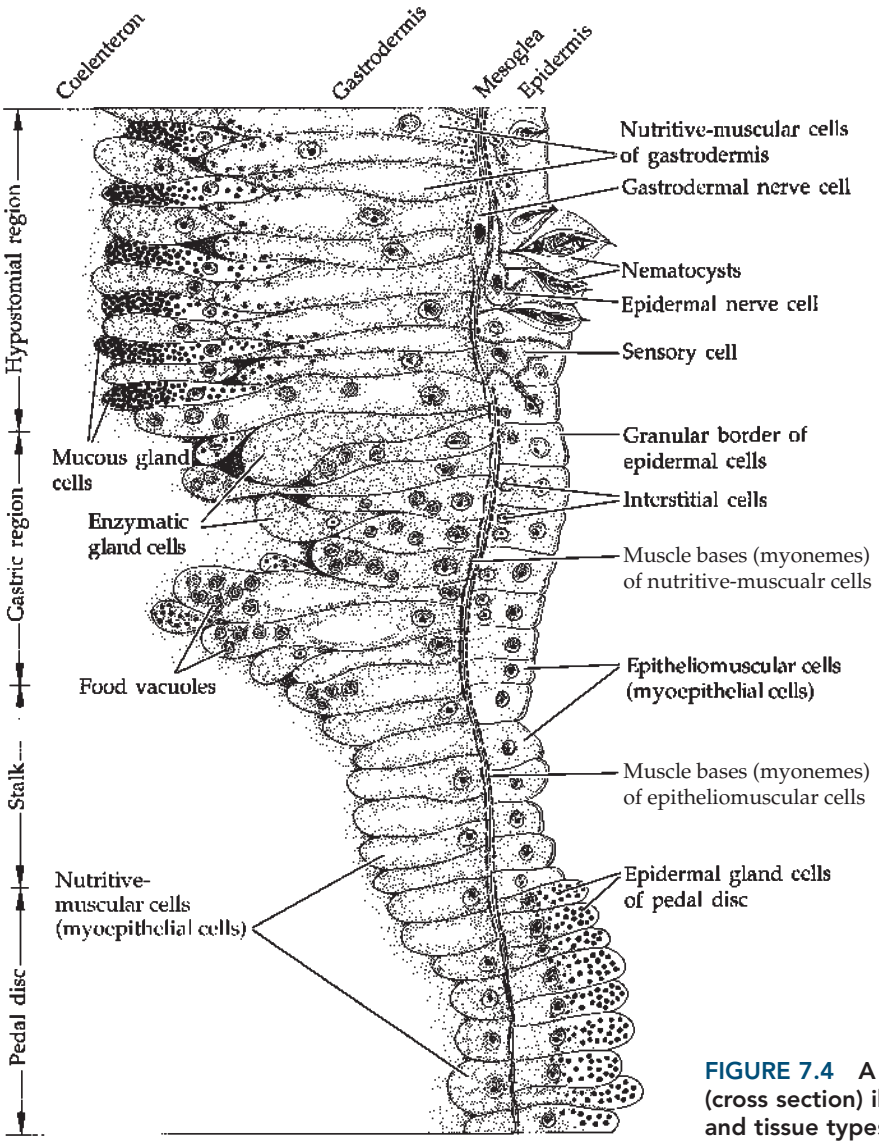

FIGURE 7.4 **A hydrozoan polyp column wall (cross section) illustrates the basic cnidarian cell and tissue types.**

body walls, with a few exceptions. The actinosporan larva of many myxosporeans has rays composed of single cells that are used to attach to the mucous membranes of vertebrate hosts. The wormlike *Buddenbrockia* has four blocks of longitudinal musculature that lie beneath the epidermis and surround a hollow, gut-free body cavity.

The polypoid form Polyp stages are much more diverse than are medusae, largely as a result of their capacities for asexual reproduction and colony formation (Figures 7.5–7.12). This diversity of form has led to an extensive lexicon of terms for the parts of polyps. This expansive terminology may at first seem a bit overwhelming, but bear with us—we won't give you anything unnecessary here. The polypoid stage occurs in the subphyla Anthozoa and Medusozoa, although it is greatly modified in the Scyphozoa, Cubozoa, and Staurozoa. A clearly defined polypoid stage appears to be lacking in the subphylum Myxozoa. Polyps are tubular structures with an outer epidermis, an inner gut sac (coelenteron) lined with gastrodermis, and a layer of jellylike mesoglea or mesenchyme in between. Most polyps are small, but the polyps of some species of sea anemones get quite large; the largest is the monstrous tropical Indo-Pacific *Stichodactyla mertensii*, which can exceed a meter in diameter, and the beautiful northeast Pacific *Metridium farcimen*, which can extend its column to a meter in height.

The fundamental polypoid symmetry is radial, although as a result of subtle modifications most species possess a biradial or quadriradial symmetry. The main body axis runs longitudinally through the mouth (oral end) to the base (aboral end) of the polyp. The aboral end may form a **pedal disc** for attaching to hard substrata (as in most common sea anemones); it may be a rounded structure—called a **physa**—adapted for digging and anchoring in soft substrata

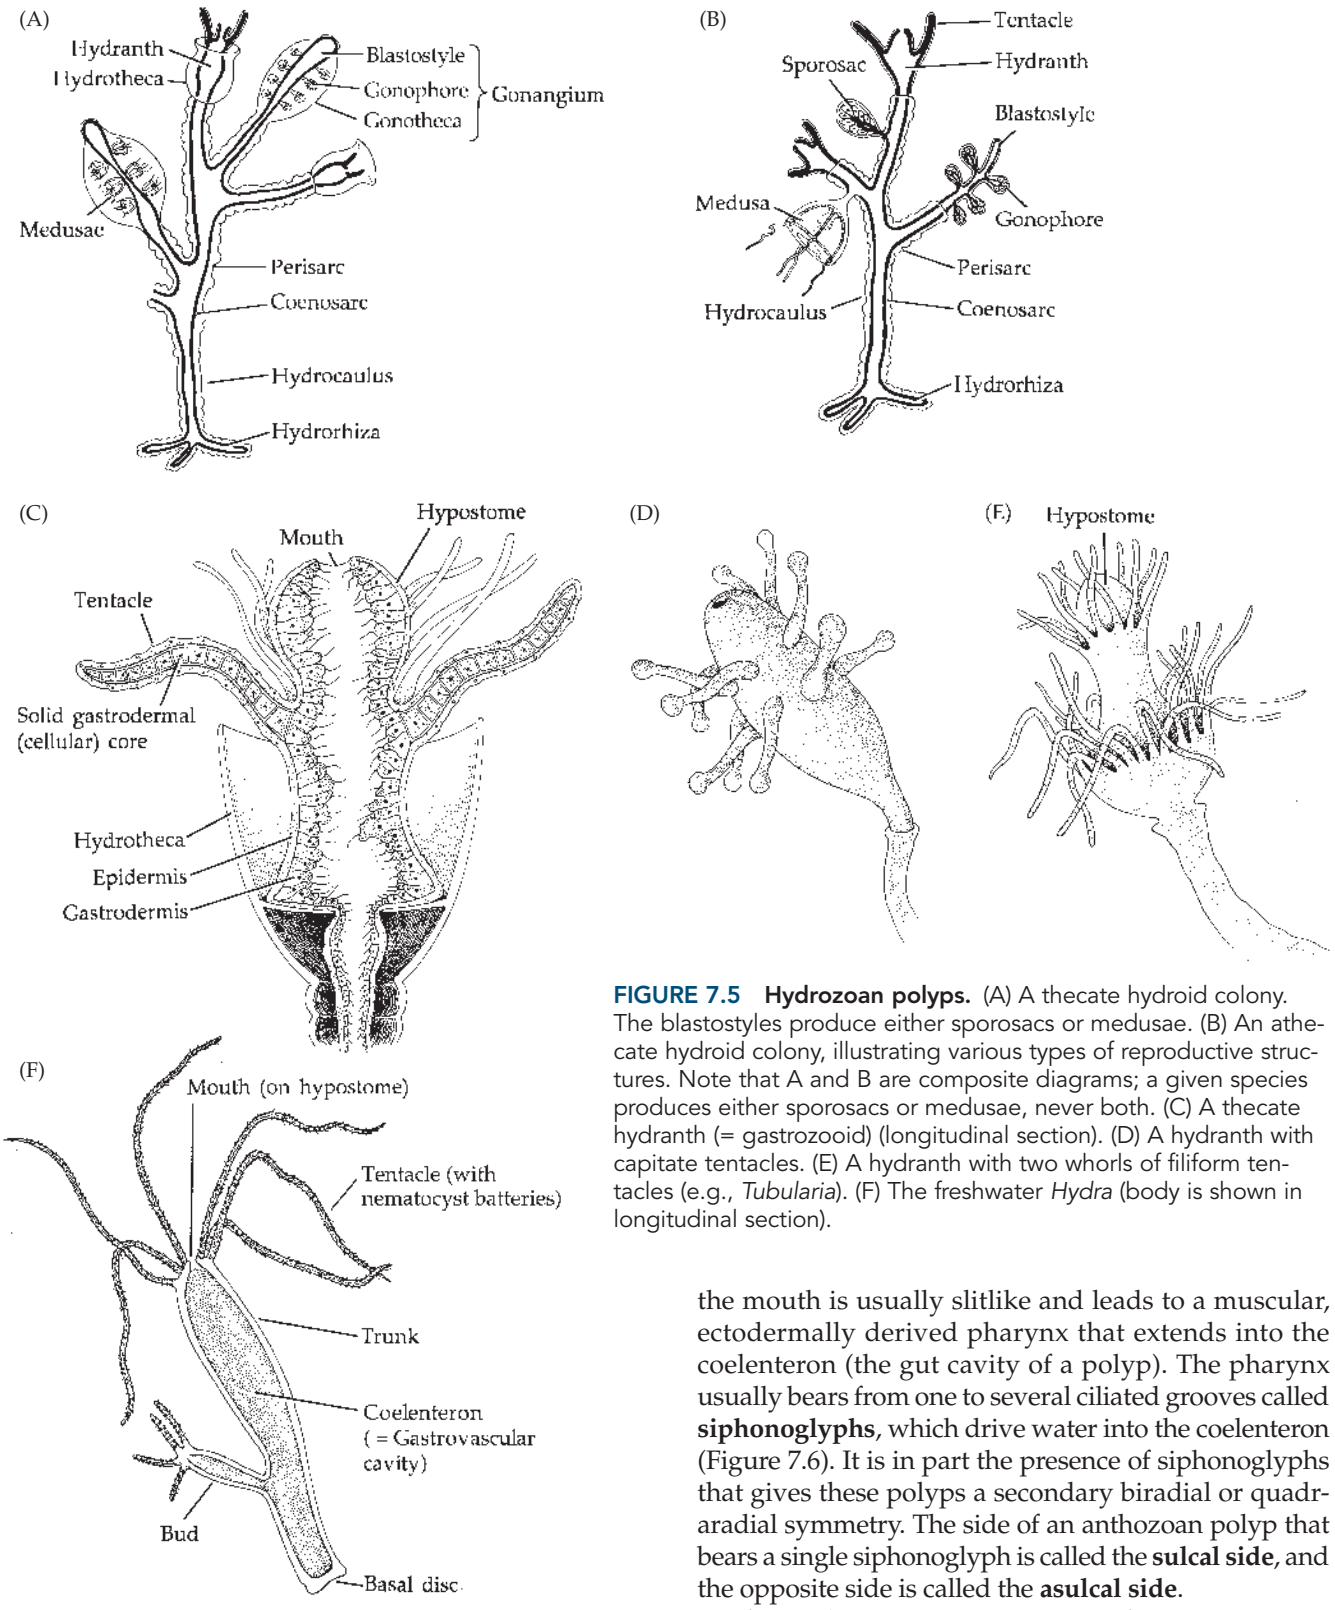

FIGURE 7.5 Hydrozoan polyps. (A) A thecate hydroid colony. The blastostyles produce either sporosacs or medusae. (B) An athecate hydroid colony, illustrating various types of reproductive structures. Note that A and B are composite diagrams; a given species produces either sporosacs or medusae, never both. (C) A thecate hydranth (= gastrozooid) (longitudinal section). (D) A hydranth with capitate tentacles. (E) A hydranth with two whorls of filiform tentacles (e.g., *Tubularia*). (F) The freshwater *Hydra* (body is shown in longitudinal section).

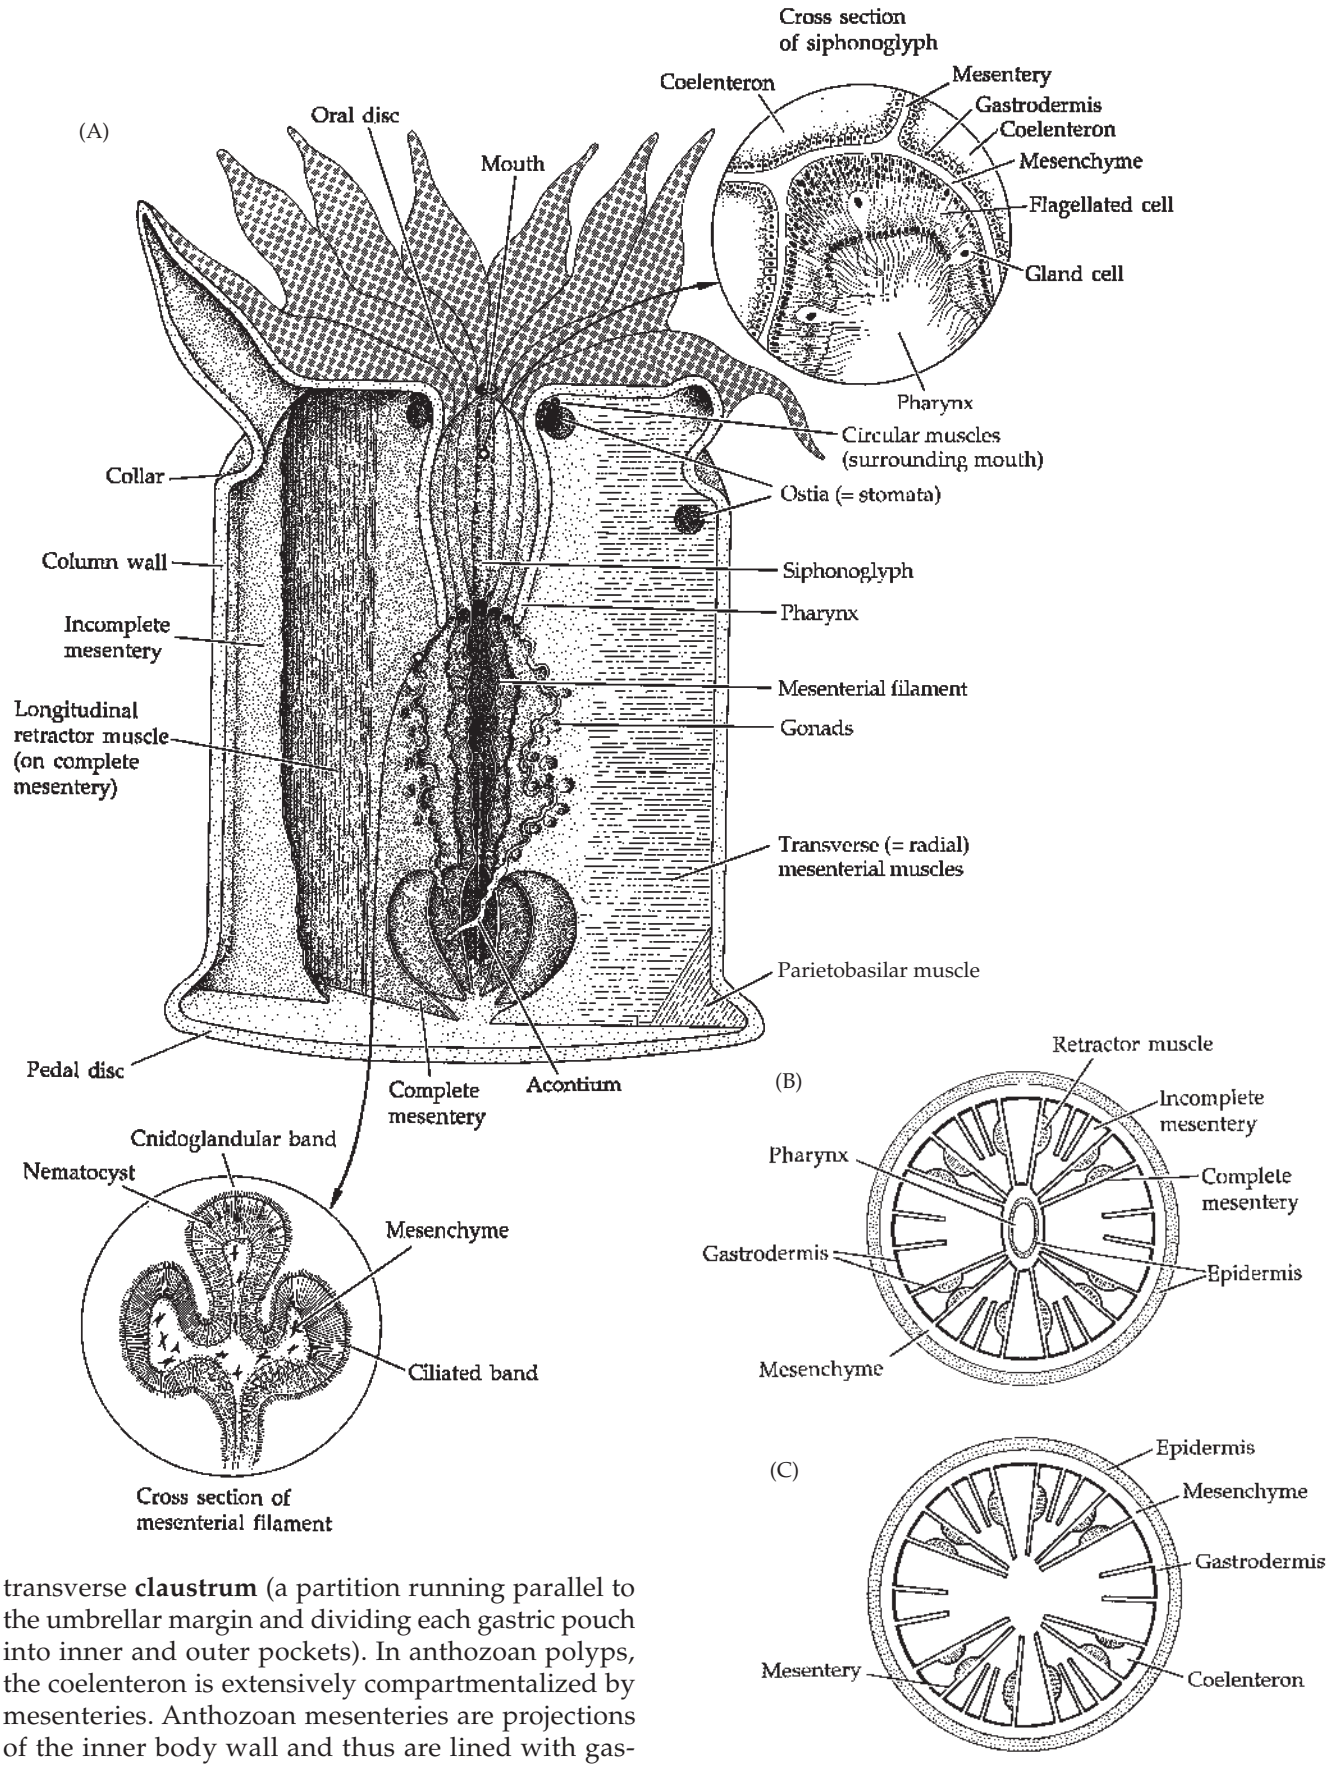
(as in burrowing anemones); or it may arise from a common mat, stalk, or stolon in colonial forms.

The mouth may be set on an elevated **hypostome** or **manubrium** as in hydrozoans, or it may be on a flat **oral disc** as in anthozoans (Figures 7.5 and 7.6). In anthozoans the mouth is usually slitlike and leads to a muscular, ectodermally derived pharynx that extends into the coelenteron (the gut cavity of a polyp). The pharynx usually bears from one to several ciliated grooves called **siphonoglyphs**, which drive water into the coelenteron (Figure 7.6). It is in part the presence of siphonoglyphs that gives these polyps a secondary biradial or quadraradial symmetry. The side of an anthozoan polyp that bears a single siphonoglyph is called the **sulcal side**, and the opposite side is called the **asulcal side**.

The **coelenteron**, or gastrovascular cavity, serves for circulation as well as digestion and distribution of food. In hydrozoan polyps, the coelenteron is a single, uncompartmentalized tube. In scyphozoan (scyphistomae) and staurozoan polyps, it is partially subdivided by four longitudinal, ridgelike mesenteries, and in some staurozoans and cubozoans, additionally by a



transverse **claustrum** (a partition running parallel to the umbrellar margin and dividing each gastric pouch into inner and outer pockets). In anthozoan polyps, the coelenteron is extensively compartmentalized by mesenteries. Anthozoan mesenteries are projections of the inner body wall and thus are lined with gastrodermis and filled with mesenchyme. They extend from the inner body wall toward the pharynx, some or all of them fusing with it as **complete mesenteries**. Those that do not connect to the pharynx are called

FIGURE 7.6 An anthozoan polyp. (A) A sea anemone (longitudinal section). (B) Cross section taken at the level of the pharynx. (C) Cross section taken below level of the pharynx.

for more ebook/ testbank/ solution manuals requests: email C9601267344@qq.com

incomplete mesenteries. In anthozoan polyps, the free inner edge of each mesentery below the pharynx has a thickened, cordlike margin armed with cnidae, cilia, and gland cells and is called the **mesenterial filament** (Figures 7.6 and 7.20). In some sea anemones these filaments give rise to long threads, called **acontia**, that hang free in the gastrovascular cavity. Acontia function in defense and feeding (see the Feeding and Digestion section). In most colonial anthozoans the cellular mesenchyme unites individual polyps (Figure 7.12). In some, such as the soft corals, gastrovascular cavities are connected to one another by canals called **solenia**.

The tentacles that surround the mouth contain hollow extensions of the coelenteron in anthozoans, whereas they house a solid core of packed gastrodermal cells in most hydrozoans. Tentacles may taper to a point (filiform tentacles) or may terminate in a conspicuous knob containing cnidae (capitate tentacles). In some polyps the tentacles are branched, often as pinnately arranged pinnules (e.g., in the octocorals).

Branched hydrozoan colonies, the individual polyps of which are called **hydropolyps**, grow in two patterns (Figure 7.7). In **monopodial growth**, the first polyp elongates continuously from a growth zone at the distal end of the simple or branched stem of the colony, the **hydrocaulus.** This primary (axial) polyp may even lose its hydranth (feeding zooid) and persist merely as a stalk. The primary hydrocaulus gives rise to secondary polyps by lateral budding. These secondary polyps grow and may give rise to lateral tertiary polyps in the same fashion. In hydrozoan colonies developing by **sympodial growth**, the primary polyp does not continue to elongate but produces one or more lateral polyps by budding and then stops growing. The new polyps extend the colony upward some distance, then stop growing and give rise to more new polyps by budding. In these colonies the main stem or axis actually represents the combined hydrocauli of many polyps, and the age of the polyps decreases from base to tip along each branch.

Most marine hydroids are surrounded, at least in part, by a nonliving protein-chitin exoskeleton secreted by the epidermis and called the **perisarc** (Figure 7.5). Interestingly, this outer covering is absent in freshwater hydroids. The living tissue inside the perisarc is termed the **coenosarc**. The perisarc may extend around each hydranth and gonozooid as a **hydrotheca** and **gonotheca**, respectively. When this occurs, the hydroids are said to be **thecate**; hydroids whose perisarcs do not extend around the zooids are **athecate**.

A complex terminology has been developed to describe hydrozoan polyps, or "hydroids" as they are commonly called (Figures 7.5 and 7.7). The reason for this special nomenclature is that hydroid colonies are usually polymorphic, containing more than one kind of polyp, or zooid. The terms **hydranth** and **gastrozooid** refer to feeding zooids, which typically bear tentacles and a mouth. Other commonly occurring polyp types include

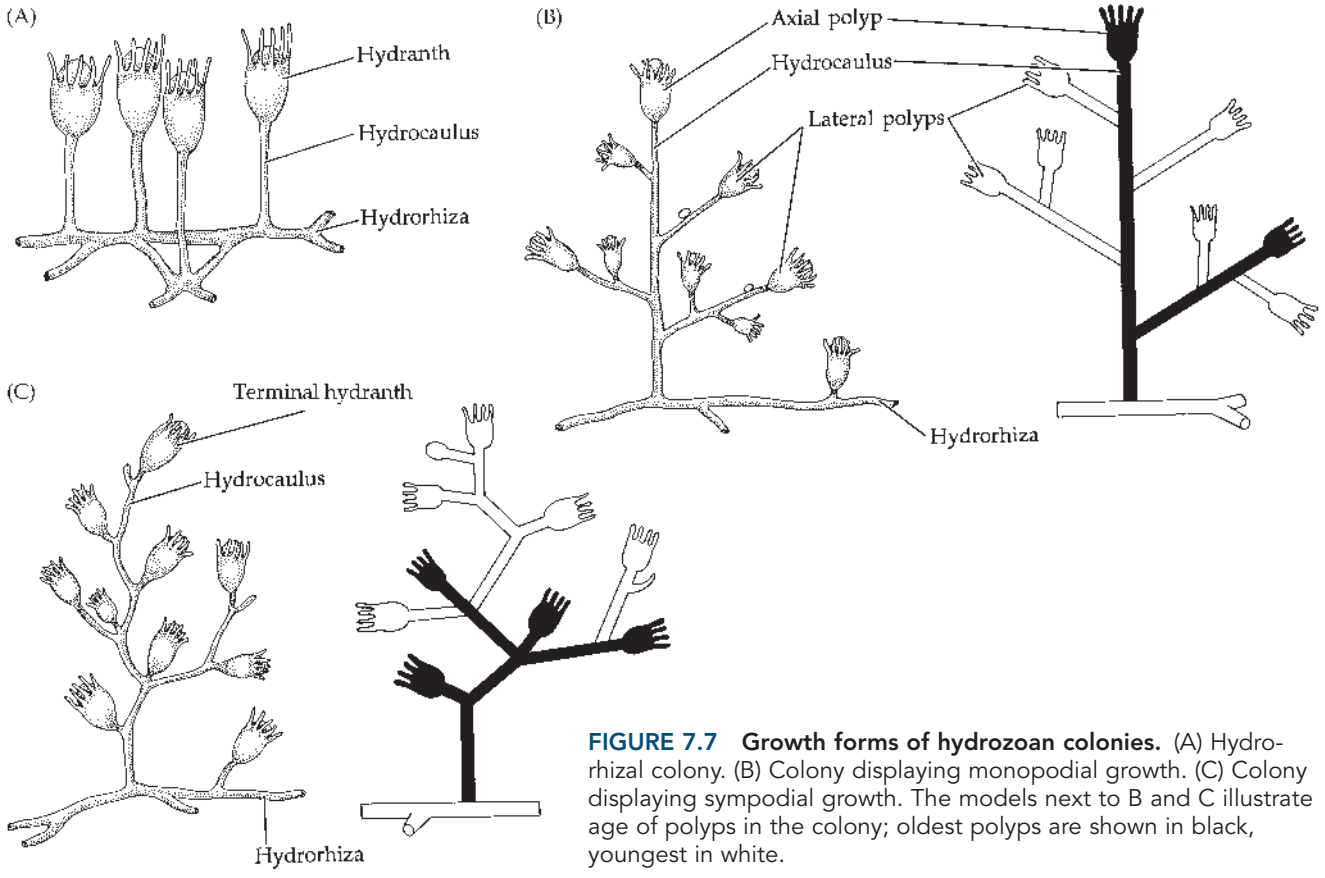


FIGURE 7.7 Growth forms of hydrozoan colonies. (A) Hydrorhizal colony. (B) Colony displaying monopodial growth. (C) Colony displaying sympodial growth. The models next to B and C illustrate age of polyps in the colony; oldest polyps are shown in black, youngest in white.

(B) *Monobrachium*, a one-tentacled hydroid that lives on clam shells. (C) *Hydractinia*, a colonial hydroid commensal on shells inhabited by hermit crabs. (D) The "chondrophoran" *Porpita* (aboral view). (E) A colony of the calcareous milleporid hydrocoral *Millepora* (fire corals). (F) A siphonophore, *Physalia* ("Portuguese man-of-war"). (G) A colony of the calcareous stylasterid hydrocoral *Stylaster*. (H) *Praya dubia*, a colonial calycophoran siphonophore from California. (I) Another siphonophore.

defensive polyps (**dactylozooids**) and reproductive polyps (**gonozooids** or **gonangia**). Each zooid typically arises from a stalk, called a **hydrocaulus** (pl. hydrocauli). In most colonial hydrozoans, the individual polyps are anchored in a rootlike stolon called a **hydrorhiza**, which grows over the substratum. From the hydrorhiza arise the hydrocauli, bearing polyps singly or in clusters.

Gastrozooids capture and ingest prey and provide energy and nutrients to the rest of the colony. Dactylozooids, which occur in a variety of sizes and shapes, are heavily armed with cnidae. Often several dactylozooids surround each gastrozooid and serve for both defense and food capture. Gonozooids produce medusa buds called **gonophores** that are either released or retained on the colony. Whether released as free medusae or retained as attached gonophores, they produce gametes for the sexual phase of the hydrozoan life cycle. The living tissue (coenosarc) of the gonozooid is called the **blastostyle**; the gonophores arise from this tissue. When a **gonotheca** surrounds the blastostyle, the zooid is called a **gonangium**.

The most dramatic examples of polymorphism among polyps are seen in the hydrozoan order Siphonophora and the anthozoan order Pennatulacea. Siphonophores (Figures 7.1N, 7.8F,H,I, and 7.9) are hydrozoan colonies composed of both polypoid and medusoid individuals, with as many as a thousand zooids in a single colony. This large order includes a great variety of unusual and poorly understood species, including the famous Portuguese man-of-war, *Physalia* (Figure 7.8F). The gastrozooids of siphonophores are actually highly modified polyps with a large mouth and one long, hollow feeding tentacle that bears many cnidae (Figure 7.9A). This feeding tentacle reaches lengths of 13 m in the Atlantic species *Physalia physalis*. The nonfeeding dactylozooids also bear one long (unbranched) tentacle (Figure 7.9B). The gonozooids (Figure 7.9C) are usually branched; they produce sessile gonophores that are never released as free medusae.

Siphonophores use one or more swimming bells (**nectophores**) or a gas-filled float (a **pneumatophore**), or both, to help maintain their position in the water. Nectophores are true medusoid individuals with many of the structures common to free-swimming medusae, although each nectophore has lost its mouth, tentacles, and sense organs. The pneumatophore, once also thought to be a modified medusa, is now known to be derived directly from the larval stage and may represent a highly modified polyp. Pneumatophores are double-walled chambers lined with chitin. Each float houses a gas gland, which consists of a mitochondria-laden glandular epithelium lining a chamber. The gland secretes a gas usually similar to air in composition, although in *Physalia* it apparently includes a surprisingly high proportion of carbon monoxide. Many siphonophores have mechanisms by which they regulate gas in their floats to keep the colony at a particular depth, much like the swim bladders of fishes.

Siphonophores were formerly classified into three suborders on the basis of colony structure: the Calycophorae included colonies with swimming bells but no float; Physonectae included those with a small float

and a long train of swimming bells; and Cystonecta had a large float and no bell. However, recent molecular phylogenetic evidence suggests that Cystonecta is the sister group to other siphonophores, with the monophyletic Calyphora nested within a paraphyletic Physonectae, both grouped for now within the suborder Codonophora (see Taxonomic History and Classification section). Calycophorans have a long tubular stem extending from the swimming bell, from which various types of zooids bud in groups called **cormidia** (Figure 7.8H). Each cormidium acts as a colony within a colony, and it is usually composed of a shieldlike bract, a gastrozooid, and one or more gonophores that may function as swimming bells. The cormidia commonly break loose from the parent colony to live an independent existence, at which time they are termed **eudoxids**. The members of the former physonectans have an apical float with a long stem bearing a series of nectophores followed by a long train of cormidia, thus a plesiomorphic condition within Codonophora. The cystonectans, including *Physalia*, usually have a large pneumatophore with a prominent budding zone at its base, which produces the various polyps and medusoids (Figure 7.8F).

Within the hydrozoan suborder Capitata, a group formerly known as the "chondrophora" is composed of colorful oceanic organisms that drift about on the sea surface in enormous flotillas, occasionally washing ashore to coat the beach with their bluish-purple bodies (Figures 7.1M and 7.10). Although they superficially resemble some siphonophores, current opinion holds these animals to be large, solitary, athecate hydranth polyps, floating upside down instead of sitting on a stalk attached to the bottom. The aberrant medusae of "chondrophorans" are short-lived and do not possess a functional mouth or gut, probably relying instead on their symbiotic zooxanthellae for nutrition. The aboral sail in *Velella* (the "by-the-wind-sailor") has no counterpart in sessile hydroids. In its ability to sail at an angle to the wind, *Velella* resembles the siphonophore *Physalia*—a similarity attributed to convergent evolution. Figure 7.10 compares a chondrophoran and a sessile hydroid, such as *Tubularia* or *Corymorpha*.

The pennatulaceans are the sea pens and sea pansies, and these are the most complex and polymorphic members of the class Anthozoa (Figures 7.1C,E and 7.11D). The colony is built around a main supportive stem, which is actually the primary polyp and buds lateral polyps in a regular fashion. The base of the primary polyp (the **stalk** or **peduncle**) is anchored in sediment, but the upper, exposed portion (the **rachis**) produces polyps in whorls or rows or sometimes united in crescent-shaped "leaves." Often these polyps are of two distinct types. **Autozooids** bear tentacles and function in feeding; **siphonozooids** are small, have reduced tentacles, and serve to create water currents through the colony. In sea pens the rachis is elongated and cylindrical; in sea pansies it is flattened and shaped like a large leaf (Figure 7.1E). In the odd deep-sea genus *Umbellula*, (Figure 7.1F) the secondary polyps radiate outward to give the colony the appearance of a pinwheel set on the end of a narrow stalk that can grow taller than a person. The first deep benthic photos of *Umbellula* had biologists scratching their heads for years, wondering to which phylum this preposterous creature might belong.

FIGURE 7.10 *Velella.* (A) A capitate hydrozoan such as *Velella* compared with (B) a sessile tubularian hydranth, in support of the view that "chondrophorans" are highly specialized, solitary tubularian zooids. (C) *Velella* skeletons in beach wrack, coast of Washington State.

Gorgonians are also colonial anthozoans (Figures 7.1D and 7.12). Some grow in bushy shapes, whereas others are planar; size and shape of the colony are often mediated by the hydrodynamics of prevailing surge and currents. Where prevailing currents are more or less in one plane (although they may move in two directions back and forth), the branches of the colony tend to grow largely in one plane also—perpendicular to the flow. In regions of mixed currents, the same species tends to grow in two planes.

The apparent polyps of *Polypodium hydriforme* (the only species in the bizarre class Polypodiozoa, of the subphylum Endocnidozoa) exist intracellularly within the ova of their fish hosts as an inverted stolon whose digestive surface faces outward. Prior to host spawning when ova are provisioned with yolk, *Polypodium* everts to assume normal cell layer position, filling its gastric cavity with host yolk and revealing tentacles distributed along the stolon's length.

The medusoid form Free medusae occur only in the subphylum Medusozoa. Although variation in form exists, medusae are far less diverse than polyps, and it is much easier to generalize about their anatomy. (After reading about the amazing variation in polypoid colonies, you're probably happy to hear this!) The relative uniformity of medusae may be largely a result of their usually similar lifestyles in open water and of their inability (except among hydrozoans) to form colonies by asexual reproduction. Sessile benthic medusae exist, but they are relatively rare (Figure 7.1G). Despite their simplicity relative to polypoid forms, medusae do vary considerably in size, ranging from 2.0 mm diameter hydromedusae to 2.0 m scyphomedusae, and depending on their habitat can exhibit particular morphological specializations associated with movement in a fluid medium. In many medusae the radial canals open near the ring canal onto the subumbrellar surface by separate pores. These are thought to be "excretory pores" for the ejection of wastes and indigestible materials that have been seen passing through them. While polyps often represent the vegetative stage of development among cnidarians, most medusae are the sexual form.

Even though the body walls of medusae and polyps are similar and both adhere to the general cnidarian body plan outlined earlier, their gross morphologies are adapted to their very different lifestyles. Medusae are bell or umbrella shaped and are usually imbued with a thick, jellylike mesogleal layer (hence the name "jellyfish" or simply "jellies"). The convex upper (aboral) surface is called the **exumbrella**; the concave lower (oral) surface is the **subumbrella**. The mouth is located in the center of the subumbrella, often suspended on a pendant, tubular extension called the **manubrium**,

which is almost always present on hydromedusae (Figure 7.13) but usually reduced or absent in scyphomedusae (Figure 7.14).

The coelenteron or gastrovascular cavity occupies the central region of the umbrella and extends radially in the body via **radial canals**. In most hydromedusae (medusae of the class Hydrozoa), a marginal ring canal within the rim of the bell connects the ends of the radial canals. The presence of four radial canals and of tentacles in multiples of four (in hydromedusae) and the division of the stomach by mesenteries into four **gastric pouches** (in scyphomedusae) give most jellyfish a quadriradial (= tetramerous) symmetry (Figure 7.3A). Most hydromedusae have

a thin circular flap of tissue, the **velum**, within the margin of the bell (Figure 7.13). Such medusae are termed **craspedote**. Those lacking a velum, such as scyphomedusae, are said to be **acraspedote** (Figures 7.14 and 7.15). The medusae of cubozoans possess an independently evolved structure, the **velarium** (Figure 7.15A), which is structurally different but functionally similar to the hydromedusan velum. As in polyps, the external surfaces of medusae are covered with epidermis, and the internal surfaces (coelenteron and canals) are lined with gastrodermis. The bulky, gelatinous middle layer is either a largely acellular mesoglea or a partly cellular mesenchyme.

Although scyphozoan genera are morphologically similar, diversity may be much greater than previously suspected. For example, molecular evidence suggests that the moon jellyfish *Aurelia aurita*, a cosmopolitan semaeostome species often used in invertebrate zoology laboratories to illustrate medusoid structure and the alternation of generations in the life cycle of cnidarians, may consist of seven or more distinct species. While morphologically indistinguishable (so far), these genetically distinct populations may have diverged as early as the Late Cretaceous (> 65 Ma).

Support

Cnidarians employ a wide range of support mechanisms. Polyps rely substantially on the hydrostatic qualities of the water-filled coelenteron, which is constrained by circular and longitudinal muscles of the body wall. With few exceptions, polyps have smooth muscle, but medusae have both smooth and striated (though mononuclear) muscles in the umbrella. However, the muscles of cnidarians lack crucial components of bilaterian striated muscles, such as genes that code

for the muscle proteins titin (a.k.a. connectin) and the troponin complex. In addition, the mesenchyme may be stiffened with fibers, particularly in the anthozoans. Colonial anthozoans may incorporate bits of sediment and shell fragments onto the column wall for further support. Many colonial hydrozoans produce a flexible, horny perisarc, composed largely of chitin secreted by the epidermis. In medusae, the principal support mechanism is the middle layer, which ranges from a fairly thin and flexible mesoglea to an extremely thick and stiffened fibrous mesenchyme, which may be almost cartilaginous in consistency. Even the small, benthic polyp phase of medusozoans typically has a thin, flexible, chitin-based covering secreted by the epidermis and similar to that seen in anthozoans.

In addition to these soft or flexible support structures, there is an impressive array of hard skeletal structures of three fundamental types: horny or woodlike axial skeletal structures, calcareous sclerites, and massive calcareous frameworks. Horny axial skeletons occur in several groups of colonial anthozoans such as gorgonians, sea pens, and antipatharian corals (Figures 7.11 and 7.12). Amebocytes in the coenenchyme secrete a flexible or stiff internal **axial rod** as a supportive base embedded in the coenenchymal mass. Axial rods are protein-mucopolysaccharide complexes (called **gorgonin** for "gorgonian" corals in the octocoral order Alcyonacea). In the antipatharians (black corals), the axial skeleton is so hard and dense that it is ground and polished to make jewelry, leading to a serious overharvesting of these animals around the world.

In most octocorals, mesenchymal cells called **scleroblasts** secrete calcareous sclerites of various shapes and colors (Figure 7.16C). It is usually these sclerites that give soft corals and gorgonians their characteristic color and texture. In many species, the sclerites become quite dense and may even fuse to form a more-or-less solid calcareous framework. The precious red corals in the genus *Corallium* are actually gorgonians with fused red coenenchymal sclerites. In the stoloniferan organ-pipe corals (*Tubipora*), the sclerites of the body walls of the individual polyps are fused into rigid tubes. Invertebrate calcium carbonate skeletons do not usually have collagen incorporated into their framework, as occurs in vertebrates. However, in at least some gorgonians (e.g., *Leptogorgia*) the calcareous spicules do include a collagen component.

Massive calcareous skeletons are found in only certain groups of Anthozoa and Hydrozoa. The best known are the stony anthozoan corals (order Scleractinia), in which epidermal cells on the lower half of the column secrete a calcium carbonate skeleton (Figure 7.17) through a complex biologically controlled process. The skeleton is covered by the thin layer of living epidermis that secretes it, and thus it might technically be considered an internal skeleton. However, because the stony coral colony generally sits atop a large nonliving calcareous framework, most biologists speak of the skeleton as being external.

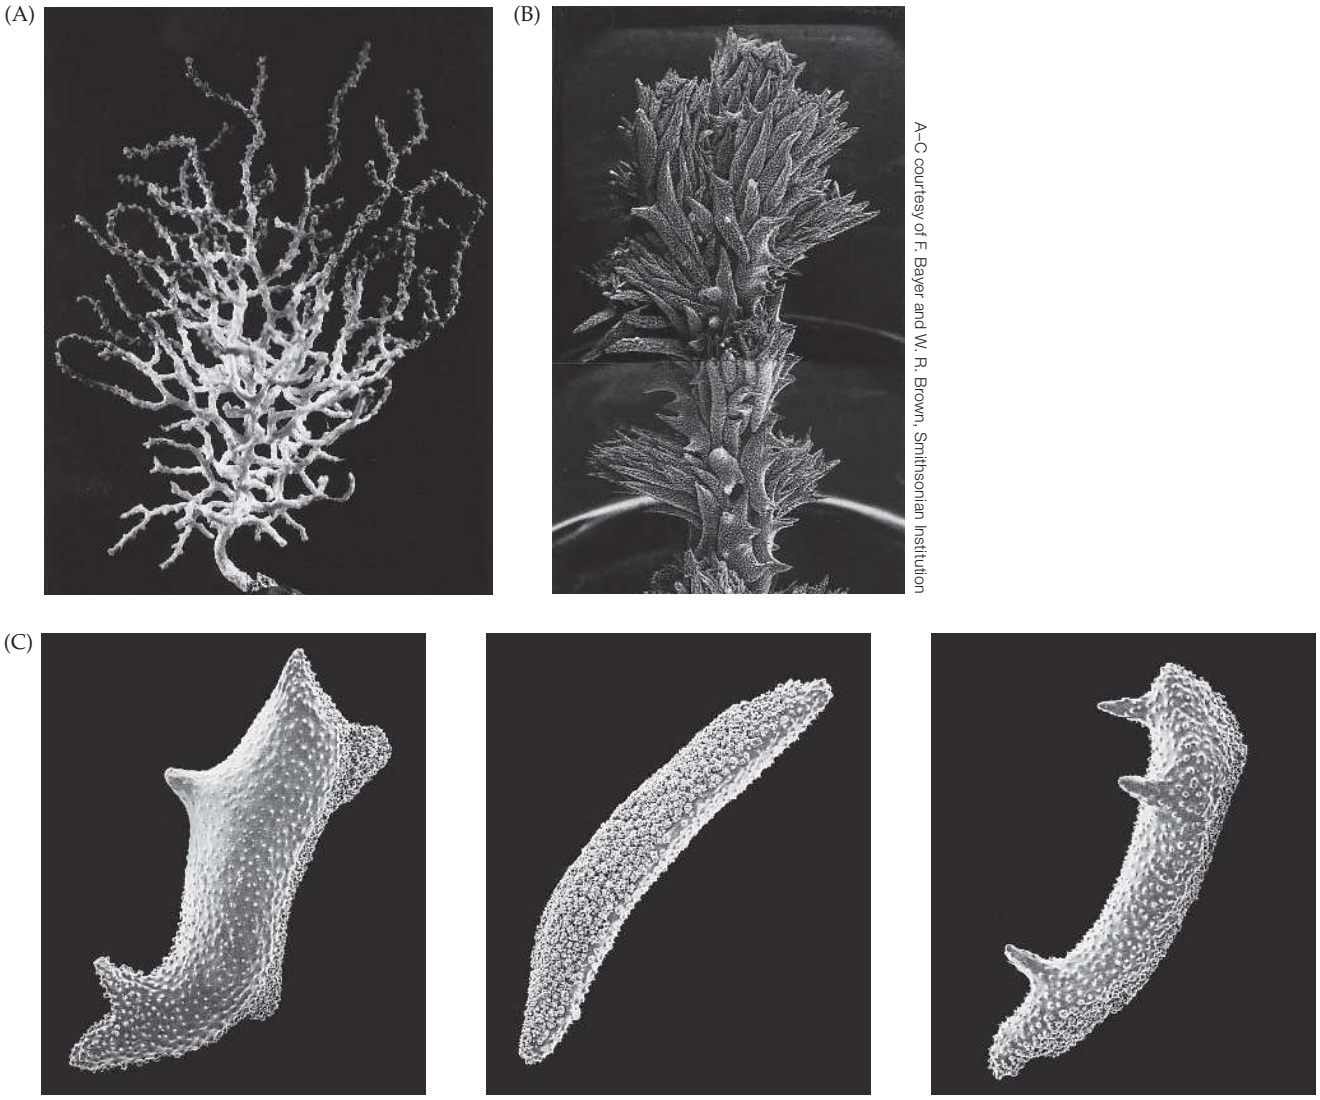

FIGURE 7.16 The skeleton of gorgonians, illustrated at successively greater magnification of the gorgonian *Muricea fruticosa*. (A) A complete colony. (B) Colony branches bear whorls of polyps. (C) Sclerites from the tissues of a single polyp.

The entire colony of a scleractinian coral is called a **corallae**, and its skeleton is the **corallum**, regardless of whether the animal is solitary or colonial; the skeleton of a single polyp, however, is called a **corallite**. The outer wall of the corallite is the **theca**; the floor is the **basal plate** (Figure 7.17). Rising from the center of the basal plate is often a supportive skeletal process called the **columella** (or pedicel). The basal plate and inner thecal walls give rise to numerous radially arranged calcareous partitions, the **septa**, which project inward and support the mesenteries of the polyp. Polyps occupy only the uppermost surface of the corallum. Skeletal thickness increases as polyps grow, and the bottoms of the corallites are sealed off by transverse calcareous partitions called **tabulae**, each of which

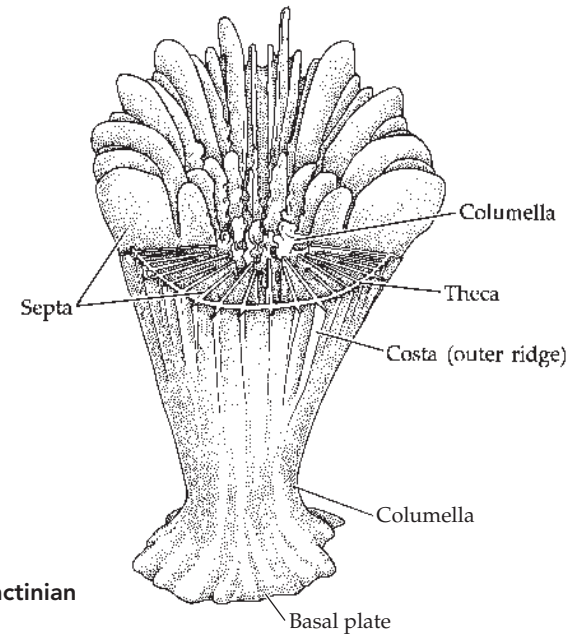

FIGURE 7.17 The corallite of a solitary scleractinian coral illustrating morphological features.

becomes the basal support of a new polyp. The corallum can assume a great variety of shapes and sizes, from simple cup-shaped structures in solitary corals to large branching or encrusting forms in colonial species.

Members of the hydrozoan families Milleporidae (fire corals) and Stylasteridae (stylasterids) also produce calcareous exoskeletons, and they are often referred to as the hydrocorals. Like stony corals (Scleractinia), milleporid colonies may assume a variety of shapes, from erect branching forms to encrustations. The milleporid exoskeleton, termed a **coenosteum**, is perforated by pores of two sizes that accommodate two kinds of polyps. The gastrozooids live in large holes, or **gastropores**, and are surrounded by a circle of smaller **dactylopores**, which house the dactylozooids. Canals lead downward from the pores into the coenosteum and are closed off below by transverse calcareous tabulae. As growth proceeds and the colony thickens, new tabulae are formed, keeping the polyp pores at a more or less fixed depth. Hydrocoral colonies thus differ from scleractinian colonies in having the skeleton penetrated by living tissue. The stylasterid skeleton is similar to the milleporid skeleton, but the margins of the gastropores often bear notches that serve as dactylopores, and the gastrozooids and dactylozooids are supported by calcareous, spine-like **gastrostyles** and low ridges called **dactylostyles**, respectively (Figure 7.18). Stylasterid gonophores arise in chambers called **ampullae**, which connect to the feeding zooids through the coenosteum. In hydrocorals such as *Millepora*, ampullae open briefly to release large numbers of tiny medusae, which for each **coralla** (colony) contain either eggs or sperm, as milleporids are gonochoristic.

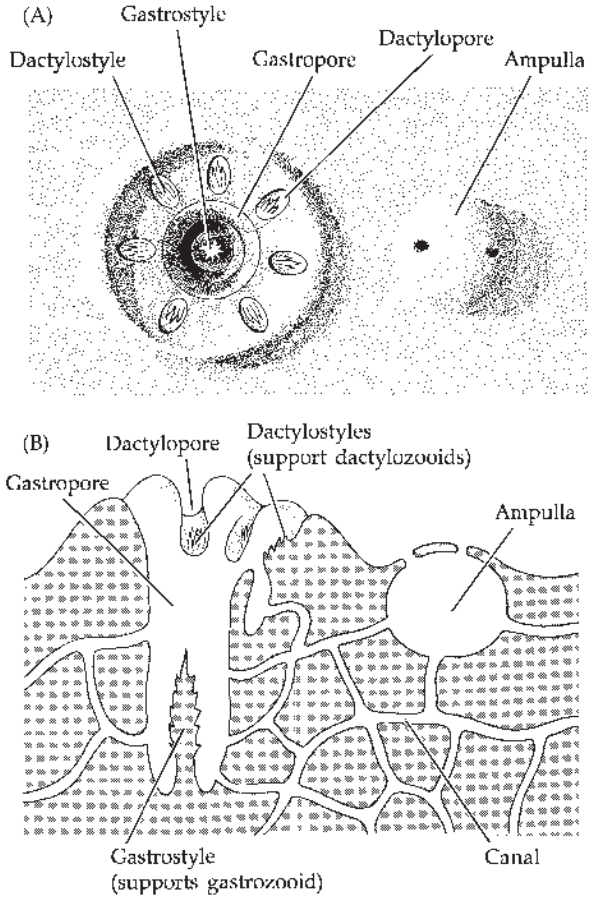

FIGURE 7.18 Hydrozoan skeletons. The stylasterid hydrocoral *Stylaster* has a calcareous skeleton. Plane view, from above (A) and cross section through the skeleton (B).

The calcium carbonate skeletons of cnidarians make them particularly vulnerable to ocean acidification—an outcome of anthropogenic carbon emissions and resulting global warming. Increased atmospheric carbon leads to more CO_2 dissolving into seawater (now estimated to occur at a rate of 1 million tons per hour), a reaction that accelerates with increasing temperature. More dissolved CO_2 reduces the pH of the ocean water, which tends to dissolve and thus destroy the primary building material of coral skeletons, calcium carbonate. Whereas calcification rates on the Great Barrier Reef increased 5.4% between 1900 and 1970, they dropped 14.2% between 1990 and 2005. The shells of echinoderms, molluscs, crustaceans, certain protists, and many other marine species are at similar and alarming risk.

Movement

The contractile elements of cnidarians are derived from their myoepithelial cells (Figure 7.19). In spite of the epithelial origin of these elements, for convenience we use the terms "muscles" and "musculature" for the sets of longitudinal and circular fibrils. In polyps, these two muscle systems work in conjunction with the gastrovascular cavity as an efficient hydrostatic skeleton, as well as facilitating body movements. However, unlike the fixed-volume hydrostatic skeletons of many animals (e.g., many worms), water can enter and leave the coelenteron of cnidarians, adding to its versatility as a support device. Polyp body musculature is most highly specialized and well developed in the anthozoans, particularly the sea anemones, and many muscles lie in the mesenchyme. In anemones, the muscles of the column wall are largely gastrodermal, although epitheliomuscular cells occur in the tentacles and oral disc. Bundles of longitudinal fibers lie along the sides of the mesenteries and act as retractor muscles for shortening the column (Figure 7.20). Circular muscles derived from the gastrodermis of the column wall are also well developed. In most anemones, the circular muscles form a distinct sphincter at the junction of the column and the oral disc. Circular fibers also occur in the tentacles and the oral disc, and circular muscles surrounding the mouth can close it completely. When an anemone contracts, the upper rim of the column is pulled over to cover the oral disc. In many sea anemones, a circular fold—the **collar**, or **parapet**—occurs near

for more ebook/ testbank/ solution manuals requests email C9601267345@qq.com

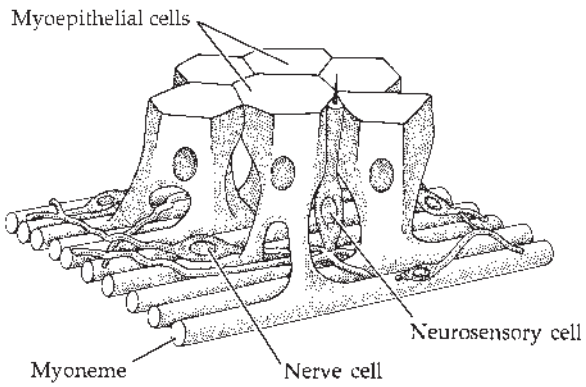

FIGURE 7.19 **Myoepithelial cells and the nerve net of cnidarian epithelium.**

the sphincter to further cover and protect the delicate oral surface upon contraction.

Polyps are sedentary or sessile. Their movements consist mainly of food-capturing actions and the withdrawal of the upper portion of the polyp during body contractions. These activities are accomplished primarily by the epidermal muscles of the tentacles and oral disc and by the strong gastrodermal muscles of the column. Circular muscles work in conjunction with the hydrostatic skeleton to distend the tentacles and body.

A variety of locomotor methods have evolved among polyps (Figure 7.21). Most can creep about slowly by using their pedal disc musculature. In some solitary hydrozoan polyps (e.g., *Hydra*), the column can bend far enough to allow the tentacles to contact and temporarily adhere to the substratum, whereupon the pedal disc releases its hold and the animal somersaults or moves like an inchworm. Simple polyps like the hydrozoan *Hydra* transfer fluid within their gastrovascular cavity using contractions of the peduncle; these contractions are biochemically mediated by RFamides, chemicals that induce cardiac contraction in higher metazoans, suggesting that muscular contractions in these distantly related taxa might share neurological similarities. A few sea anemones can detach from the substratum and actually swim away by "rapid" flexing or bending of the column (e.g., *Actinostola*, *Stomphia* [Figure 7.21E]); others swim by thrashing the tentacles (e.g., *Boloceroides*). These swimming activities are temporary behaviors, generally elicited by the approach or contact of a predator. In a few species of sea anemones, the basal disc may detach and secrete a gas bubble, permitting the polyp to float away to a new location.

Many species of small anthozoans can temporarily float hanging upside down on the sea surface by using water surface-tension forces (e.g., *Epiactis*, *Diadumene*). Sea anemones of one family (Minyadidae) are wholly pelagic and float upside down in the sea by means of a gas bubble enclosed within the folded pedal disc. *Hydra* also is known to float upside down by means of a mucus-coated gas bubble on the bottom of its pedal disc. One of the oddest forms of polyp locomotion is that of the sea anemone *Liponema brevicorne* of the Bering Sea, which is capable of drawing itself into a tight ball that can be rolled around the seafloor by the bottom currents (Figure 7.21D). Even colonial sea pansies (Pennatulacea) are motile, in that they can use their muscular peduncle to move to different depths on the seafloor.

Most ceriantharian anemones are burrowing, tube-building organisms (Figure 7.11E). They differ from the sea anemones (Actiniaria) in several important ways. They have no sphincter muscle, and their weak longitudinal gastrodermal muscles do not form distinct retractors in the mesenteries. As a result, cerianthariens cannot retract the oral disc and tentacles as they withdraw into their tubes. In contrast to other anemones, however, they possess a complete layer of longitudinal epidermal muscles in the column, which allows a very rapid withdrawal response. The mere shadow of a passing hand will cause a ceriantharian to rapidly pull itself deep into its long, buried tube.

In medusae, epidermal and subepidermal musculatures predominate, and the gastrodermal muscles that are so important in polyps are reduced or lacking. The epidermal musculature is best developed around the bell margin and over the subumbrellar

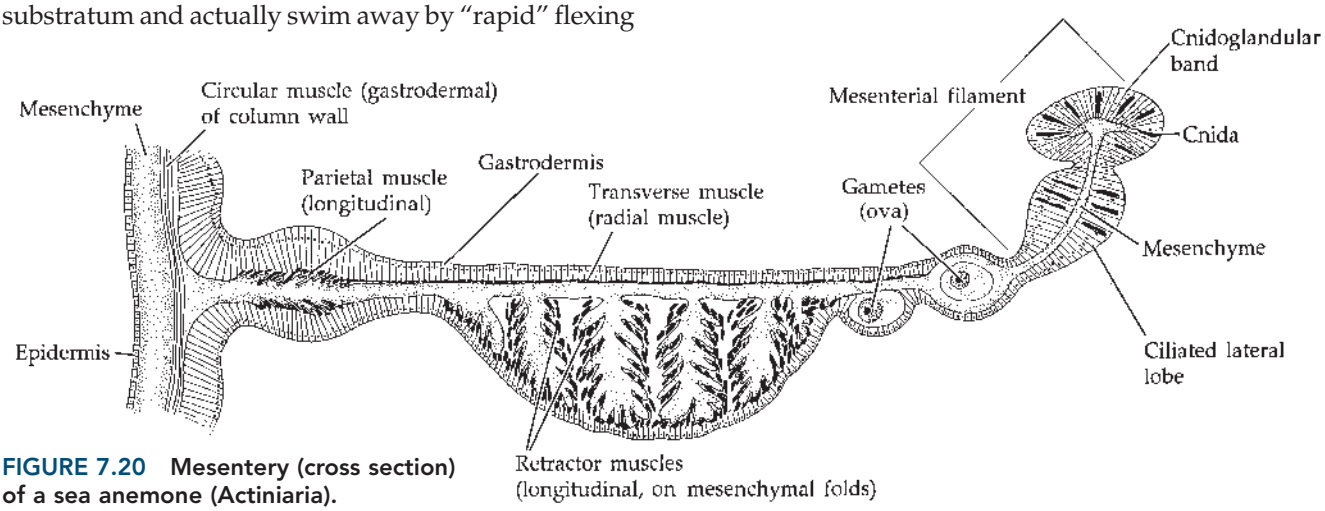

FIGURE 7.20 **Mesentery (cross section) of a sea anemone (Actiniaria).**

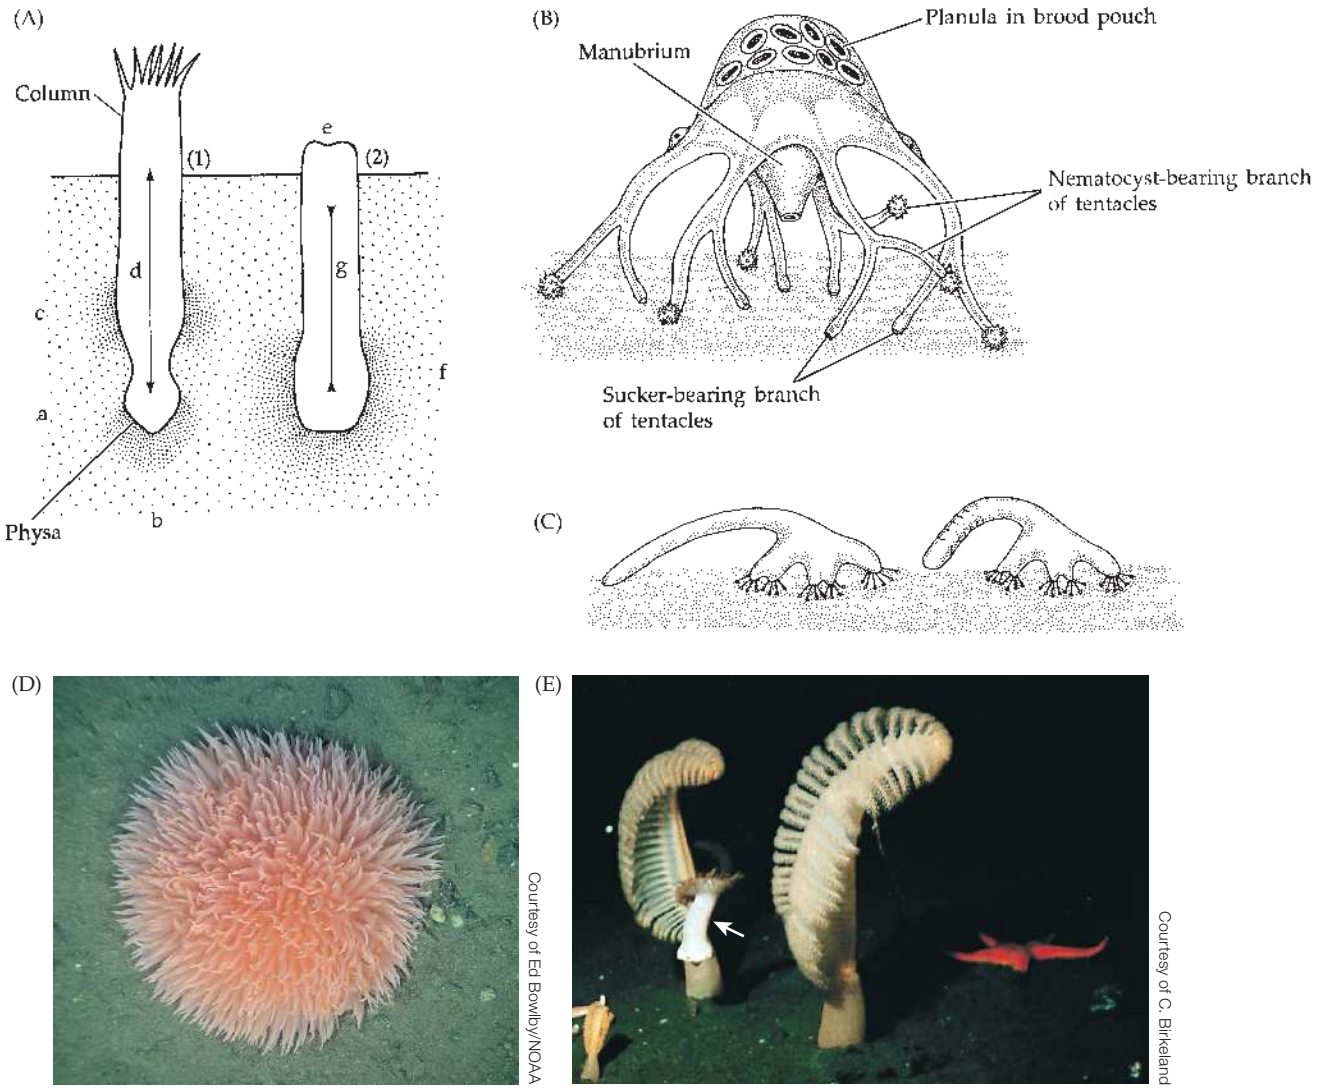

FIGURE 7.21 Benthic locomotion in some cnidarians. (A) A sea anemone burrowing: (1) eversion of the physa with displacement of sand (a) and further penetration (b) into substratum; the anemone is held by a column anchor (c) as extension (d) follows retraction in (2); with the tentacles folded inward (e), the physa is swollen to form an anchor (f), which allows retractor muscles (g) to pull the anemone into the sand. (B) The hydromedusan *Eleutheria*, which creeps about on its tentacles. (C) The staurozoan *Lucernaria*, which also creeps about on its tentacles. (D) *Liponema brevicorne*, a sea anemone that folds itself into a "ball" and rolls about on the seafloor with the bottom currents. (E) The sea anemone *Stomphia* (white arrow) swimming off the substratum by undulatory back-and-forth contractions of the column—an escape response to the predatory sea star *Gephyreaster swifti*, visible in this photo (Puget Sound, Washington).

surface. Here the muscle fibers usually form circular sheets called **coronal muscles** that are partly embedded in the mesenchyme or mesoglea. Contractions of the coronal muscles produce rhythmic pulsations of the bell, driving water out from beneath the subumbrella and moving the animal by jet propulsion. The restriction of striated myofibrils to epithelial cells appears to constrain the force with which bell musculature may contract, favoring either small solitary or prolate (streamlined) bells that move by jet propulsion (e.g., Anthoathecata, Trachymedusae, Siphonophora, Cubozoa) or larger, oblate (flattened) bells that move by more gentle contractions of the bell margin, sometimes called "rowing" (e.g., Leptothecata, Narcomedusae, scyphozoan medusae). In addition to this "pushing water" movement by medusae, there is evidence that bell contractions also generate low-pressure areas on the exumbrellar surface that help "pull" the animal forward through the water.

The stiffened cellular collenchyme of scyphomedusae and cubomedusae includes elastic fibers that provide the antagonistic force to restore the bell shape between contractions. Many medusae also possess radial muscles that aid in opening the bell between pulses. In craspedote forms, the velum serves to reduce the size of the subumbrellar aperture, thus increasing the force of the water jet (Figure 7.13). The velarium of the fast-swimming cubomedusae has

for more ebook/ testbank/ solution manuals requests email 9601267345@qq.com

the same effect (Figure 7.15A), and the evolutionary forces that produced these two convergent features were probably similar.

Most medusae spend their time swimming upward in the water column, then sinking slowly down to capture prey by chance encounter, thereafter to pulsate upward once again. Some medusae have the ability to change direction as they swim, however, and many are strongly attracted to light (especially those species that harbor symbiotic zooxanthellae). The medusoid form also appears to correlate with feeding mode. Jet propulsion is associated with ambush foraging by medusae that lie motionless, waiting for motile prey to swim into their tentacles before rapidly consuming the ensnared prey, whereas "rowing" propulsion is associated with cruising foraging by medusae that swim continuously with tentacles extended to capture slow-moving or floating prey. At least some medusae house their zooxanthellae in small pockets that remain contracted at night but expand during the day, exposing the algae to light.

Medusae can be abundant in certain localities. Some, such as the moon jelly *Aurelia* (Figure 7.22), are known to aggregate at temperature or salinity discontinuity layers in the sea, where they feed on small zooplankters, which also concentrate at these boundaries. Large flotillas of scyphomedusae are sometimes seen at sea (e.g., *Phacellophora* in the eastern Pacific). A few unusual groups of medusae are benthic. Some hydromedusae (e.g., *Eleutheria*, *Gonionemus*) crawl about on algae or sea grasses by adhesive discs on their tentacles (Figure 7.21B). Members of the class Staurozoa (e.g., *Haliclystus*) develop directly from the stauropolyp stage and affix to algae and other substrata by an aboral adhesive disc (Figure 7.1F). Aggregations are common in scypho- and cubomedusae, possibly to enhance feeding or defense. Almost all cubomedusae are tropical to subtropical in their range, but a large temperate species (*Carybdea branchi*) occurs on the Skeleton Coast of southwestern Africa, where it can occur in dense "clouds" of an acre or more across.

Cnidae

Before considering feeding and other aspects of cnidarian biology, it is necessary to present some information on the structure and function of cnidae. **Cnidae** (sing. cnida), often casually referred to collectively as "nematocysts" in older works, are unique to the phylum Cnidaria. They have a variety of functions, including prey capture, defense, locomotion, and attachment. They are produced inside cells called **cnidoblasts**, which develop from interstitial cells (also called I-cells), a type of proliferative cell in the epidermis and, in many groups, also in the gastrodermis. Once the cnida is fully formed, the cell is properly called a **cnidocyte**. During formation of a cnida, the cnidoblast produces a large internal vacuole in which a complex but poorly understood intracellular reorganization takes place. Cnidae may be complex secretory products of the Golgi apparatus of the cnidoblast.

Cnidae are among the largest and most complex intracellular structures known. When fully formed, they are cigar- or flask-shaped capsules, 5–100 μm or more long, with thin walls composed of a collagen-like protein. One end of the capsule is turned inward as a long, hollow, coiled, eversible tubule (Figure 7.23). The outer capsule wall consists of globular proteins of uncertain function. The inner wall is composed of bundles of collagen-like fibrils having a spacing of 50–100 nm, with cross striations every 32 nm (in the nematocysts of *Hydra*). The distinct pattern of minicollagen fibers provides the tensile strength necessary to withstand the high pressure in the capsule. The entire structure is anchored to adjacent epithelial cells (supporting cells) or to the underlying mesenchyme.

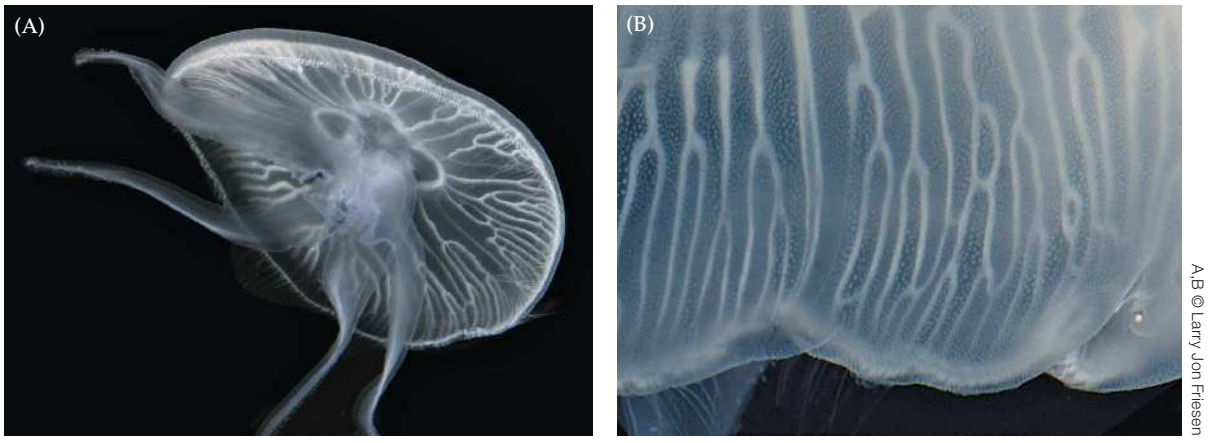

FIGURE 7.22 The semaeostoman medusa *Aurelia* (moon jellies) often form large swarms. (A) *Aurelia aurita*; notice elongated oral arms. (B) *Aurelia* radial canals and rhopalium.

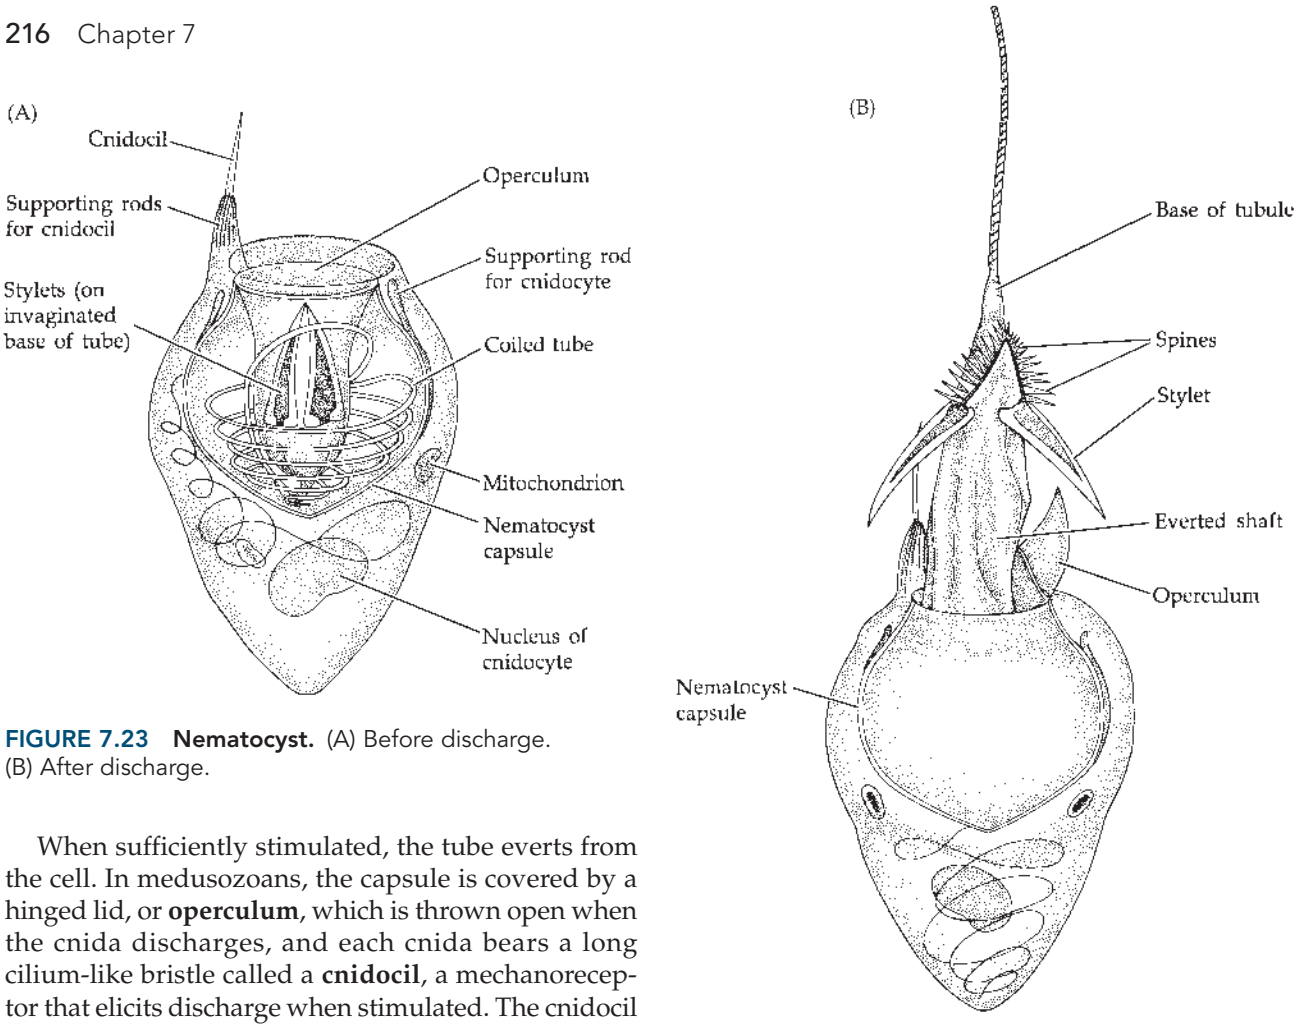

FIGURE 7.23 Nematocyst. (A) Before discharge. (B) After discharge.

When sufficiently stimulated, the tube everts from the cell. In medusozoans, the capsule is covered by a hinged lid, or **operculum**, which is thrown open when the cnida discharges, and each cnida bears a long cilium-like bristle called a **cnidocil**, a mechanoreceptor that elicits discharge when stimulated. The cnidocil responds to specific waterborne vibration frequencies. Anthozoan cnidae lack a cnidocil and have a tripartite apical flap instead of an operculum (anthozoan cnidae are only spirocysts and ptychocysts). Cnidocytes are most abundant in the epidermis of the oral region and the tentacles, where they often occur in clusters of wartlike structures called **nematocyst batteries**.

About 30 kinds of cnidae have been described, and 2–6 types usually occur in any given species (Figures 7.24 and 7.25). Combinations of cnida types, called **cnidomes**, occur in recognizable taxonomic patterns within Cnidaria, and these have had limited resolution in the phylogenetic patterns in the phylum. However, cnidae more or less sort out as three basic types. True **nematocysts** have double-walled capsules containing a toxic mixture of phenols and proteins. The tubule of most types is armed with spines or barbs that aid in penetration of and anchorage in the victim's flesh. The toxin is injected into the victim through a terminal pore in the thread or is carried into the wound on the tubule surface. **Spirocysts** have single-walled capsules containing mucoprotein or glycoprotein. Their adhesive tubules wrap around and stick to the victim rather than penetrating it. The capsule tubules of spirocysts never have an apical pore. Nematocysts occur in members of all cnidarian classes except within the Myxozoa; spirocysts occur only in the Hexacorallia. The third kind of cnidae, the **ptychocyst**, differs morphologically and functionally from both nematocysts and spirocysts. The capsule tubule of a ptychocyst lacks spines and an apical pore and is strictly adhesive in nature. In addition, the tubule is folded into pleats rather than coiled within the capsule. Ptychocysts occur only in the cerianthariens and function in forming the unique tube in which these animals reside.

The **polar capsules** of myxozoans are now widely viewed as homologous with other cnidarian cnidae, although they are simpler in form. Polar capsules are found in both myxosporean and actinosporean life stages of myxozoans. The capsules consist of a thick capsular wall; an eversible hollow filament that is spiraled along its length, may vary in length (up to ten times the length of the capsule), and is contiguous with the capsule; and a stopperlike structure that covers the inverted filament at its base. A variety of substances have been explored as possible inducers of polar filament extrusion, and like cnidae, polar capsules appear to be sensitive to pressure and extreme pH and K^+ concentrations. However, no consistent physical or chemical cue responsible for extrusion appears to exist across most taxa.

Cnidae have usually been viewed as independent effectors, and, indeed, they often discharge upon direct stimulation. However, experimental evidence suggests that the animals do have at least

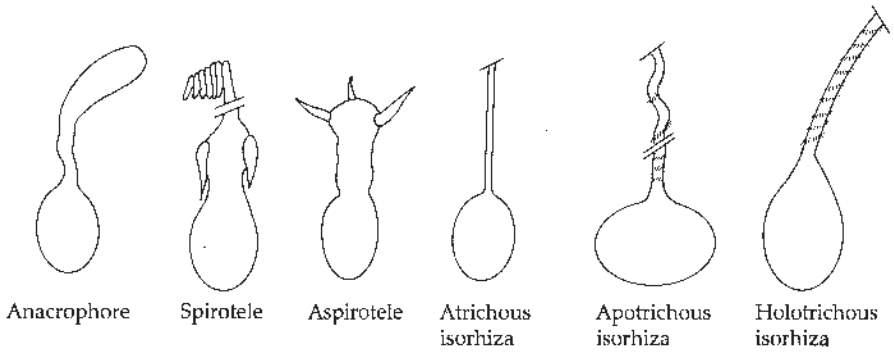

FIGURE 7.25 Some types of cnidae and their specialized nomenclature.

some control of the action of their cnidae. For example, starved anemones seem to have a lower firing threshold than satiated animals. It has also been demonstrated that stimulating discharge of cnidae in one area of the body results in discharge in surrounding areas. Still, chemical and/or mechanical stimuli, initially perceived by the cnidocil or a similar structure, cause most cnidae to fire. Cnidarians are known to discharge their cnidae in the presence of various sugars and low-molecular-weight amino compounds.

The rapid protrusion of the tubule from a cnida is called **exocytosis**, and an individual cnida can be fired only once. Three hypotheses have been proposed to explain the mechanism of firing: (1) the discharge is the result of increased hydrostatic pressure caused by a rapid influx of water (the osmotic hypothesis); (2) intrinsic tension forces generated during cnidogenesis are released at discharge (the tension hypothesis); and (3) contractile units enveloping the cnida cause the discharge by "squeezing" the capsule (the contractile hypothesis). Because of the small size of cnidae and the extreme speed of the exocytosis process, these hypotheses have been difficult to test. Recent work using ultra-high-speed microcinematography suggests that both the osmotic and tension models may be at work and that capsules have very high internal pressures. The coiled capsular tubule is forcibly everted and thrown out of the bursting cell to penetrate or wrap around a portion of the unwary victim. It takes only a few milliseconds for the cnida to fire, and the everting tubule may reach a velocity of 2 m/sec—an acceleration force of about 40,000 g—making it one of the fastest cellular processes in nature. The firing mechanism of hydrozoan cnidae is thwarted by certain nudibranch gastropods that, in order to feed upon and capture intact cnidae from their prey, release copious amounts of mucus to entangle and envelop hydroid tentacles containing still-intact cnidae.

Most nematocysts contain several different toxins that vary in activity and strength, but as a class of chemicals they are all potent, complex, biological poisons capable of subduing large, active prey, including fish. Most appear to be neurotoxins. The toxins of some cnidarians are powerful enough to affect humans (e.g., those of cubozoans; some jellyfish; certain colonial hydroids, such as *Macrorhynchia*; medusae of some *Gonionemus* species; many hydrocorals, such as *Millepora*; and many siphonophores, such as *Physalia*). The toxins of most scyphozoans are not strong enough to create problems for most people, unless they have an allergic reaction; even the effects of *Physalia* stings typically disappear within a few hours. However, toxins of most cubomedusans (box jellies) are another story altogether; they kill dozens of people annually (mostly in the west Pacific), and their venom is estimated to be as potent as cobra venom. In tropical Australia, twice as many people die annually from box jellies as from sharks. Stings by *Chironex* (the "sea wasp") usually result in severe pain at least, and they cause fatal respiratory or cardiac failure at worst. If you want to swim in an area known to be frequented by dangerous jellies, you can always do what lifeguards in northern Australia do—don a pair of pantyhose (not fishnet!), which seem to offer some protection.

Most cubozoan victims die from cardiac arrest within minutes. Surprisingly the exact nature of cnidarian nematocyst toxins is still debated. One hypothesis holds that the venom contains proteins called porins, which puncture red blood cells and release potassium, disrupting the electrical rhythm that keeps the heart beating. High levels of potassium in the blood, or hyperkalemia, is well known to cause cardiac arrest. Another hypothesis suggests certain compounds in the venom are ion channel blockers, molecules that disrupt movement of ions in and out of cells. The blockage shuts down nerve and muscles cells, including those that keep the heart pumping. One recently developed commercial antidote contains copper gluconate; when applied to the sting, it is said, it inhibits the injected venom.

Feeding and Digestion

All cnidarians are carnivores (or parasites), and the gastrodermis of the gut of the various species produces a spectrum of enzymes that hydrolyze carbohydrates, proteins, and lipids (Figure 7.4). Typically, nematocyst-laden feeding tentacles capture animal prey and carry it to the mouth region, where it is ingested whole (Figure 7.26). Digestion is initially extracellular in the coelenteron. In many groups, gastrodermal cilia (or flagella) aid in mixing of the gut contents. In the absence of a true circulatory system, the gastrovascular cavity distributes the partially digested material. The larger the cnidarian, the more extensively branched or partitioned is its coelenteron. The product of this preliminary breakdown is a soupy broth, from which polypeptides, fats, and carbohydrates are taken into the nutritive-muscular cells by phagocytosis and pinocytosis. Digestion is completed intracellularly within food vacuoles. Undigested wastes in the coelenteron are expelled through the mouth. In cubozoans, and at least some hydrozoans, ciliary movement of material in the coelenteron is enhanced by peristaltic movements.

In anthozoans, the free edges of most of the gastrovascular mesenteries are thickened to form three-lobed mesenterial filaments (Figures 7.6 and 7.20). The lateral lobes are ciliated and aid in circulating the digestive juices in the coelenteron. The middle lobe, called the **cnidoglandular band**, bears cnidae and gland cells. In some sea anemones (e.g., *Aiptasia*, *Anthothoe*, *Calliactis*, *Cylista*, *Diadumene*, *Metridium*), the cnidoglandular band continues beyond the base of the pharynx as a free thread called an acontium, which floats about in the coelenteron. The cnida-bearing acontia not only

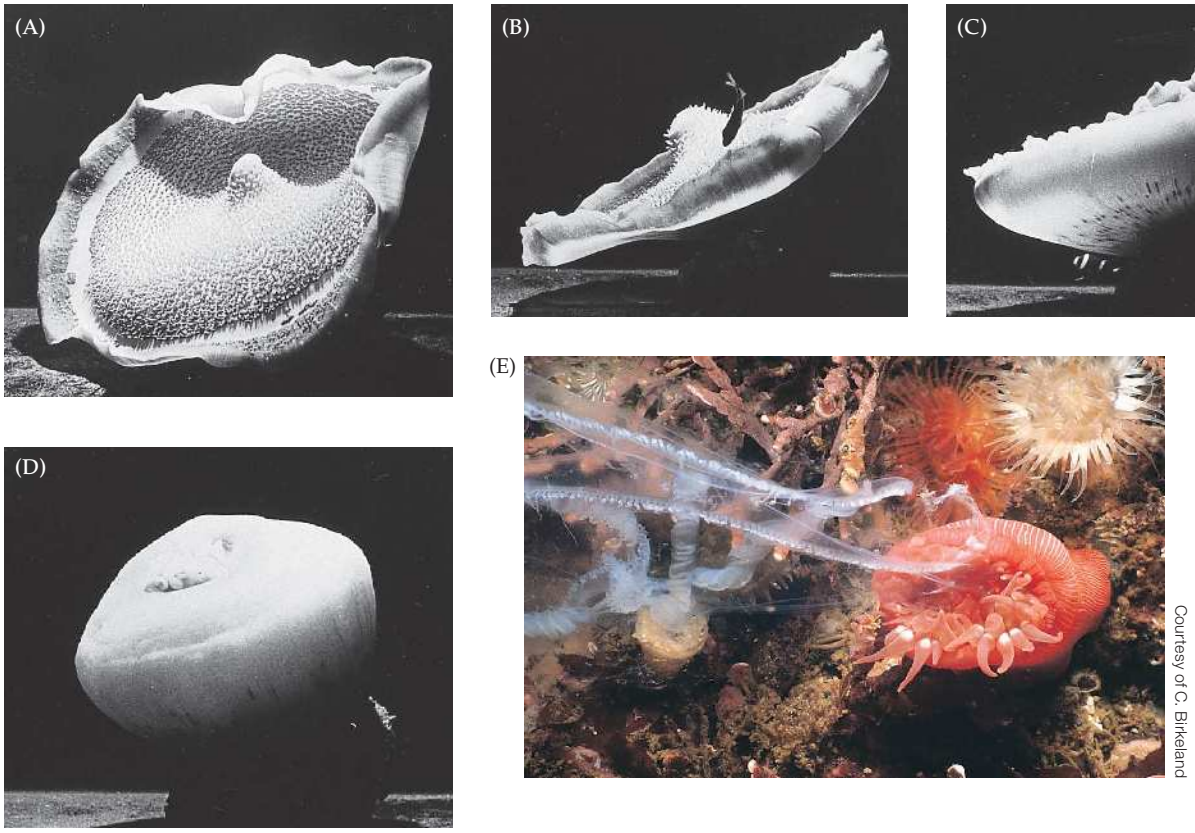

FIGURE 7.26 Feeding anemones. (A–D) Feeding sequence in the tropical sea anemone *Amplexidiscus fenestrafer*. (A) An expanded oral disc has a tentacle-free area near the periphery, and an oral cone. (B) An expanded disc (side view). (C) Closure one-third complete, 1 second after stimulation of the oral disc. (D) Complete closure, 3 seconds after stimulation. (E) The temperate sea anemone *Epiactis prolifera* capturing a jellyfish (*Aequorea*?).

subdue live prey within the coelenteron, but may be shot out through the mouth or through pores in the body wall (called **cinclides**) when the animal contracts violently; when this occurs, the acontia presumably play a defensive role.

Prey type appears to influence medusoid form. Most oblate medusae feed on small ciliated or soft-bodied prey, following their quarry by continuous rowing (using their large flat bell), and then using nematocysts on the tentacles, the oral arms, or both to capture their victims. *Pelagia noctiluca*, an open-sea diurnal migrator, follows the other migrating macrozooplankton upon which it feeds, uses its marginal tentacles to paralyze and capture moving prey, then transports them to the oral arms dangling from the center of the subumbrella. The oral arms transport the prey to the mouth. Motionless prey are also captured by the oral arms directly through chance contact. Most prolate medusae feed on actively swimming prey. These species often retract their tentacles while swimming, to reduce drag. Cubomedusae such as *Chironex* spp. feed actively on fish and can swim in bursts of up to 5 feet/sec. Because of their higher metabolic demands, unlike other Medusozoa, they move semidigested food from their central gastrovascular cavity to canals lining the interior walls of each tentacle for absorption. Some cubomedusae catch and ingest fish and prawns matching their own diameter, and a large *Chironex* can eat fish 20–50 cm in length! Some cubomedusae are less active hunter-predators and feed primarily by passive hunting (e.g., *Tripedalia cystophora*, and perhaps also *Chironex fleckeri* and *Carybdea rastonii*), and in these cases their eyes may be used to position themselves in the right food-rich habitat.

Several groups of cnidarians have adopted feeding methods other than the direct use of nematocyst-laden tentacles. One group of large tropical anemones in the order Corallimorpharia (e.g., *Amplexidiscus*) lacks nematocysts on the external surfaces of most tentacles. These remarkable anemones capture prey directly with the oral disc, which can envelop crustaceans and small fishes, rather like a fisherman's cast net (Figure 7.26A–D).

In addition to tentacular feeding on small plankters, many corals are capable of mucous-net suspension feeding, which is accomplished by spreading thin mucous strands or sheets over the colony surface and collecting organic particulate matter that rains down from the water. The food-laden mucus is driven by cilia to the mouth. In a few corals (e.g., members of the family Agariciidae), the tentacles are greatly reduced

or absent, and all direct feeding is by the mucous-net suspension method. The amount of mucus produced by corals is so great that it is an important food source for certain fishes and other reef organisms, which feed directly off the coral or recover mucus sloughed into the surrounding seawater. Coral mucus released into the sea contains a variable mixture of macromolecular components (glycoproteins, lipids, and mucopolysaccharides) or a mucous lipoglycoprotein of specific character for a given species. These loose mucous webs, or flocs, are usually enriched by bacterial colonies and entrapped detrital materials, further enhancing their nutritional value.

The role of cnidarians as potentially significant members of food webs depends largely on location and circumstance. It has been estimated that as much as 25% of marine biodiversity is associated with coral reefs. Stony corals obviously hold critical trophic positions in tropical reef environments, as do zoantharians and octocorals in many tropical and subtropical habitats. In many warm and temperate areas sea pens and sea pansies dominate benthic sandy habitats. Large scyphomedusae (e.g., *Aurelia*, *Cyanea, Pelagia*, *Phacellophora*) often occur in great swarms and may consume high numbers of larvae of commercially important fishes, as well as competing with other fishes for food. Swarms of jellyfish may be so dense that they clog and damage fishing nets and power plant intake systems. The first author once witnessed a swarm of *Phacellophora* in the Gulf of California that ran like a broad river from Loreto to La Paz, a distance of about 200 km. Certain scyphozoans (e.g., *Chrysaora*) have undergone population blooms in their native habitats, perhaps due to climate shifts, while other species (e.g., *Phyllorhiza*) have become invasive after transport by ships or in shifting currents. In large numbers jellies significantly influence local fish and plankton populations.

Hydromedusae are often major components of temperate pelagic food webs. Members of several hydrozoan genera also occur in huge congregations in tropical seas, where they are important carnivores in the neustonic food web. Best known among these are the "chondrophorans" *Porpita* (which actively feeds on motile crustaceans, such as copepods) and *Velella* (which feeds on relatively passive prey, such as fish eggs and crustacean larvae), and the siphonophore *Physalia* (which actively catches and consumes fish). Other siphonophores inhabiting deep-sea environments (e.g., *Erenna* sp.) possess bioluminescent and red-fluorescent lures that may be important for capturing fish sensitive to long-wavelength light. Like scyphomedusae, hydromedusae and siphonophores can reach high densities in surface waters and have significant effects on zooplankton and human populations. The Chinese freshwater limnomedusa *Craspedacusta sowerbii* is now established throughout the United States and Europe, where it can undergo "blooms" and impact fisheries. The Portuguese man-of-war, *Physalia* sp., is a known menace for swimmers during summer months in coastal areas throughout the world.

Defense, Interactions, and Symbiosis

There are so many interesting aspects of cnidarian biology that do not fall neatly into our usual coverage of each group that we present this special section. The following discussion also points out the surprising level of sophistication possible at the relatively simple diploblastic, radiate grade of complexity.

In most cnidarians, defense and feeding are intimately related. The tentacles of most anemones and jellyfish usually serve both purposes, and the defense polyps (dactylozooids) of hydroid colonies often aid in feeding. In some cases, however, the two functions are performed by distinctly separate structures (as in most siphonophores).

Some species of acontiate sea anemones (e.g., *Metridium*) bear separate and distinct feeding tentacles and defense tentacles. Whereas the former usually move in concert to capture and handle prey, the defense tentacles move singly, in a so-called searching behavior, in which they extend to three or four times their resting length, gently touch the substratum, retract, and extend again. Defense tentacles are used in aggressive interactions with other sea anemones, either those of a different species or nonclonemates of the same species. The aggressive behavior consists of an initial contact with the opponent followed by autonomous separation of the defense tentacle tip, leaving the tip behind attached to the other sea anemone. Severe necrosis develops at the site of the attached tentacle tip, occasionally leading to death. Defense tentacles develop from feeding tentacles and tend to increase under crowded conditions. The development involves loss of typical feeding tentacle cnidae (largely spirocysts) and acquisition of true nematocysts and gland cells, which dominate in defense tentacles. Similarly, elongated "sweeper tentacles" in many species of corals are used for defense and competition for space, by direct contact or release of toxic exudates.

The **acrorhagi** (= marginal tubercles or bumps) that ring the collar of some sea anemones (e.g., *Anthopleura*) also have a defensive function. These normally inconspicuous vesicles at the base of the tentacles bear nematocysts and usually spirocysts. In *A. elegantissima*, contact of an acrorhagi-bearing sea anemone with nonclonemates or other species causes the acrorhagi in the area of contact to swell and elongate. The expanded acrorhagi are placed on the victim and withdrawn, and the application may be repeated. Pieces of acrorhagial epidermis break off and remain on the victim, resulting in localized necrosis. Interclonal strips of bare rock are maintained by this aggressive behavior (Figure 7.27A). In addition to this behavior, the acrorhagi are exposed as a ring of nematocyst batteries around the top of the constricted column

whenever an acrorhagi-bearing sea anemone contracts in response to violent stimulation. Other competitive interactions are known among stony corals (Figure 7.27C).

Octocorals, which lack toxic stinging nematocysts, have been shown to be a rich source of biologically active and structurally unusual compounds that appear to provide protection against predators and may allow them to colonize new habitats by causing tissue necrosis in potential competitors. These compounds include prostaglandins, diterpenoids, and antimicrobials. In contrast to many coastal and reef-dwelling species, octocorals are remarkably free from predation except by the few species that are specialized to use them as food. While sclerites have also been proposed to provide antipredatory benefits, there is little clear evidence that sclerites decrease the nutritional value of octocorals sufficiently to deter predation. Thus, like sponges, octocorals appear to use secondary metabolic compounds as their primary antipredator defense. Chemical defenses may have evolved to compensate for poor regenerative abilities in these slow-growing cnidarians or because their sessile habit makes them especially conspicuous to visual predators.

There are many examples of associations between cnidarians and other organisms, some of which are truly symbiotic, others of which are less intimate. With the exception of myxozoans, few groups of cnidarians are truly parasitic, although several species of hydroids infest marine fishes. The polyps of some of these hydroids lack feeding tentacles and occasionally even lack cnidae. The basal portion of the polyp erodes the fish's epidermis and underlying tissues, and nutrients are absorbed directly from the host. One species invades the ovaries of Russian sturgeons (a caviar feeder!).

However, the Myxozoa, by any standard, are indeed parasitic. This group consists of about 2,200 species of tiny parasites, previously classified among the protists as the phylum Myxozoa. Morphological data, DNA sequence data, and the presence of metazoan Hox genes all provide evidence that these strange creatures are allied with the cnidarians, as a sister group to the Medusozoa (Figure 7.44). The coiled polar filaments housed within polar capsules of myxozoans are now viewed as modified cnidae (Figure 7.28).

Myxozoan cnidarians infect annelids and various poikilothermic vertebrates, especially fishes (Figure 7.29). The life cycle begins when **actinospore** larvae (which may vary in form) are released from spores, contact the mucous membranes of an appropriate vertebrate host (either by ingestion or contact; Figure 7.29, part 1), and extrude their **polar filaments** to release sporoplasm into the host cells. Presporogonic development occurs within these cells, producing infective cell-doublets, which rupture host cells and disperse to infect other cells (Figure 7.29, part 2). Infection can spread to other tissues, particularly neural tissue, and can cause disruption of host tissue structure (e.g., a blackened tail in infected trout) or behavior.

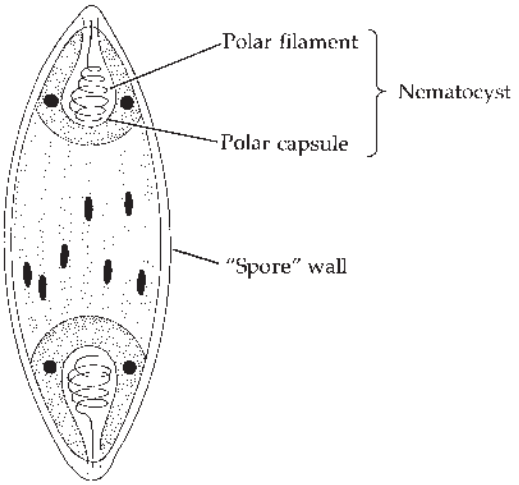

FIGURE 7.28 Previously considered to be protists, myxozoans are now viewed as highly specialized, parasitic cnidarians.

Sporulation often occurs in particular tissues (e.g., cartilage in *Myxobolus cerebralis*), where a multinucleated **plasmodium** develops and produces sporoblasts with variable numbers of internal spores, depending on the species (Figure 7.29, part 3).

Within plasmodia, valvogenic cells produce **spore valves**, which enclose capsulogenic cells that become polar capsules as well as sporoplasm. When complete, this process generates **myxospores** that are released by the vertebrate host and are infective to annelids (Figure 7.29, part 4). Polar filaments facilitate cell penetration of gut cells where multinucleate cells form by a process often called **schizogony** (although this is probably not the same process seen in sporozoan protists; Figure 7.29, parts 5 and 6). These cells then produce numerous uninucleate cells that may either generate other plasmodia or fuse with other cells to become binucleate within the worm gut. Binucleate cells differentiate into multinucleate cells with α or β nuclei that develop into complementary gametes by the end of gametogony, which fuse to produce **pansporocysts** containing zygotes (Figure 7.29, parts 7–9). Zygotes differentiate into infective actinosporean spores that are released in worm feces or remain within the worm's body. Infection of the vertebrate host occurs when spores containing worm feces contact mucous membranes or when spore-bearing worms are ingested (Figure 7.29, part 10).

Most myxozoan species appear to include both a vertebrate and an invertebrate host in their life cycle. *Myxobolus cerebralis*, a parasite of freshwater fishes (especially trout, Figure 7.1O), devours the host's cartilage, leaving the fish deformed. Inflammation resulting from the infection puts pressure on nerves and disrupts balance, causing the fish to swim in circles—a condition known as whirling disease. When an infected fish dies, *M. cerebralis* spores are released from the decaying carcass and may survive for up to 30 years in sediment. Eventually, the spores are consumed by *Tubifex* worms (oligochaete annelids). They reside in this intermediate host until eaten by a new host fish.

Mutualism is common among cnidarians. Many species of hydroids live on the shells of various molluscs, hermit crabs, and other crustaceans. The hydroid gets a free ride, and the host perhaps gains some protection and camouflage. Many members of the leptomedusan family Eirenidae (e.g., *Eugymnanthea*) occupy the mantle cavities of bivalves, where they protect their hosts against trematode parasites by consuming the infective sporocysts. Hydroids of the genus *Zanclea* are epifaunal on bryozoans, where they sting and discourage smaller predators and adjacent competitors, helping the bryozoans to survive and overgrow competing species. The bryozoan lends protection to the hydroid with its coarse skeleton, and the mutualism seems to allow both taxa to cover a larger area than either could individually. The bizarre, aberrant hydroid *Proboscidactyla* lives on the rim of polychaete worm tubes (Figure 7.8A) and dines on food particles dislodged by the host's activities. Another filiferan, *Brinckmannia hexactinellidophila*, lives within the tissues of Arctic glass sponges.

Some sea anemones attach to snail shells inhabited by hermit crabs. These partnerships are mutualistic; the sea anemone gains motility and food scraps while protecting the hermit crab from predators. The most extreme case of this mutualism might be that of the cloak anemones (e.g., *Adamsia*, *Stylobates*), which wrap themselves around a hermit crab's gastropod shell and grow as the crab does (Figure 7.30). Initially, the anemone's pedal disc secretes a chitinous cuticle over the small gastropod shell occupied by the hermit. Such fortunate crabs need not seek new, larger shells as they grow, for the cloak anemone simply grows and provides the hermit with a living protective cnidarian "shell," often dissolving the original gastropod shell over time. As if it were itself a gastropod, the sea anemone grows to produce a flexible coiled house called a **carcinoecium**. In fact, these odd anemone "shells" were initially described and classified as flexible gastropod shells. A similar relationship exists between some hermit crabs of the genus *Parapagurus* and certain species of *Epizoanthus*. The hydroid *Janaria mirabilis* secretes a "long-spined" shell-like casing that is inhabited by hermit crabs, and in an extraordinary case of evolutionary convergence, so does the bryozoan *Hippoporidra calcarea* (Figure 7.31).

So effective are cnidae that many groups of animals have figured out ways to capture or otherwise utilize these structures for their own defense, a phenomenon known as kleptocnidism. Kleptocnidism is best known among nudibranchs, but it has evolved between 10 and 18 times in members of the phyla Ctenophora, Porifera, Platyhelminthes, and Mollusca, as well as in the Acoelomorpha. Several aeolid sea slugs consume cnidarian prey, ingesting and then storing the unfired nematocysts in fingerlike processes on their dorsal surfaces, where they use them for their own defense. The ctenophore *Haeckelia rubra* feeds on certain hydromedusae

and incorporates their nematocysts into its tentacles. The freshwater flatworm *Microstomum caudatum* feeds on *Hydra*, risking being eaten itself, and then uses the stored nematocysts to capture its own prey. Several species of hermit crabs and brachyuran crabs carry sea anemones (e.g., *Calliactis*, *Sagartiomorphe*) on their shells or claws and use them as living weapons to deter would-be predators. The hermit crabs transfer their anemone partners to new shells, or the anemones move on their own, when the hermits take new shells. Some hermit crabs of the genus *Pagurus* often have their shells covered by a mat of symbiotic colonial hydroids (e.g., *Hydractinia*, *Podocoryne*). The presence of the hydroid coat deters more-aggressive hermits (e.g., *Clibanarius*) from commandeering the pagurid's shell.

Several cases of fish-cnidarian symbiosis have been documented. The well-known association of anemone fishes (clown fishes) and their host sea anemones serves an obvious protective function for the fish. About a dozen species of sea anemones participate in this interesting relationship. The fish's ability to live among the sea anemone's tentacles is still not fully understood. However, the sea anemone does not voluntarily fail to spend its nematocysts on its fish partner; rather, the fish alters the chemical nature of its own mucous coating, perhaps by accumulating mucus from the sea anemone, thereby masking the normal chemical stimulus to which the anemone's cnidae would respond. *Nomeus gronovii* is a small fish that lives symbiotically among the tentacles of *Physalia* and appears to survive by simply avoiding direct contact with the

FIGURE 7.32 Zooxanthellae in cnidarians (A) An octocoral with zooxanthellae distributed throughout the gastrodermis (schematic section). (B) *Mastigias* sp., a rhizostomean medusa, harbors zooxanthellae in its cells.

beast. When stung accidentally, however, it shows a much higher survival rate than do other fishes of the same size. *Nomeus* feeds on prey captured by its host.

A number of associations are known between cnidarians and crustaceans. Nearly all amphipods of the suborder Hyperiidea are symbionts on gelatinous zooplankters, including medusae, and many species of amphipods, crabs, shrimps, and copepods are symbionts with sea anemones (which provide food in the form of uneaten materials and mucus). The nature of many of these associations is unclear, but various species of the amphipods are known to use their hosts as a nursery for the young and perhaps for dispersal. Some actually live among and eat the nematocyst-bearing parts of the host, such as the tentacles or oral arms. Many are commonly found inside the medusa's coelenteron, where they seem unaffected by the host's digestive enzymes. In a relationship similar to that of anemone fish, a few cases of anemone shrimp are known, at least one that is obligate for the shrimp (*Ancylocaris brevicarpalis*).

One of the most noteworthy evolutionary achievements of cnidarians is their close relationship with unicellular photosynthetic partners. The relationship is widespread and occurs in many shallow-water cnidarians. The symbionts of freshwater hydrozoans (e.g., some species of *Hydra*) are single-celled species of green algae (Chlorophyta) called **zoochlorellae**. In marine cnidarians, the protists are unicellular cryptomonads and dinoflagellates called **zooxanthellae**, in several genera (Figure 7.32). In some cases, these algae are capable of living free from their hosts, and perhaps do so normally, but very little is known about their natural history. Dinoflagellates in the family Symbiodiniaceae (e.g., *Symbiodinium*, *Breviolum*) are essential for reef-building (hermatypic) corals, and these symbionts have been shown to transfer photosynthates (glycerol, glucose) directly to their coral hosts. The algae typically reside in the host's gastrodermis or epidermis, although some cnidarians harbor extracellular zooxanthellae in the mesoglea. It is usually the algal symbionts that give cnidarians their green, blue-green, or brownish color, and different strains or species of Symbiodiniaceae can give different colors to individuals of the same coral species. Corals that are reef builders (i.e., **hermatypic corals**), if living in the photic zone, always harbor zooxanthellae (they are "zooxanthellate corals"). Resident populations of zooxanthellae in these corals may reach a density of 30,000 algal cells per cubic millimeter of host tissue (or 1–2 million cells per square centimeter of coral surface). Zooxanthellae also occur in many tropical octocorals, anemones, and zoantharians, as well as in other phyla. Obviously, zooxanthellate corals are restricted to the photic zone in the sea, although many can live at depths that receive 15 to 300 times less photon flux than the surface (in the "twilight" zone, or at "mesophotic" depths). Corals living at greater depths shift their energy budget increasingly toward heterotrophic predation. Many

corals have fluorescent pigments that provide a photobiological system for regulating the light environment of their symbionts, and in excessive sunlight some of these are photoprotective. Some fluorescent pigments (produced by the corals themselves) have been shown to also enhance the resistance to bleaching of corals during periods of heat stress. However, some of the most heavily pigmented (blue) corals have actually shown a greater susceptibility to heat stress, so the protection effect of these fluorescent pigments is variable. Although not common, deep-water, azooxanthellate coral reefs (sometimes called "cold-water coral reefs") also exist, and these depend upon sinking detritus and plankton as a food resource.

Surprisingly, both zoochlorellae and zooxanthellae occur within the tissues and cells of one group of sea anemones, *Anthopleura* of the northeast Pacific coast: *A. elegantissima* and *A. xanthogrammica*. Data suggest that zoochlorellae in these anemones photosynthesize more efficiently and grow faster at lower temperatures and light, whereas zooxanthellae do so under higher temperatures or light regimes. The two anemones are the most abundant rocky intertidal anemones in their range, from Alaska to Baja California, and the distributions of their symbionts have been shown to be (predictably) related to latitude and intertidal position.

Even some scyphozoans harbor large colonies of zooxanthellae in their bodies, and it is now known that these protist colonies produce much of the energy required by their host jellyfish (e.g., *Cassiopea*, *Linuche*, *Mastigias*). Some of this information comes from studies on the scyphomedusa *Mastigias* (Figure 7.32C). These jellyfish live in marine lakes on the islands of Palau, where they may occur in densities exceeding 1,000 per cubic meter. In these lakes, *Mastigias* makes daily vertical migrations between the oxygenated, nutrient-poor upper layers and the anoxic, nutrient-rich lower layers, as well as horizontal migrations to track the movement of the sun across the lake. This behavior appears to be related to the light and nutrient requirements of its symbiotic zooxanthellae. Unlike the zooxanthellae in benthic cnidarians, which tend to reproduce more-or-less evenly over a 24-hour period, the zooxanthellae of *Mastigias* show a distinct reproductive peak during the hours when their host occupies a position in the deeper, nitrogen-rich layers of the lakes. This reproductive peak may be a result of the alga's use of free ammonia as a nutrient source.

Many cnidarians seem to derive only modest nutritional benefit from their algal symbionts, but in many others a significant amount of the hosts' nutritional needs appears to be provided by the algae. In such cases, a large portion of the organic compounds produced by photosynthesis of the symbiont may be passed on to the cnidarian host, probably as glycerol but also as glucose and the amino acid alanine. In return, metabolic wastes produced by the cnidarian provide the symbiotic alga with needed nitrogen and phosphorus. In corals, the symbiosis is thought to be important for rapid growth and for efficient deposition of the calcareous skeleton, and many corals can only form reefs when they maintain a viable dinoflagellate population in their tissues. Different coral species serve as hosts to genetically distinct algal symbiont taxa. Each of these appears to be adapted to its host as well as that host's particular ambient light regime. Although the precise physiological-nutritional link between corals and their zooxanthellae has been elusive, the algae clearly seem to increase the rate of calcium carbonate production. Corals and other cnidarians can be deprived of their algal symbionts by experimentally placing the hosts in dark environments. In such cases the algae may simply die, they may be expelled from the host, or they may (to a limited extent) actually be consumed directly by the host. Because they are dependent on light, zooxanthellate corals can live to depths of only 90 m or so. Most zooxanthellate corals also require warm waters and thus occur almost exclusively in shallow tropical seas (although zooxanthellae occur in some high-latitude anemones). As noted above, deep-water and cold-water corals also exist but tend to be entirely carnivorous. They grow at extremely slow rates and thus tend to produce reefs that have existed for thousands and even millions of years, providing a detailed record of changes in sea temperature. Due to their old age and slow growth rates, these reefs are extremely vulnerable and have recently attracted attention by conservation biologists.

Under stress, such as unusually high temperatures, corals may lose their zooxanthellae—a process known as **coral bleaching**. The long-term impact of coral bleaching, now accelerating throughout the world's tropics, due to a combination of warming seas and changes in oceanic acid-base balance due to increased atmospheric CO_2, is unclear. Certainly it seems detrimental in the short run and often leads to death of entire coral colonies and large fractions of reefs. In addition, anthropogenic pollution such as increases in phosphates, nitrates, and ammonia in the sea is enhancing growth of algae and bacteria that compete with coral. A 2018 study found the median return time between severe bleaching events worldwide to be just six years, and diminishing, suggesting that the interval between events may be too short for full recovery of mature assemblages. Caribbean reefs have been devastated over the last few decades, having lost about 80% of their historical coral cover. Interestingly, a few recent studies have suggested that bleaching might lead to corals acquiring new types of zooxanthellae better adapted to the changing environment. If true, it would remain to be seen whether this symbiont switch could take place quickly enough to keep up with today's rapidly changing ocean chemistry. Evidence that selectivity between symbiotic partners

for more ebook/ testbank/ solution manual requests: email C960126734@qq.com

may exist could mean slower symbiotic reassociations (i.e., certain combinations of hosts and algae are favored while others are impossible). Additionally, there is tantalizing evidence that corals in some areas are adapting to the warmer sea temperatures. However, current thinking is that they may not be able to adapt fast enough (and the interval between recurrent bouts of coral bleaching may be too short) for full recovery of mature reef coral assemblages.

Loss of zooxanthellae by corals usually results in loss of the ability to secrete the calcium carbonate skeleton. The widespread disappearance of Caribbean corals is now considered responsible for a 32%–72% decrease in reef fish populations, a potentially catastrophic change for coastal communities dependent on fishing. Coral reef biodiversity correlates with reef area, thus the long-term effects of reef loss are likely to be cumulative and difficult to reverse. However, one recent experiment found that colonies of some coral species that lost their calcium carbonate skeleton continued to exist as soft-bodied polyps. These recent discoveries have suggested a possible explanation for the geologically "sudden" appearance of the modern stony corals (Scleractinia) in the Middle Triassic, when geochemically perturbed oceans returned to "normal." Before this time, corals and reefs had disappeared from the fossil record for millions of years, but perhaps they continued to exist as "naked corals" (and thus not contributing to the fossil record).

Circulation, Gas Exchange, Excretion, and Osmoregulation

There is no independent circulatory system in cnidarians. The coelenteron largely serves this role by circulating partly digested nutrients through the interior of the body, absorbing metabolic wastes from the gastrodermis, and eventually expelling waste products of all types through the mouth. But large anemones and large medusae confront a serious surface-area-to-volume ratio dilemma. In such cases, the efficiency of the gastrovascular system as a transport device is enhanced by the presence of mesenteries in anemones and the radially arranged canal system in medusae.

Cnidarians also lack special organs for gas exchange or excretion. The body wall of most polyps either is fairly thin or has a large internal surface area, and the thickness of many medusae is due largely to the gel-like mesoglea or mesenchyme. Thus, diffusion distances are kept to a minimum. Gas exchange occurs across the internal and external body surfaces. Facultative anaerobic respiration occurs in some species, such as anemones that are routinely buried in soft sediments. Nitrogenous wastes are in the form of ammonia, which diffuses through the general body surface to the exterior or into the coelenteron. In freshwater species there is a continual influx of water into the body. Osmotic stress in such cases is relieved by periodic expulsion of fluids from the gastrovascular cavity, which is kept hyposmotic to the tissue fluids.

Nervous System and Sense Organs

Cnidarians (and ctenophores) are among the first metazoans to have evolved a distinct, multicellular, integrated nervous system, which is largely in the form of a nerve net(s), or nerve plexus. Consistent with their radially symmetrical body plan, cnidarians generally have a diffuse, noncentralized nervous system; however, great variation exists. Some degree of centralization (not to be confused with cephalization) has been documented in some species of Anthozoa and Medusozoa. In *Hydra*, for example, there is a series of "functional nerve-net networks," these being anatomically nonoverlapping and associated with specific behaviors. Similarly, in the sea anemone *Nematostella vectensis* the nervous system consists of several distinct neural territories along the oral–aboral axis, including pharyngeal and oral nerve rings, and the larval apical tuft. Nonetheless, the neurosensory cells of cnidarians are the most primitive in the animal kingdom, being naked and largely nonpolar. Usually the neurons are arranged in two reticular arrays, called **nerve nets**, one between the epidermis and the mesenchyme and another between the gastrodermis and the mesenchyme (Figure 7.33). This arrangement of an ectodermal and an endodermal nerve net appears to be unique to Cnidaria. The subgastrodermal net is generally less well developed than the subepidermal net and is absent altogether in some species; in cubozoan polyps, there is a nerve net *within* the gastrodermis. Some hydrozoan medusae possess one or two additional nerve nets, whereas in the polyps of hydrozoans and cubozoans there appears to be only a single epidermal nerve ring. Both bi- and multipolar neurons enable the conduction in either direction, allowing a stimulation to progress quickly throughout a network. Despite the seeming simplicity of cnidarian nervous systems, it has been shown that they possess at least some of the classic interneuronal and neuromuscular synapse neurotransmitters seen in Bilateria, including serotonin, suggesting that both catecholamine and indolamine neurotransmitters may be present (at least in sea anemones). Neuronal communication in cnidarians uses transmission through both chemical synapses and electrical synapses mediated by gap junctions. There is also evidence for epithelial conduction through junctions between epithelial cells in some cnidarians.

A few nerve cells and synapses are polarized and allow for transmission in only one direction, but most cnidarian neurons and synapses are nonpolar—that is, impulses can travel in either direction along the cell or across the synapse. Thus, sufficient stimulus sends an impulse spreading in every direction. In

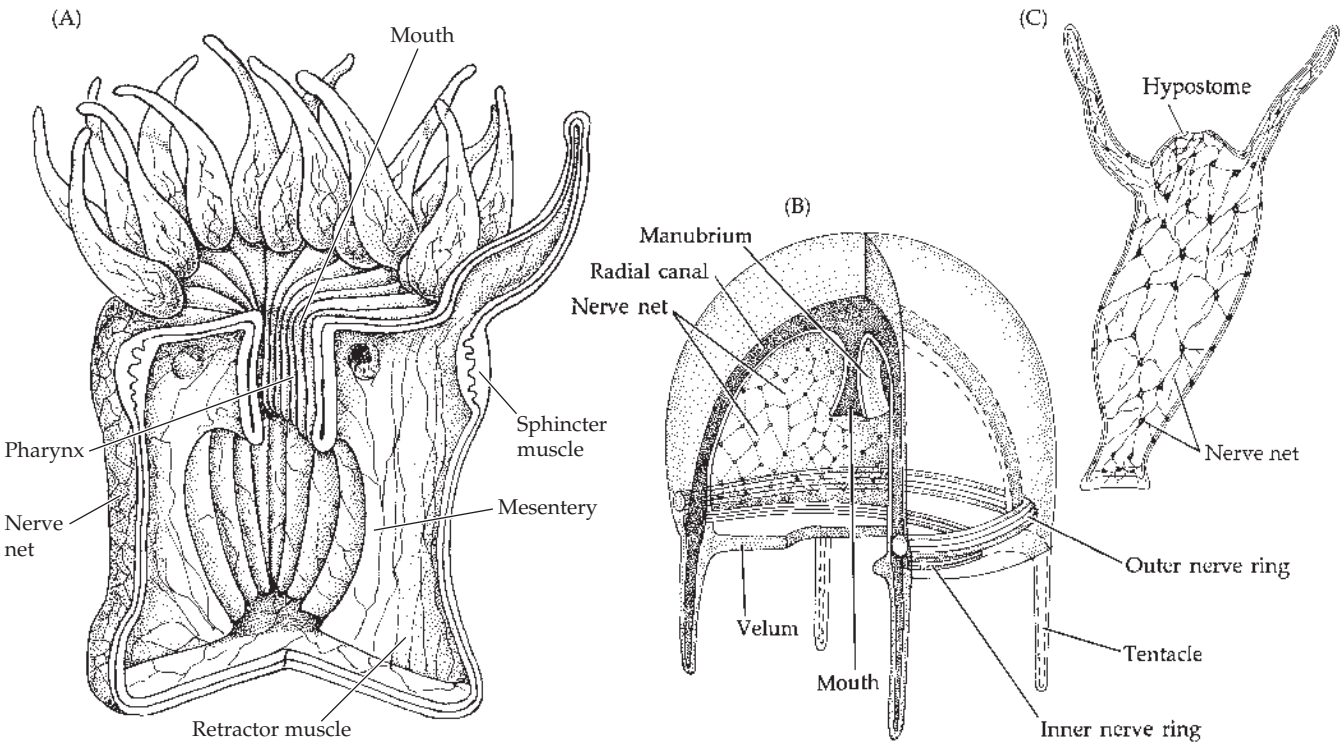

FIGURE 7.33 Cnidarian nerve nets. (A) Nerve net of a typical sea anemone (Anthozoa). (B) Nerve net in a hydromedusa (Hydrozoa). (C) Nerve net of *Hydra* (Hydrozoa).

some cnidarians where both nerve nets are well developed, one net serves as a diffuse slow-conducting system of nonpolar neurons, and the other as a rapid through-conducting system of bipolar neurons.

Polyps generally have very few sensory structures. The general body surface has various minute hairlike structures developed from individual cells. These serve as mechanoreceptors, and perhaps as chemoreceptors, and are most abundant on the tentacles and other regions where cnidae are concentrated. They are involved in behavior such as tentacle movement toward a prey or predator and in general body movements. Some appear to be associated specifically with discharged cnidae, such as the ciliary cone apparatus of anthozoan polyps, which is believed to function in the same way as the cnidocil in hydrozoan and scyphozoan nematocysts (Figure 7.34). Oddly, these structures do not appear to be connected directly to the nerve nets. In addition, most polyps show a general sensitivity to light, not mediated by any known receptor but presumably associated with neurons concentrated in or just beneath the translucent surface of epidermal cells.

The genome of the anemone *Nematostella vectensis* has been sequenced and much of its development mapped. It has been shown to possess a complex neural morphology that is modified during development from the larval to adult (polyp) form (there is no medusa stage in this species). The nervous system is a diffuse nerve net with both ectodermal sensory and effector cells, and endodermal multipolar ganglion cells. *Nematostella vectensis* has specialized neural structures with distinct populations of neurons are located at the pharyngeal nerve ring, at the oral nerve ring, innervating the mesenteries, and at the tentacle tips of the adults, as well as at the larval apical tuft. Thus, the nerve net consists

(E) A pigment-cup ocellus (cross section) of a hydrozoan medusa. (F) The eye of a cubozoan (*Carybdea*) (cross section).

of several distinct neural territories. Interestingly, these neuralized regions correspond to expression of conserved bilaterian neural developmental regulatory genes, including homeodomain transcription factors. This suggests that, even though *N. vectensis* lacks a centralized nervous system, its neural systems seems to be patterned along an oral–aboral axis.

As might be expected, motile medusae have more sophisticated nervous systems and sense organs than do the sessile polyps (Figure 7.35). In many groups, especially the hydromedusae, the epidermal nerve net of the bell is condensed into two nerve rings near the bell margin. These nerve rings connect with fibers innervating the tentacles, muscles, and sense organs. The inner ring stimulates rhythmic pulsations of the

bell. This ring is also connected to statocysts, when present, on the bell margin, which is supplied with general sensory cells and with radially distributed ocelli and (probably) chemoreceptors. The general sensory cells are neurons whose receptor processes are exposed at the epidermal surface. The ocelli are usually patches of pigment and photoreceptor cells organized as a disc or a pit. Statocysts may be in the form of pits or closed vesicles, the latter housing a calcareous statolith adjacent to a sensory cilium. When one side of the bell tips upward, the statocysts on that side are stimulated. Statocyst stimulation inhibits adjacent muscular contraction, and the medusa contracts muscles on the opposite side. Many medusae maintain themselves in a particular photoregime by directed swimming behaviors. This action is seen especially in those medusae harboring large populations of zooxanthellae, such as the upside-down jelly *Cassiopea*, which lies upside down on the shallow seafloor, exposing to light the dense zooxanthellae population residing in tissues of its tentacles and oral arms.

There is great variation in eye type and structure among cnidarians, including among hydrozoan medusae. Some cnidarians have structural eyes (even camera-type eyes), but others have pigment-cup ocelli of varying complexity, or only simple eyespots, or just a generally photosensitive neuronal system. Among the hydromedusae, structural eyes are usually well-defined ocelli that vary in complexity from a simple ectodermal layer with sensory and pigment cells, through pigment-cup eyes, to small camera-type eyes with pigmented retina and lens- or cornea-like structures. The axons of the photosensory cells may join in bundles that collect to form an "optic nerve" that runs to the outer nerve ring in the bell. In addition, hydrozoans have been shown to possess a cytoplasmic conducting system similar in nature to that of sponges. Epidermal cells and muscle elements appear to be the principal components of the system. Although the impulse seems to move slowly, it is initiated by nerve cells and relies on gap junctions.

In the codonophoran siphonophores, a linear condensation of the nerve net produces longitudinal "giant axons" in the stem and the nerve tracts in the tentacles. One of these axons is actually a neuronal syncytium that originates by fusion of neurons from the nerve net of the stem. The high-speed impulses in these large-diameter nerve tracts enable codonophorans to contract rapidly and initiate a fast escape reaction.

Image-forming and simpler eyes both exist in cnidarians, and even eyeless species show light-sensing behavior, supporting the idea that ancestors without eyes already sensed light with dispersed photoreceptor cells and that eyes evolved multiple times within the phylum. Cnidae also act as sensory cells by responding to stimuli and are integrated with the nervous system through synapses. The bell margins of cubomedusae and scyphomedusae usually bear club-shaped structures called **rhopalia**, which are situated between a pair of flaps or **lappets** (Figure 7.35A). The rhopalia are complex sensory centers, each containing a concentration of epidermal neurons, a pair of chemosensory pits, a statocyst, and eyes of various design. One pit is located on the exumbrellar side of the hood of the rhopalium, the other on the subumbrellar side.

Cubomedusae are strong swimmers that are able to make rapid directional changes in response to visual stimuli. They have been shown to be attracted to light, to avoid dark objects, and even to navigate around obstacles. They are active predators that "rest" at night. Although cubomedusae have the basic cnidarian nerve net and subumbrellar nerve ring close to the bell margin (sometimes called the "ring nerve"), they also have the most elaborate visual system in Cnidaria, located on four rhopalia. Each rhopalium has six eyes, of four morphological types: paired pit-shaped pigment-cup eyes, paired slit-shaped pigment-cup eyes, and two complex camera-type eyes with cornea, lens, and retina (one small upper lensed eye, and one large lower lensed eye). Although the retina of the camera eye is only one cell thick, it is multilayered, containing a sensory layer, a pigmented layer, a nuclear layer, and a region of nerve fibers. The number of sensory cells, or photoreceptors, in each of these remarkable eyes varies from about 300 to 1,000, depending on the species. Each rhopalium also has a crystalline concretion, the statolith, which is often called a statocyst. Neuronal signals from the rhopalia are presumably transmitted to swimming pacemaker neurons to direct visually guided swimming movements. Giant neurons have been identified on either side of the cubomedusan rhopalium.

Despite the structural simplicity of the cubozoan planula larva, being composed of only six cell types, it possesses rhabdomeric photoreceptors of the pigment-cup ocelli type. These comprise 10–15 ocelli arranged as individual photoreceptor cells. Each contains screening pigment in a cavity filled with microvilli (the sites of photoreception) and a single cilium. The cilium is the typical 9+2 structure and is likely motile, rather than sensory. There is no synaptic or electrical (gap junction) connection between the ocelli and any other cell in the larva. The ocelli of cubozoan planulae appear to represent one of the simplest visual systems in the animal kingdom.

Scyphozoan medusae have structurally simple visual eyespots located in the rhopalia, which also contain gravity-sensing structures, the statocysts. The eyespots are simple ectodermal pigment-cup eyes, consisting of photosensory cells containing pigment granules or of photosensory cells alternating with pigment cells, or they are pigment-cup eyes with ectodermal sensory cells and gastrodermal pigment cells. The sensory cells make contact with the ectodermal nerve net.

Bioluminescence is common in cnidarians and has been documented in all classes except the Cubozoa and the poorly known Staurozoa. In some forms (e.g., many hydromedusae), luminescence consists of a single flash in response to a local stimulus. In others, bursts of flashes propagate as waves across the body or colony surface (e.g., sea pens and sea pansies). One of the most complicated luminescent behaviors occurs in some hydropolyps, where a series of multiple flashes is propagated. The sea pansy *Renilla* (an octocoral) also has very elaborate luminescent displays. Propagated luminescence is probably controlled by the nervous system, although this phenomenon is not well understood. In at least one hydromedusa (*Aequorea*), luminescence appears not to be the result of the usual luciferin-luciferase reaction; rather, a high-energy protein, named **aequorin**, emits light in the presence of calcium.

Reproduction and Development

Asexual reproduction takes many forms in cnidarians, and regeneration after major injuries is common. Many anemones can be cut in half and then regenerate the two halves flawlessly. Sometimes injuries to the oral region result in the production of two or more mouths, each with its own set of feeding tentacles.

Sexual reproduction in Anthozoa is the least complex, usually involving a motile **planula larva** that settles and grows into a sessile adult polyp. However, sexual reproductive processes in Medusozoa are intimately tied to the alternation of generations that characterizes this clade. As you have already read, medusozoan life cycles commonly involve an asexually reproducing polyp stage, alternating with a sexual medusoid stage that produces a characteristic motile planula larva. Hence, cubozoans have motile planulae, which settle to grow into polyps that in turn produce sexual medusae. Scyphozoans also follow the planula-to-sessile-polyp mode, but the polypoid stage generates multiple juvenile medusae, called **ephyrae**, by transverse fission or **strobilation** at the polyp's oral end; ephyrae later mature as the sexual medusoid stage. Planulae, polyps, and medusae all appear in many hydrozoan species' life cycles. Medusae, when present, develop from a laterally budding tissue mass called the **entocodon**, but polyp or medusa stages may be entirely missing from certain life cycles. Because of these many variations in life cycle, we will discuss the cnidarian classes separately.

Anthozoan reproduction Members of this class are exclusively polypoid, and the variety of ways that new individuals can be produced asexually nearly defies imagination. Asexual reproduction is common in sea anemones, and longitudinal fission of polyps can result in two separate individuals (Figure 7.36A), or the daughter anemones can remain close together to produce large groups (clones) of genetically identical individuals (e.g., seen in some species of *Anthopleura*, *Diadumene*, and *Metridium*). During longitudinal fission, the body column stretches to the point of ripping itself apart, each half then regenerating its missing parts. The less common process of pedal laceration (e.g., seen in some acontiate sea anemones: *Diadumene*, *Haliplanella*, *Metridium*) can also lead to clonal populations. During pedal laceration, the pedal disc spreads and the anemone simply glides away, leaving behind a circle of small fragments of the disc, each of which develops into a young sea anemone. This behavior is easily observed in aquaria, where anemones can affix themselves to the glass walls.

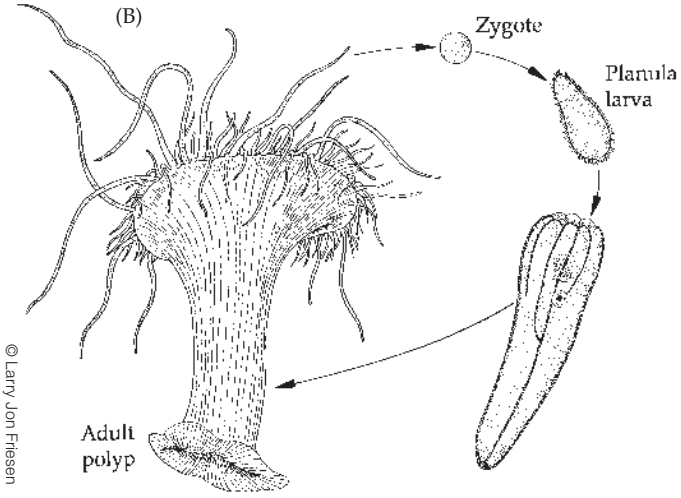

FIGURE 7.36 Reproduction in Anthozoa. (A) Asexual reproduction by longitudinal fission in the aggregating anemone *Anthopleura elegantissima*. (B) A typical anthozoan sexual life cycle: the adult polyp releases gametes that fuse externally, or fertilized eggs are released, and zygotes develop into a planula larva; the larva settles and transforms directly into a young polyp.

In addition to these two common modes of asexual reproduction, at least a few species of sea anemones undergo transverse fission (e.g., *Edwardsiella lineata*, *Nematostella vectensis*). Transverse fission is usually by way of a constriction and then separation in the lower part of the column that results in the formation of a small aboral compartment and a larger oral region, each of which then grows its missing region. Transverse fission has also been reported by a process called "polarity reversal," in which the aboral end spontaneously sprouts new tentacles and a new mouth; eventually a new physa forms in the midsection of the anemone and the two individuals separate (e.g., *Gonactinia*). Certain sagartiid sea anemones engage in intratentacular budding, wherein multiple mouth openings result from repeated longitudinal fission through the pharynges of existing individuals. This process produces bandlike colonies that resemble the elongated polyps of certain meandroid corals. Also, certain populations of *Anthopleura* engage in mesenterial budding of tiny polyps, which are brooded within the gastrovascular cavity before release from the parent anemone. In these anemones, no evidence of gonadal or gametic development has been found, suggesting that these populations are primarily if not entirely asexual.

One family of sea anemones (Boloceroididae) swims actively and produces new individuals by longitudinal fission, pedal laceration, and a bizarre process called tentacular shedding (or tentacle budding) in which tentacle fragments are pinched off at basal sphincters and moved into the coelenteron, where they are brooded as they develop into new polyps before being released. Certain anemones and at least one scleractinian coral (*Pocillopora damicornis*) are known to produce planula larvae parthenogenetically and brood them until release. And, among all these odd asexual modes of reproduction there is the so-called "polyp bailout" of some corals, where under conditions of stress (e.g., high salinity, low pH, acute temperature shock) the nonskeletonized portion of the polyp detaches itself and disperses to a new site, whereupon it settles and builds a new skeleton. The detached polyps appear to retain their endosymbiotic zooxanthellae.

Anthozoans are typically gonochoristic, although most scleractinian corals are hermaphroditic. Fertilization can take place internally, but in most species it occurs externally, in the open sea. A typical anthozoan life cycle is shown in Figure 7.36B. Eggs are free or, occasionally, pooled into a gelatinous egg mass (even through fertilization). Sperm are usually equipped with mitochondria and flagella suited for propulsion, although structural differences among anthozoan sperm are remarkable. Cleavage is typically radial and holoblastic, resulting in a hollow spherical, uniformly ciliated, coeloblastula. Gastrulation occurs by way of ingression or invagination, to produce distinct ectodermal and endodermal germ layers, and thence a ciliated planula larva. When invagination occurs, the blastopore remains open and sinks inward, drawing with it a tube of ectoderm that becomes the adult pharynx. Because the mouth forms at the site of gastrulation (at the animal pole), anemones/cnidarians are, by definition, true protostomes, suggesting that protostomy predated the cnidarian-bilaterian divergence. The planula larva may develop one or a few pairs of tentacles at the oral end, as well as a rudimentary pharynx and mesenteries, before settling. Some anthozoan planulae are planktotrophic, although very yolky ones do not feed. The ability of some larvae to feed allows them a potentially longer larval life, enhancing dispersal and selection of an appropriate settlement site. Some anthozoan planulae (e.g., *Anthopleura*) appear to obtain zooxanthellae by ingestion. In some species, the planulae develop up to eight complete mesenteries before settling, and this is the so-called **edwardsia stage**, named after the octamesenterial genus *Edwardsia*. The larva eventually settles on its aboral end and tentacles grow around the upwardly directed mouth and oral disc. Development in *Nematostella vectensis* includes an early chaotic cleavage stage and a hollow blastula that gastrulates by unipolar invagination to a swimming planula, which settles and grows tentacles surrounding its oral opening to the gut to form a polyp.

Many coral populations undergo synchronous spawning over large areas on reefs, a process mediated by moonlight-sensitive molecules called **cryptochromes**, which have also been associated with control of circadian activity in vertebrates and insects. In some cases this synchrony is restricted to colonies of a single species, or it is only loosely correlated with lunar cycles, but widespread synchronous spawning events involving over 100 different coral species have been reported (on the Great Barrier Reef, Australia), perhaps as an adaptation to satiate predators. The synchronized release of massive numbers of eggs and sperm into the water by individuals in an area is called broadcast spawning. Unfertilized eggs apparently die within hours if not fertilized by sperm. Such events create a pulse of nutrients into the surrounding ecosystem and also may lead to hybridization among scleractinian corals. Verified cases of hybridization between members of different coral genera exist, and this may explain the great range of polymorphism seen in many coral "species." Because hybrid individuals can become secondarily clonal, they may persist within populations for years, but the degree to which interbreeding by hybrids or their introgression into parental populations occurs is unclear. Some coral planula larvae are long-lived, spending several weeks or months in the plankton, an obvious means of dispersal. Other corals release benthic planulae that crawl away from the parent and settle nearby. In the Caribbean coral *Porites astreoides* the larva hosts zooxanthellae, and an analysis of differential gene expression during competency has

for more ebook/ testbank/ solution manuals requests: email:960126734@qq.com

shown that the dinoflagellate endosymbionts may play a significant role in the transition from nonprobing to probing behavior in larvae.

Octocorals are usually gonochoristic and often spawn synchronously, although the timing of gonadal development appears to be highly variable among temperate and tropical species, evidently due to variability in water temperature or resource availability, respectively. Although little is known about the reproductive biology of most ceriantharians, it appears that antipatharians, anemones, and stony corals may be gonochoristic or hermaphroditic. In some species, colonial forms can contain males, females, and hermaphrodites. The gametes arise from patches of tissue on the gastrodermis of all or only some mesenteries. Eggs are fertilized either in the coelenteron, followed by early development in the gut chambers, or more commonly outside the body, in the sea. A number of anemones brood their developing embryos internally or on the external body surface. The northeast Pacific sea anemone *Aulactinia incubans* releases its brooded young through a pore at the tip of each tentacle! Some corals undergo internal fertilization, brooding, and then release of planula larvae. The eastern Pacific solitary coral *Balanophyllia elegans* builds skeletal chambers within which oocytes and embryos may be carried apart from the main digestive cavity, a structural arrangement that allows continued brooding through advanced developmental stages. These calcareous structures are preserved in the fossil record. Some octocorals (e.g., *Briareum*, *Alcyonium*) brood their embryos in a mucous coat on the body surface; then the planula larvae escape. Others shed their gametes and rely on external fertilization and planktonic development. *Heliopora coerulea* is a gonochoristic hermatypic octocoral that broods its planulae at the surface of female colonies before their annual release.

Cylista troglodytes is the only sea anemone known to copulate. The coupling starts when a female glides up to a receptive male, whereupon their pedal discs are pressed together in such a way that they create a chamber into which the gametes are shed and fertilization occurs. The copulatory position, which forms a temporary marsupium, is maintained for several days, presumably until planula larvae have developed. This behavior may be an adaptation to areas of great water movement that might otherwise scatter gametes and reduce the probability of successful fertilization.

Recent work on the sea anemone *Nematostella vectensis* has revealed cnidarians to possess some (but not all) of the genes involved in dorsal–ventral patterning in the Bilateria. Although these homologues are expressed in somewhat haphazard ways during development, their expression has suggested to some workers the possibility that the oral–aboral polarity of cnidarians might be equivalent to the anterior–posterior polarity of bilaterians. In fact, homologues of five Hox genes known to regulate anterior–posterior axis patterning in Bilateria are also known from *N. vectensis* (and other cnidarians), although Cnidaria lack a definitive anterior–posterior axis. These genes show a staggered domain expression in the oral–aboral axis patterning of the anemone. This suggests that the earliest stages of what was to become bilaterality had its roots at least as deep in the evolution of the Metazoa as the Cnidaria. Thus, what we recognize as "biradiality" in anemones (e.g., the right–left arrangement of feeding tentacles, pharyngeal siphonoglyph, coelenteron mesenteries) might, in fact, be a rudimentary form of bilaterality.

Scyphozoan reproduction Most scyphozoan jellyfish species have a metagenic life cycle involving a benthic, asexually reproducing polyp stage and a sexually reproducing medusa stage. However, the life cycles of most species are poorly known because their benthic stages occur in yet unknown locations. The asexual form of scyphozoan cnidarians is a small polyp called the **scyphistoma** (= scyphopolyp; Figure 7.37A). It may produce new scyphistomae by budding from the column wall or from stolons. At certain times of the year, generally in the spring, medusae are produced by repeated transverse fission of the scyphistoma, a process called **strobilation** (Figure 7.37B). During this process the polyp is known as a **strobila**. Medusae may be produced one at a time (**monodisc strobilation**), or numerous immature medusae may stack up like soup bowls and then be released one after the other as they mature (**polydisc strobilation**). Immature and newly released medusae are called **ephyrae** (sing. ephyra). An individual scyphistoma may survive only one strobilation event, or it may persist for several years, asexually giving rise to more scyphistomae and releasing ephyrae annually.

Ephyrae are very small larvae with characteristically incised bell margins (Figure 7.37C,D). The ephyral arms, or primary tentacles, mark the position of what becomes the adult lappets and rhopalia. In some genera (e.g., *Aurelia*) the number of ephyral arms is quite variable. Maturation involves growth between these arms to complete the bell. Development into sexually mature adult scyphomedusae takes a few months to a few years, depending on the species.

The gamete-forming tissue in adult scyphomedusae is always derived from the gastrodermis, usually on the floor of the gastric pouches, and gametes are generally released through the mouth. Most species are gonochoristic. Fertilization takes place in the open sea or in the gastric pouches of the female. Gastrulation is by ingression or invagination and results in a mouthless, double-layered planula larva; when invagination occurs, the blastopore closes. The planula larva eventually settles and grows into a new scyphistoma.

The medusa phase dominates the life cycles of most scyphozoans. The small polyp stage is often significantly suppressed or absent altogether. For

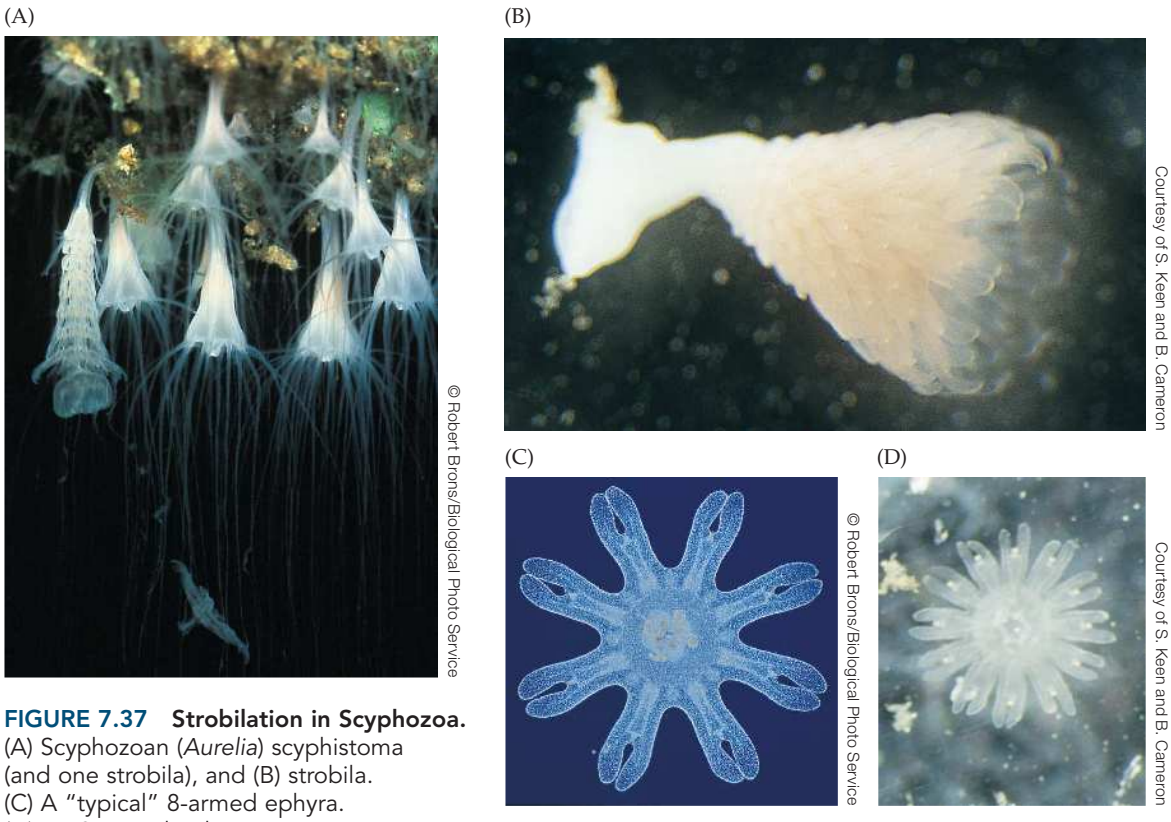

FIGURE 7.37 Strobilation in Scyphozoa.
(A) Scyphozoan (*Aurelia*) scyphistoma (and one strobila), and (B) strobila. (C) A "typical" 8-armed ephyra. (D) A 12-armed ephyra.

example, many pelagic scyphomedusae have eliminated the scyphistoma, and the planula larva transforms directly into a young medusa (e.g., *Atolla*, *Pelagia*, *Periphylla*). In others, the larvae are brooded, developing in cysts on the parent medusa's body (e.g., *Chrysaora*, *Cyanea*). A few genera have branching colonial scyphistomae with a supportive skeletal tube and an abbreviated or suppressed medusoid stage (e.g., *Nausithoe*, *Stephanoscyphistoma*). None, however, has lost the medusoid stage altogether. Some scyphozoan life cycles are shown in Figure 7.38.

Cubozoan reproduction The reproductive biology of cubozoans is only just beginning to be understood. Apparently, each polyp metamorphoses directly into a single medusa, rather than undergoing the kind of strobilation seen in scyphozoan polyps. Some cubozoan medusae are known to engage in a form of copulation, in which the male uses his tentacles to bring the female close enough to transfer a sperm packet, or spermatophore, directly to her. In *Copula sivickisi* and *Tripedalia cystophora*, this courtship results in the female moving the spermatophore to her mouth to be ingested. Once in the gastrovascular system, spermatophores are transferred to specialized structures that function in sperm storage. Females accept spermatophores from multiple males yet may only produce one embryo strand (a packet of fertilized ova that eventually attaches to algae). During courtship, mature females may exhibit conspicuous velar spots that may provide a visual signal to courting males.

Staurozoan reproduction Reproduction in staurozoans has been observed in only a few species. So far as is known, all species are gonochoristic and free-spawn gametes into the water, where fertilization takes place. The zygotes quickly settle and develop into creeping, nonciliated planulae, each with a fixed number of cells. Planulae develop into a nonfeeding "microhydrula" stage and may asexually produce creeping frustules that later develop into stauropolyps, or the microhydrula stage may develop directly into stauropolyps, which later develop into stauromedusae.

Hydrozoan reproduction Hydrozoan polyps reproduce asexually by budding. This is a rather simple process wherein the body wall evaginates as a bud, incorporating an extension of the gastrovascular cavity with it. A mouth and tentacles arise at the distal end, and eventually the bud either detaches from the parent and becomes an independent polyp or, in the case of colonial forms, remains attached. Asexual reproduction in the latter case creates larger and more-complex polypoid colonies that have greater reproductive capacity.

Medusa buds, or gonophores, are also produced by polyps in a similar fashion, although the process is sometimes quite complex. A rather special kind of

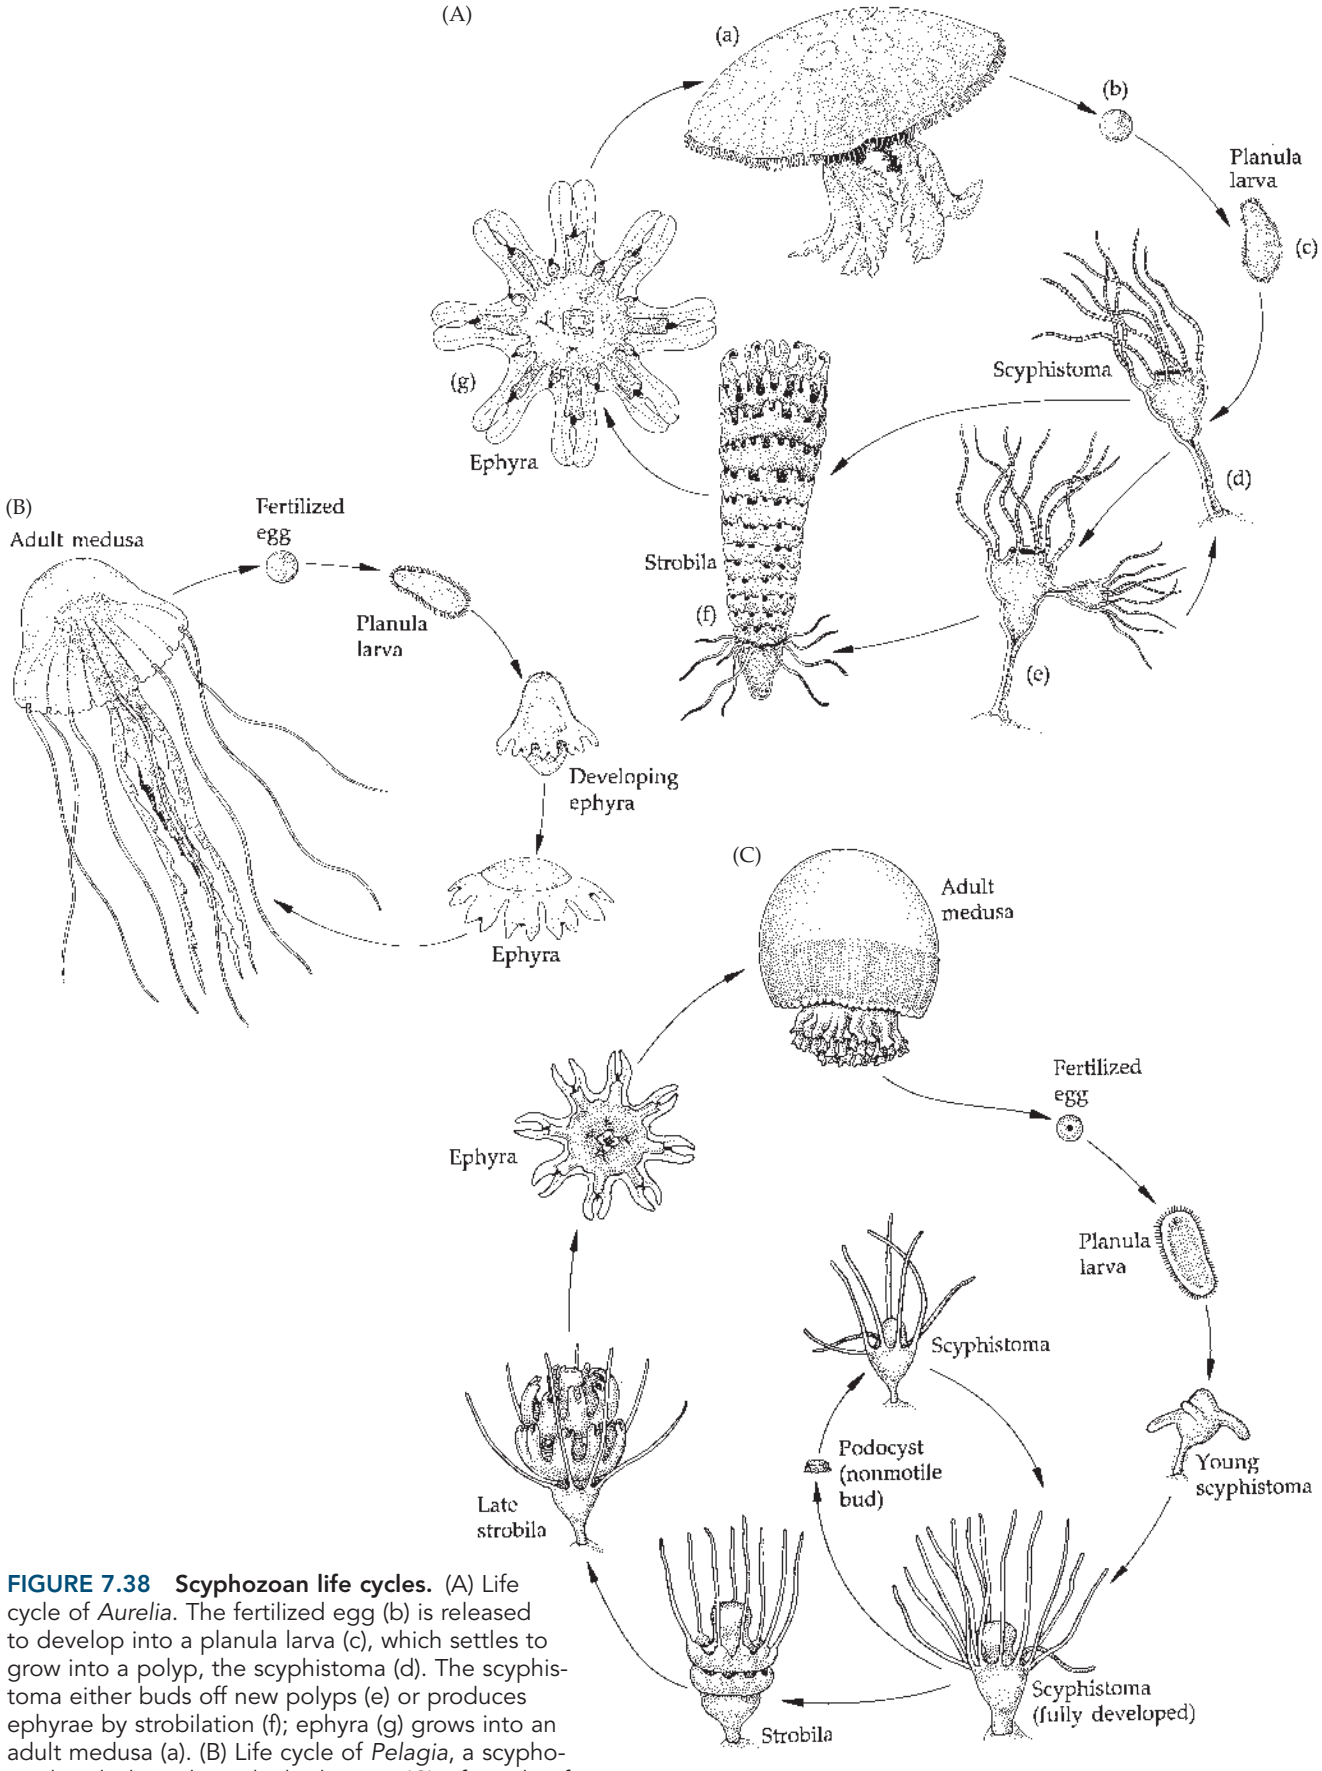

FIGURE 7.38 Scyphozoan life cycles. (A) Life cycle of *Aurelia*. The fertilized egg (b) is released to develop into a planula larva (c), which settles to grow into a polyp, the scyphistoma (d). The scyphistoma either buds off new polyps (e) or produces ephyrae by strobilation (f); ephyra (g) grows into an adult medusa (a). (B) Life cycle of *Pelagia*, a scyphomedusa lacking the polyploid stage. (C) Life cycle of the "cannonball jellyfish," *Stomolophus meleagris*.

budding occurs in the siphonophores, in which the floating colonies produce chains of individuals called **cormidia**, which may break free to begin a new colony.

Certain hydromedusae also undergo asexual reproduction, either by the direct budding of young medusae (Figure 7.39) or by longitudinal fission. The latter process often involves the formation of multiple gastric pouches (**polygastry**) followed by longitudinal splitting, which produces two daughter medusae. In some species (e.g., *Aequorea macrodactyla*), direct fission may take place. Polygastry does not occur during this process; instead, the entire bell folds in half, severing the stomach, ring canal, and velum (Figure 7.40). Eventually the whole medusa splits in half, and each part regenerates the missing portions.

Cnidarians in general have a great capacity for regeneration, as exemplified by experiments on *Hydra*. The eighteenth-century naturalist Abraham Trembley (from the Republic of Geneva) had the clever idea of turning a *Hydra* inside out—and he did. To his delight, the animal survived quite well, with the gastrodermal cells functioning as the "new epidermis" and vice versa. Cells removed from the body of a *Hydra* also have a modest degree of reaggregative ability, like that seen so dramatically in sponges. In some cases, entire animals will reconstruct from cells taken only from the gastrodermis or only from the epidermis.

A typical *Hydra* consists of only about 100,000 cells of roughly a dozen different types. Although distinct epidermis and gastrodermis exist, these tissues are very similar to one another, comprising mainly epitheliomuscular cells. It takes only a few weeks for all the cells in a *Hydra* to replace themselves, or "turn over," including the nerve cells. These attributes make *Hydra* an ideal creature for studies of developmental biology, histogenesis, and morphogenesis.

All hydrozoan cnidarians have a sexual phase in their life cycle (Figure 7.41). However, in solitary species such as those in the genus *Hydra*, and perhaps in many colonial forms, the medusoid phase (typically the gamete-producing stage) is suppressed or absent. Instead, the polyp epidermis develops simple, transient gamete-producing structures called **sporosacs** (Figure 7.5B). Most colonial hydroids produce medusa buds (gonophores) either from the walls of the hydranths or from separate gonozooids. The gonophores may grow into medusae that are released as free-living sexually reproducing individuals, or they may remain attached to the polyps as incipient medusae that produce gametes in place. For example, *Gonothyraea loveni* has reduced medusae that remain attached to the colony, and the embryos are brooded within these medusae. The embryos of *G. loveni* lack a blastocoel, and gastrulation proceeds through delamination to produce a parenchymula (a developmental stage in which flagellated ectodermal cells surround a mass of parenchyma-like endodermal cells), which then grows to become the free-swimming planula larva. The planula settles and grows into a primary polyp that initiates a new colony.

Milleporid hydrozoans produce short-lived sexual medusae that are released over several days during particular seasons. Temporal segregation of spawning seems to occur among colonies of different species. Colonies within species are gonochoristic and so release exclusively male medusae, bearing a sperm sac

FIGURE 7.40 Asexual reproduction in the hydromedusa *Aequorea*. The sequence of photographs shows the direct fission of *A. macrodactyla*. (A) This oral view shows a nondividing medusa with its marginal fishing tentacles (mt) deployed. (B) Initiation of invagination (i). (C–E) A progression of the direct fission process. The oral (C) and marginal (D) views illustrate the severing of the umbrellar margin (um) and the separation of exumbrellar (ex) halves. (E) The exumbrellar surface beginning to pull apart, producing free-swimming daughter medusae; healing is nearly complete in the smaller daughter medusa on the left. ot: oral tentacles; m: mouth; rc: radial canals.

located at the vestigial manubrium, or female medusae bearing three to five ova in the subumbrellar cavity. Male medusae appear to be released into the water column by their corallae a few hours before female medusae are released. Gametes are released by both medusa types, and fertilization occurs externally.

In free-living hydromedusae, germinal cells arise from interstitial epidermal cells that migrate to specific sites on the bell surface, where they consolidate into a temporary gonadal mass. Subsequently, gametogenic tissue appears on the surface of the manubrium, beneath the radial canals, or on the general subumbrellar surface. Hydromedusae are typically gonochoristic, with either sperm or eggs usually being released directly into the water, where fertilization occurs. In some, only sperm are released and fertilization occurs on or in the female medusa's body. Free hydromedusae are especially common in temperate waters, where they may be very abundant seasonally and easily collected in plankton nets. Siphonophores appear to be ancestrally gonochoristic, but hermaphroditic forms exist among the Physonectae and exclusively among the Calycophorae (Codonophora). Planktonic dispersal of sexual forms would seem to mitigate against genetic differentiation of coastal populations, but considerable genetic population structure has been demonstrated among morphologically similar populations of *Obelia geniculata*, with estimated divergence times among reciprocally monophyletic lineages exceeding several million years.

One of the most famous of the hydromedusae is *Turritopsis dohrnii*, known as the "immortal jellyfish," which lives most of its life as a small hydromedusa found worldwide in cooler waters. It has the ability (as do a few other cnidarian species) to revert from a solitary, sexually mature adult medusa to a sexually immature, clonal polypoid stage on the seafloor. The clonal stage resembles that of the postplanula colony that originally gave rise to the medusa. The transformation is apparently triggered by environmental stress, predation, or "old age," and it is accomplished by a cell developmental process called transdifferentiation. Theoretically, the process can go on indefinitely, rendering the organism immortal.

Hydrozoans display remarkable variety in their embryonic and early postembryonic development. In most cases, cleavage is total and subequal, with a unilateral cleavage furrow during early cell divisions, leading to a coeloblastula or morula; gastrulation occurs in practically all known patterns except invagination (e.g., unipolar and multipolar migration, syncytial delamination, epiboly, etc.), typically resulting in a stereogastrula. However, the overall motif is fundamentally radial and holoblastic. The interior cell mass is endoderm; the

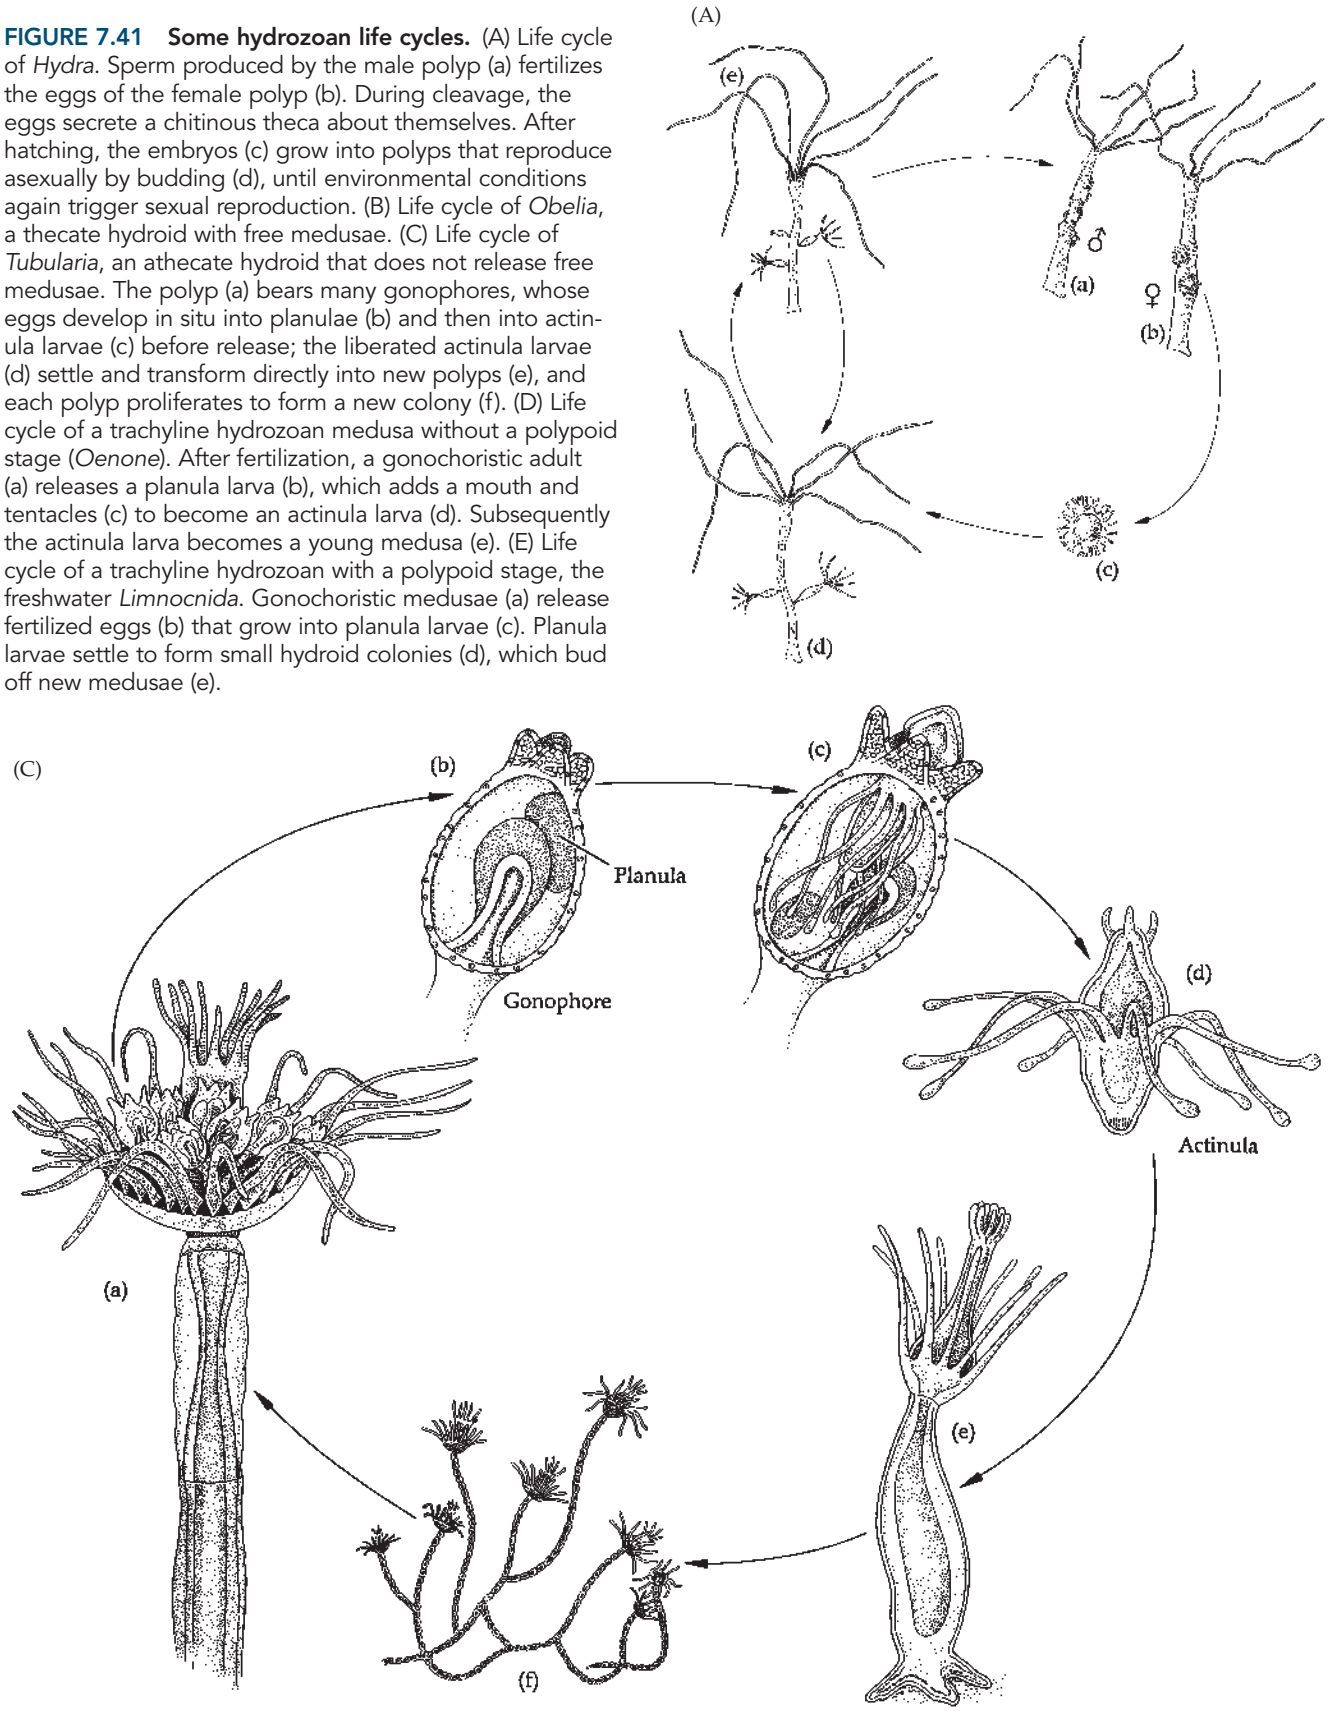

FIGURE 7.41 Some hydrozoan life cycles. (A) Life cycle of *Hydra*. Sperm produced by the male polyp (a) fertilizes the eggs of the female polyp (b). During cleavage, the eggs secrete a chitinous theca about themselves. After hatching, the embryos (c) grow into polyps that reproduce asexually by budding (d), until environmental conditions again trigger sexual reproduction. (B) Life cycle of *Obelia*, a thecate hydroid with free medusae. (C) Life cycle of *Tubularia*, an athecate hydroid that does not release free medusae. The polyp (a) bears many gonophores, whose eggs develop in situ into planulae (b) and then into actinula larvae (c) before release; the liberated actinula larvae (d) settle and transform directly into new polyps (e), and each polyp proliferates to form a new colony (f). (D) Life cycle of a trachyline hydrozoan medusa without a polypoid stage (*Oenone*). After fertilization, a gonochoristic adult (a) releases a planula larva (b), which adds a mouth and tentacles (c) to become an actinula larva (d). Subsequently the actinula larva becomes a young medusa (e). (E) Life cycle of a trachyline hydrozoan with a polypoid stage, the freshwater *Limnocnida*. Gonochoristic medusae (a) release fertilized eggs (b) that grow into planula larvae (c). Planula larvae settle to form small hydroid colonies (d), which bud off new medusae (e).

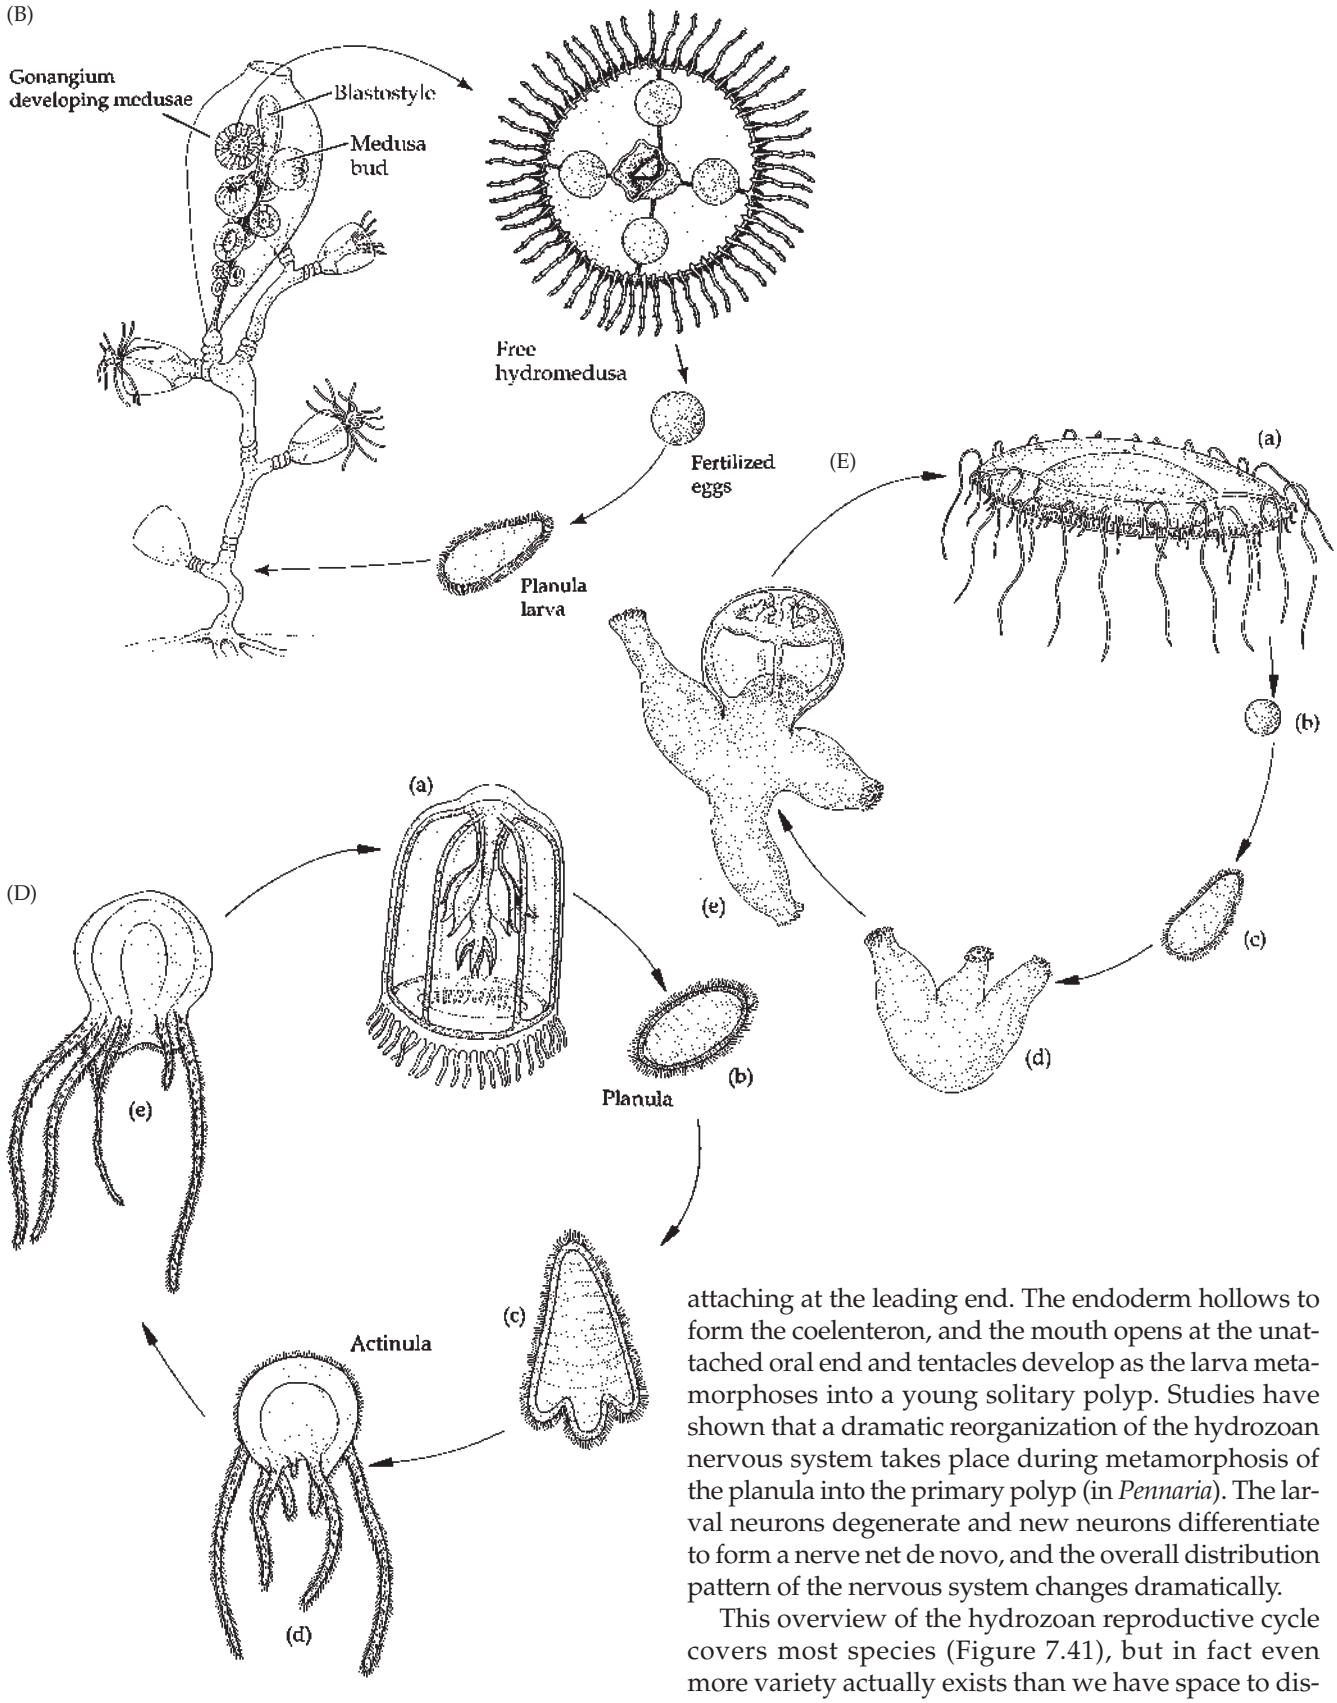
exterior cell layer is ectoderm (Figure 7.42). The stereogastrula elongates to form a unique, solid or hollow, nonfeeding, usually free-swimming **planula larva** (Figure 7.43). The planula larva is radially symmetrical, but it swims with a distinct "anterior–posterior" orientation. The ectodermal cells are monociliated and destined to become the adult epidermis; the endoderm is destined to become the adult gastrodermis. The trailing end of



the larva (of all cnidarians) becomes the oral end of the adult, and even in the larval stage a mouth sometimes develops at this end. Hydrozoan planulae swim about for a few hours to a few weeks before settling by attaching at the leading end. The endoderm hollows to form the coelenteron, and the mouth opens at the unattached oral end and tentacles develop as the larva metamorphoses into a young solitary polyp. Studies have shown that a dramatic reorganization of the hydrozoan nervous system takes place during metamorphosis of the planula into the primary polyp (in *Pennaria*). The larval neurons degenerate and new neurons differentiate to form a nerve net de novo, and the overall distribution pattern of the nervous system changes dramatically.

This overview of the hydrozoan reproductive cycle covers most species (Figure 7.41), but in fact even more variety actually exists than we have space to discuss. For example, in some trachylines, the polypoid stage is apparently lost altogether. The medusae produce planula larvae that develop into actinula larvae, which metamorphose into adult medusae, bypassing any sessile polypoid phase. Some trachylines and some

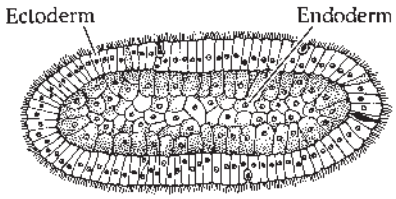


FIGURE 7.42 **A typical solid hydrozoan planula larva resulting from ingression.**

siphonophores undergo direct development, bypassing the larval stage altogether. Within the Trachylina, members of the family Rhopalonematidae (a trachymedusae formerly classified in Actinulida) exhibit minute interstitial polyps that lack a medusoid stage (or possibly these forms represent creeping medusae) and have suppressed the larval phase. The adult polyp is ciliated and resembles an actinula larva (hence the prior placement within Actinulida).

Myxozoan reproduction Myxozoan cnidarians have such aberrant life cycles that it is difficult to identify either polypoid or medusa stages within them. No planula stage is known to exist. Such marked differences from other cnidarian taxa have contributed to the uncertain status of myxozoans within the phylum to date, although recent phylogenomic work suggests they may be the sister group of Medusozoa. Nevertheless, an alternation of sexual and asexual generations within vertebrate and annelid hosts does occur, albeit as parasitic forms as described above. Asexual reproduction occurs within the vertebrate host, producing infective myxospores as already described (Figure 7.29). Sexual reproduction occurs within annelids and other coelomate worms, generating infective actinospores. The separation of the sexual and asexual stages of the life cycle of these parasites is similar to that which occurs in other parasitic species and could suggest that some developmental genetic homologies exist between the asexual and sexual stages of myxozoans and the polyp and medusa stages of other cnidarians. However, the reproductive modes of most myxozoans remain poorly known. Recent genomic studies have revealed myxozoan genomes to be among the smallest across all Metazoa, with only about 5,500 genes and lacking key factors for signaling pathways typically needed for multicellular development.

Cnidarian Evolutionary History

Earliest Cnidaria

Cnidarians have one of the longest fossil histories among the Metazoa. They are well represented from the early Cambrian onward, and the major lineages of the phylum had already diversified by the Fortunian Age. A possible sea pen, a hydroid, and two sea anemones have been described from the Fortunian Chengjiang biota in China. But the first apparent cnidarian fossils date from the Precambrian Ediacaran Period, from the famous Ediacara Hills of South Australia, which contain possible medusae and polypoid colonies (e.g., sea pen–like creatures) that lived nearly 600 million years ago. However, these early circular and frond-like impressions cannot be unequivocally assigned to any modern Cnidarian taxa. Some researchers doubt that they represent true cnidarians, even though some of the circular forms have marginal tentacles such as those seen in most medusae. Other possible Neoproterozoic polypoids include impressions that may be the floats of the pelagic "chondrophorans" and fossils with triradiate symmetry (e.g., *Tribrachidium*), as well as pentaradiate and octoradiate symmetry, thus differing fundamentally from any living cnidarians. Some workers consider these fossils to be parts of other organisms, such as isolated holdfast structures; others have placed them in an extinct class of Cnidaria, the Trilobozoa. Still others view them as primitive triradiate echinoderms.

In the 1980s, the German paleontologist Adolf Seilacher, frustrated by attempts to assign these Neoproterozoic Era fossils to modern phyla, created an entirely new phylum, the Vendobionta (or Vendozoa), suggesting that it might be a sister group to the Eumetazoa (metazoans above the poriferan grade). The Vendozoa, Seilacher noted, seemed to have a quiltlike construction of thin, lightly sclerotized but flexible, outer skin separated into compartments by more rigid internal struts (which in fossil impressions appear to be sutures). Later workers placed these fossils in an extinct cnidarian order, the Rangeomorpha, and called other, more bilaterally symmetrical forms Erinettomorpha. One of the most famous of these latter forms is the oval-shaped *Dickinsonia*, which may

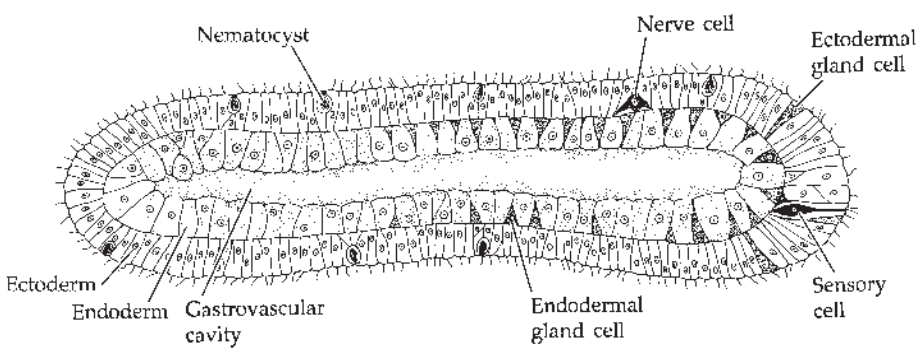

FIGURE 7.43 **The hollow planula larva of the hydroid *Gonothyraea* (longitudinal section).**

for more ebook/ testbank/ solution manuals requests email 9601267345@qq.com

have measured over a meter in length but been only a few millimeters in thickness. Some workers consider *Dickinsonia* to be medusa-like, but it has also been assigned to the Platyhelminthes, to the Annelida (due to hints of possible body segmentation), to an extinct phylum (Proarticulata), to Placozoa, and to an entirely new kingdom! Today, *Dickinsonia* is identified as being a mobile organism, but like many Ediacaran macrofossils it lacks any structures that can be convincingly interpreted as a mouth or gut, and thus it cannot be placed in any existing phylum. The presence of cholesteroids as the dominant lipids in *Dickinsonia* and allied taxa supports an affinity of these organisms with Filozoa, the clade that unites metazoans with Filasterea and Choanoflagellatea.

Attempts to place the Ediacaran fossils within the Cnidaria (or other extant phyla) met with limited success until 2014. For example, differences in apparent growth patterns and frond structure between extant cnidarians (e.g., pennatulaceans) and frond-like Ediacaran species had argued against a direct cnidarian relationship. Then, in 2014, a 560-million-year-old (Ediacaran) cnidarian-like fossil (named *Haootia quadriformis*) was reported from Newfoundland, with quadraradial symmetry and clearly preserved bundled muscular fibers. *Haootia* appears to be a nearly 6 cm long polyp, or perhaps an attached medusa. Another strong candidate for Ediacaran ancestry is *Corumbella werneri*, recovered from both South American and U.S. sites, which bears strong resemblance to coronate Scyphozoa. Remarkable embryos of probable scyphozoan affinity have also been reported form the lower Cambrian of China. Exceptionally well-preserved jellyfish fossils (including phosphatized fossil embryos) are known from early Cambrian (~535 Ma) Chengjiang and Kuanchuanpu formations in China and the middle Cambrian (~505 Ma) of Utah. Early trace fossils have also been assigned to the phylum Cnidaria. Burrows assigned to sea anemones occur in the early Cambrian, and some strata have meandering tracks that appear to be traces left from mucous trails of creeping anemones (some modern anemones move in this fashion, using ciliary activity).

Cnidarian Phylogeny

Like Porifera, cnidarian body plans appear to have remained essentially unchanged since the Cambrian, and molecular phylogenetic analyses clearly position Cnidaria below the origin of bilaterality and possibly as the sister group to Bilateria. In Chapter 4 we reviewed the important embryological differences between the coelomate metazoan clades known as the protostomes and deuterostomes. To the extent that these traits occur in noncoelomate Metazoa, it is of phylogenetic importance to note them. For example, radial cleavage is characteristic of the deuterostomes (but also occurs in a few protostomes), but it probably arose very early in metazoan evolution; it occurs in cnidarians and, in a slightly different form, in most sponges. Thus it appears to be the plesiomorphic type of cleavage among animals. Spiral cleavage, on the other hand, defines an entire clade of protostomes (the Spiralia), suggesting it is a more derived cleavage pattern in Metazoa.

The phylogeny of Cnidaria has been argued for decades, nearly all possible relationships among the major lineages have been hypothesized, and there has been a long debate about whether the polyp or the medusa came first. Anatomical evidence has been equivocal on the question of which living class of Cnidaria resembles the most ancestral members of the phylum. Some workers have favored a view that the first cnidarian was a medusa, based largely on the conjecture that the sexual stage must have appeared first (the **medusoid hypothesis**), suggesting that the medusoid stage was lost in the class Anthozoa. Other workers have favored the view that the polypoid form is primitive within Cnidaria, because polyps occur in all classes of the phylum (except the parasitic Myxozoa) and thus must be part of the primitive cnidarian body plan (the **polypoid hypothesis**).

Phylogenetic studies inform us that the phylum comprises three major living clades: Anthozoa, Endocnidozoa, and Medusozoa. Phylogenomic analyses strongly support a basal split in Cnidaria into two clades, Anthozoa and Medusozoa (Myxozoa aside), which does not provide strong support for either the polypoid or the medusoid hypothesis (i.e., the ancestral cnidarian could have been an anthozoan-like polyp, or it could have had a medusa stage that was lost in the Anthozoa line) (Figure 7.44). Microbial symbioses appear to have evolved multiple times independently among the Cnidaria (e.g., in hexacorals, octocorals, scyphozoans, and hydrozoans). The origin of a medusa stage probably occurred only once. The polyp stage was lost in the lineages leading to Endocnidozoa and within Trachylina. In addition, we now know that, among cnidarians, only the anthozoans possess circular mitochondrial DNA, a trait they share with most other Metazoa (including the Placozoa). Members of the Medusozoa clade all have linear mtDNA and the unique cnidocil, both viewed as derived traits within cnidarians. Over half of the described species of Cnidaria belong to the polyp-only clade Anthozoa (e.g., sea anemones, corals, sea fans, and sea pens). Medusozoa consists of four clades: Scyphozoa, Cubozoa, Hydrozoa, and Staurozoa. Endocnidozoa is an entirely parasitic clade that includes about 2,200 species of Myxozoa and a single known species of Polypodiozoa—minute endoparasites of invertebrates and vertebrates with complex life cycles.

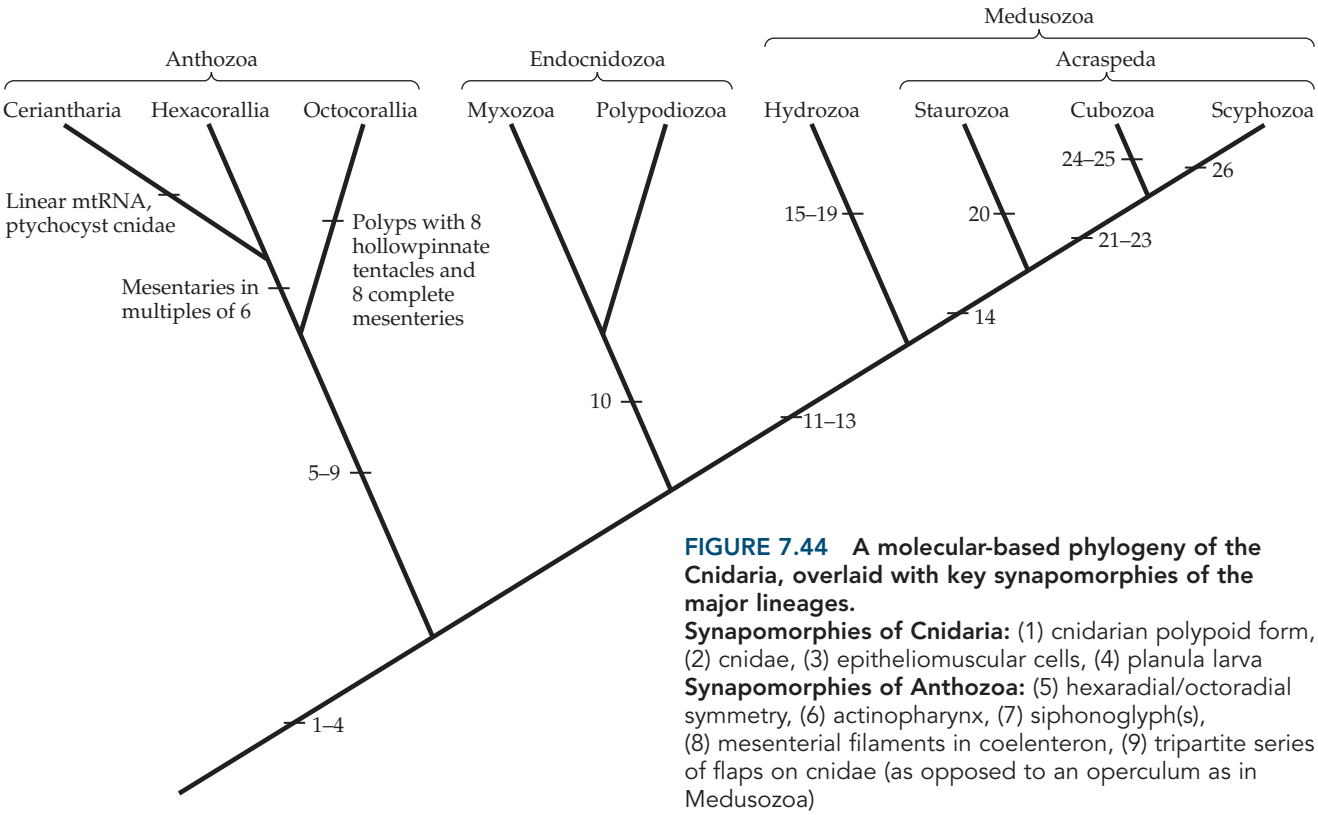

FIGURE 7.44 A molecular-based phylogeny of the Cnidaria, overlaid with key synapomorphies of the major lineages.
Synapomorphies of Cnidaria: (1) cnidarian polypoid form, (2) cnidae, (3) epitheliomuscular cells, (4) planula larva
Synapomorphies of Anthozoa: (5) hexaradial/octoradial symmetry, (6) actinopharynx, (7) siphonoglyph(s), (8) mesenterial filaments in coelenteron, (9) tripartite series of flaps on cnidae (as opposed to an operculum as in Medusozoa)
Synapomorphies of Endocnidozoa: (10) obligatory endoparasitism and complex life cycle
Synapomorphies of Medusozoa: (11) with medusae and alternation of generations, (12) linear mtDNA (also seen in ceriantharian Anthozoa), (13) operculate cnidae (with cnidocil)
Synapomorphies of Acraspeda: (14) medusae acraspedote (without a velum)
Synapomorphies of Hydrozoa: (15) relocation of gamete-forming tissue to epidermis, (16) absence of gut mesenteries, (17) simplification of middle layer to an acellular mesoglea, (18) craspedote medusae, (19) loss of gastrodermal nematocysts
Synapomorphies of Staurozoa: (20) evolution of unique life cycle, with stauropolyps and sessile stauromedusae
Synapomorphies of Cubozoa-Scyphozoa: (21) reduction or loss of polyp, (22) rhopalia, (23) lensed rhopaliar eyes
Synapomorphies of Cubozoa: (24) boxlike medusa form, (25) velarium
Synapomorphies of Scyphozoa: (26) strobilation

Phylogeny within each of the cnidarian classes is equally interesting but largely beyond the scope of this text. However, a few generalizations can be made about some important events. Coloniality has been a common and important evolutionary theme within Cnidaria. Coloniality in the hydrozoans may have arisen by retention of young polyps during asexual reproduction, and this development ultimately led to the highly specialized colonial groups such as the Siphonophora, Milleporidae, and Stylasteridae. In the class Scyphozoa, evolution favored increasing specialization of the pelagic medusoid form and diminishing importance of the polypoid stage in the life cycle. Scyphomedusae and cubomedusae have evolved large size, special musculature, a cellular or fibrous mesenchyme, a complex gastrovascular system, and a fairly sophisticated sensory system.

Anthozoans are characterized by several unique synapomorphies: hexaradial or octoradial symmetry (transformed into biradial symmetry in most); the actinopharynx, siphonoglyphs, and unique mesenterial filaments in the coelenteron; absence of a cnidal operculum and cnidocil; tripartite flaps on the cnidae; and special ciliary cones associated with the cnidocytes. Anthozoans also possess a more complex gastrovascular and nervous system than seen among the Medusozoa, as well as a greater degree of cellularity of the mesenchyme. Although the position of Ceriantharia is not yet fully resolved, most data support a sister-group relationship with Hexacorallia.

Among members of the class Anthozoa, evolution has produced a grand series of experiments in colonial polypoid living, resulting in such "superorganisms" as stony corals, octocorals, pennatulaceans, and zoantharians. Within the Hexacorallia, stony corals (scleractinians) first appear in the fossil record at the base of the Late Triassic Epoch, about 237 million years ago, although the first scleractinians were not reef builders. Scleractinian origins (and radiations) are still not well understood. Suggested extinct ancestors of Scleractinia include three Paleozoic coral groups: the Rugosa, the

for more ebook/ testbank/ solution manuals requests: email C9601267345@qq.com

Heterocorallia, and the Tabulata. The Rugosa (sometimes called horn corals) and Heterocorallia had their polyps divided by septa into four cycles (rather than six as in Scleractinia), and the septa arose in a pinnate fashion (rather than cyclically as in Scleractinia). Tabulate corals were nonseptate. The connection between rugose corals, which formed calcite skeletons, and modern scleractinians, whose skeletons are aragonitic, is tightened by the discovery of Cretaceous scleractinians with calcite skeletons. Rugose corals, which ranged in size from a centimeter or so to over a meter in length, lived from the Ordovician Period to the late Permian and were solitary or colonial.

Within the Scleractinia, molecular evidence appears to confirm the existence of two clades, "robust" species with solid, heavily calcified skeletons forming massive or platelike structures, and "complex" species with lighter, more porous and more complex skeleton structures. Within these clades, only the Poritiina and Dendrophylliina appear to be monophyletic, suggesting that relationships based on morphology alone are likely to be misleading in this group. Possibly contributing to this diversity, recent evidence suggests that coloniality and symbiosis with zooxanthellae have been repeatedly acquired and lost throughout the history of stony corals, a tendency that may have allowed scleractinians to diversify within reef and nonreef communities, as well as recover from repeated local extinctions over evolutionary time. An increase in polyp size within the Anthozoa seems to have occurred over time, along with the evolution of complex structural components of the mesenchyme and increasingly efficient musculature. Anthozoans, of course, have greatly exploited a commensal relationship with zooxanthellae—more so than members of the other classes. Convergent evolution has occurred frequently throughout the Cnidaria, as witnessed by such features as colonies, calcareous skeletons, the velum-velarium structures, and various means of suppressing the medusoid or polypoid stage in the life cycle.

Chapter Summary

Cnidaria is a clade of diploblastic metazoans that arose in the Precambrian, before bilaterality had been achieved in the Animal Kingdom. They are notable for their possession of cnidae, radial symmetry, a gastrovascular cavity with a single opening, unique myoepithelial cells, planula larvae, and a life cycle that may be dimorphic and include both polyp and medusoid stages. Cnidae are housed in a cnidocyte cell and have a variety of functions, including prey capture, defense, locomotion, and attachment. Most cnidarians are marine, free-living forms but some freshwater species and parasites (notably the endoparasitic Polypodiozoa and Myxozoa) are also known. Colonialism and symbiotic relationships with dinoflagellates are common among the free-living species and have evolved multiple times independently. The phylum comprises three major lineages: Anthozoa, a polypoid lineage lacking medusae; Medusozoa, a diverse clade including species exhibiting primarily motile medusoid forms as well as forms with both medusoid and polypoid life stages; and Endocnidozoa, a clade of highly simplified obligate endoparasites. Polypoid forms, especially colonial species, have an impressive array of flexible (chitin–based) and hard ($CaCO_3$–based) skeletons. Corals and other cnidarians hosting symbionts, when stressed (e.g., warming ocean waters), may loose their symbiotic dinoflagellates (zooxanthellae) through a process known as "coral bleaching." With over 13,300 described living species and an old fossil record dating at least to the Cambrian, Cnidaria is a highly successful phylum.

CHAPTER 8

A Brief Introduction to the Bilateria and Its Major Clades

Courtesy of G. Rouse

While the relationships of the nonbilaterians still remain stubbornly unresolved, the monophyly of Bilateria is strongly supported. However, our understanding of the relationships among the phyla *within* Bilateria has changed considerably since the emergence of molecular phylogenetics in the 1990s. Our current view of bilaterian relationships is shown in Figure 8.1 (and in more detail in subsequent chapters). In this short chapter, we will walk you through the bilaterian tree, step-by-step, before sending you off to the following chapters where you will dive into the individual subclades and phyla. There may be some taxonomic names here that are new to you and also some names whose meanings have changed in recent years. Several long-standing groups, such as Protostomia and Deuterostomia, have changed in their phylum memberships, and a number of new higher-level clades have emerged.

The Bilateria

The Bilateria (or Triploblastica) is a clade of animals whose adult tissues are derived from three embryonic germ layers—endoderm, mesoderm, and ectoderm—and whose body axis is anteroposterior. This type of axial patterning makes individuals divisible into two symmetrical halves, left and right, a pattern known as bilateral symmetry. In addition, the presence of bilaterality and an anterior–posterior axis has led to regional specialization, perhaps most importantly the concentration of nerves and sensory structures in the anterior area—a process known as cephalization (i.e., the formation of a head end). The concept of Bilateria was codified (and the name created) by Hatschek in 1888, and the clade is supported by all modern phylogenetic analyses. Developmentally, Bilateria is also supported by the presence of the three classes of Hox genes: anterior, central, and posterior; in contrast, only anterior and posterior ones are found in nonbilaterians. Further, the presence of mesoderm in bilaterians has led to the development of numerous derivative tissues, such as mesodermal muscles, blood, and various organs. Mesoderm is also associated with the formation of a true body cavity in most bilaterians, or coelom (also called a secondary body cavity, as opposed to the primary embryonic body cavity, or blastocoelom). A true coelomic cavity can be recognized as mesodermal by the fact that its lining is a true epithelium, with polarized cells interconnected by apical adherens junctions.

The recently recognized phylum Xenacoelomorpha (Chapter 9) is seen as the sister group to all the remaining living bilaterian phyla, which form a clade called Nephrozoa (the name recognizes that these are mostly "kidney-bearing" animals, although all these "kidneys" may not be homologous). The clade Nephrozoa is sometimes also called "Eubilateria." Most animals are nephrozoans—26 of the 31

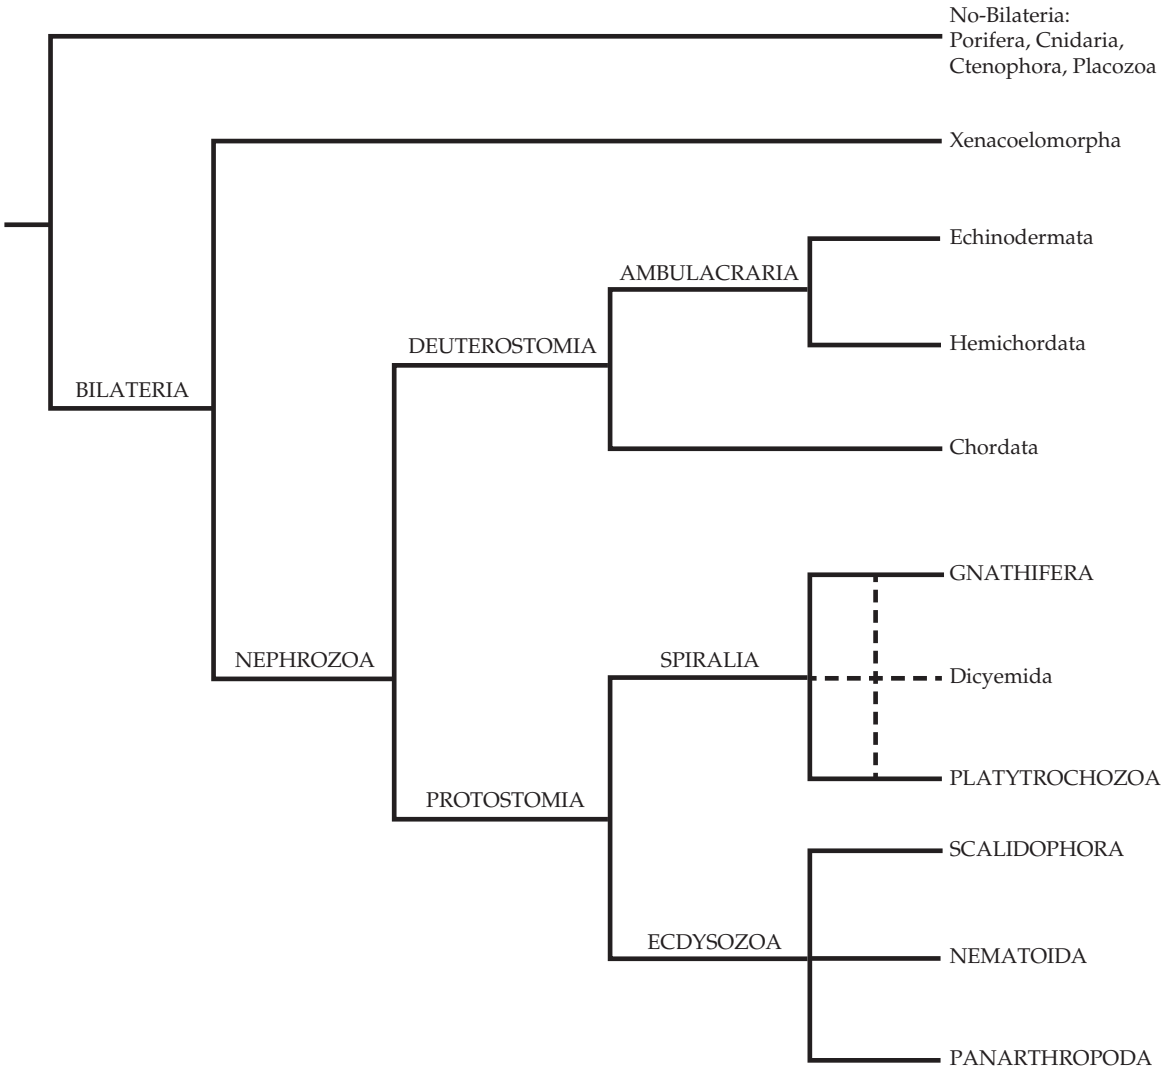

FIGURE 8.1 A phylogenetic tree of the Bilateria showing major clades. Most of the bilaterian clades (indicated in all capital letters) are also defined by morphological apomorphies. Apomorphies of Bilateria include bilateral symmetry, cephalization, three germ layers, and the presence of mesodermally derived organs. Apomorphies of Nephrozoa include the presence of a through gut (complete gut, with an anus), complex organ structures, and the *Hox3* gene. Probable apomorphies of Deuterostomia are pharyngeal gill slits and possibly enterocoelic development and a trimeric condition of coelomic cavities. Probable apomorphies of Protostomia are a circumesophageal brain and ventral nerve cords. An important apomorphy of Ecdysozoa is molting of the cuticle during the life cycle. Other possible apomorphies of Ecdysozoa are a trilayered cuticle, formation of the epicuticle from the tips of epidermal microvilli, lack of locomotory cilia, and a terminal position of the mouth. Spiral cleavage is a likely apomorphy for the Spiralia, although it was apparently secondarily lost in some groups (e.g., Lophophorata). Ambulacraria share a unique excretory heart-kidney system and the probably homologous tornaria/dipleurula larvae.

The clade Gnathifera includes the phyla Chaetognatha, Gnathostomulida, Micrognathozoa, and Rotifera. The clade Platytrochozoa includes the phyla Cycliophora, Entoprocta, Nemertea, Mollusca, Annelida, Phoronida, Bryozoa, and Brachiopoda (the last three comprising the Lophophorata). The clade Nematoida includes the phyla Nematoda and Nematomorpha. The clade Scalidophora includes the phyla Kinorhyncha, Priapula, and Loricifera. The clade Panarthropoda includes the phyla Tardigrada, Onychophora, and Arthropoda.

living phyla. Simply put, the Nephrozoa are bilaterians that evolved large body sizes and the need to develop complex organs for circulation, gas exchange, osmoregulation, excretion, muscular movement, structural support, etc. A through gut (a complete gut, with an anus) is an apomorphy of the Nephrozoa (with a reduction in several clades, most notably Platyhelminthes). Although most have protonephridia or some kind of metanephridium, many small-bodied nephrozoans (e.g., Chaetognatha, Bryozoa) may still rely on diffusion across the body wall. In addition to the three main classes of Hox genes found in all bilaterians (anterior, central, posterior), which have increased in complexity in Nephrozoa; the nephrozoans have also acquired a unique family of *Hox3* genes (not present in Xenacoelomorpha).

Deuterostomes and Protostomes

Within the Nephrozoa are the two great clades Deuterostomia and Protostomia (Figure 8.1). These are legacy

for more ebook/ testbank/ solution manual requests: email 9601267340@qq.com

names that have been around since the nineteenth century, and they are names zoologists are very familiar with. The names were originally based on what was known at the time about early embryonic development, especially the fate of the blastopore. Deuterostomia were those animals in which the blastopore became the adult anus, the mouth thus forming de novo, secondarily, from the bottom of the archenteron. Hence the name: *deutero* = "second," *stoma* = "mouth." In Protostomia (*proto* = "first"), on the other hand, the blastopore gave rise to the mouth, and the anus formed elsewhere. However, we now know that some Protostomia have deuterostomous development (e.g., nematomorphs and priapulans, some brachiopods), and in some Deuterostomia the anus does not originate from the blastopore. In fact, it seems that the blastopore, the mouth, and the anus have a degree of developmental independence. Egg development with radial cleavage was also sometimes used to define the Deuterostomia, but that type of cleavage also occurs in a number of nondeuterostome phyla, so it cannot be an apomorphy of deuterostomes. Enterocoelic coelom formation (see Chapter 4) was also once thought to define the Deuterostomia, with schizocoelic coelom formation being typical of Protostomia; but we now know that schizocoely occurs in some deuterostomes. Thus, as more and more animals are studied, modern phylogenetic research has revealed that these developmental patterns are more varied than originally thought and show inconsistencies with phylogenetic patterns. And further, the new tree of life reveals that three phyla once classified in Deuterostomia are actually nested within the Protostomia. These are the three lophophorate phyla: Phoronida, Bryozoa, and Brachiopoda (the clade Lophophorata; see Chapter 16).

Thus, Deuterostomia includes only 3 phyla: Chordata, Hemichordata, and Echinodermata. When these are compared with the 23 phyla in Protostomia, deuterostomes may seem like an early, spurious, evolutionary experiment, or perhaps even appear to be a "dead-end" lineage, probably originating in the Precambrian. However, 2 of the 3 deuterostome phyla have been hugely successful. With 7,300 living species, Echinodermata is one of the most important animal groups in the sea, and of course the Chordata (with 63,000 species) includes the large land animals—the vertebrates (and, therefore, us).

What morphological characters define the Deuterostomia? There is a strong indication that the ancestral deuterostome had pharyngeal gill slits. These are present in hemichordates and chordates, and in some extinct stem-group echinoderms. Another likely apomorphy is a widely conserved deuterostome-specific cluster of six ordered genes, including four transcription factors expressed during the development of pharyngeal gill slits and the branchial apparatus. Another possible apomorphy of Deuterostomia is enterocoelic development and a trimeric condition of coelomic cavities, at least in the first deuterostomes, although this feature is lacking in the phylum Chordata. It could have been lost in the evolution of chordates (and thus it would be an "underlying apomorphy"), or alternatively it could be a feature only of Ambulacraria—the clade uniting Echinodermata and Hemichordata. The deuterostomes are introduced in Chapter 25 and covered in Chapters 25, 26, and 27.

Protostomia is a monophyletic lineage containing the two large clades, Spiralia and Ecdysozoa. Protostomia is introduced in Chapter 10. Although strongly supported by molecular phylogenetics, Protostomia is tricky to define by any morphological synapomorphies. A ventral nerve cord is probably a good apomorphy, although it is not distinct in the soft-bodied, flattened, platyhelminth and nemertean worms. And in some cigar-shaped animals (e.g., Priapula), "ventral" is defined by the position of the nerve cord, and thus it becomes a circular argument. Similarly, protostomes tend to have a circumesophageal brain (leading to the ventral nerve cords), but deviations from this occur. Protostomes constitute 95% of Earth's known species diversity, and they include 15 phyla in the clade Spiralia and 8 in the clade Ecdysozoa.

Spiralia includes all those bilaterians with spiral cleavage—a highly stereotyped egg cleavage pattern described in detail in Chapter 4. However, Spiralia also includes some phyla without spiral cleavage (e.g., the Lophophorata), suggesting this embryonic patterning has been lost in some cases through evolutionary reversal. Robust morphological apomorphies for Spiralia are not yet known, and the hunt for them is one of the more exciting things going on in biology today. Our tree shows the odd parasitic phylum Dicyemida having three possible origins, because the phylogenetic position of these animals in molecular analyses is still unstable (see Chapter 10). The two relatively well-supported clades Gnathifera (4 phyla) and Platytrochozoa (10 phyla) are discussed in Chapters 11 and 12.

Ecdysozoa is composed of animals that molt their cuticles during their life cycle as a solution for growth. The clade is strongly supported by both molecular and morphological analyses. In addition to ecdysone-based molting, other apomorphies for Ecdysozoa have been proposed, such as a trilayered cuticle, formation of the epicuticle from the tips of epidermal microvilli, lack of locomotory cilia, and a terminal position of the mouth. There are some deviations in these characters among the Ecdysozoa, but they may still prove to be good apomorphies of the first ecdysozoans. A terminal mouth is prevalent in Cambrian fossils assigned to stem-group ecdysozoans, including arthropods and onychophorans, and it is present in scalidophorans and some tardigrades. Segmentation is found in 4 of the 8 ecdysozoan phyla, but it is still uncertain how many times it might have evolved. Relationships within this clade remain in flux, and our tree shows an unresolved trichotomy of three subclades that are largely defined by morphological, not molecular, characters.

CHAPTER 9

Phylum Xenacoelomorpha

Basal Bilaterians

As you read in Chapter 8, the invention of a third (middle) germ layer, the true mesoderm, and evolution of a bilateral body plan opened up vast new avenues for evolutionary expansion among animals. The appearance of this inner body layer led to greater specialization in tissue formation, including highly specialized organ systems and condensed nervous systems (e.g., central nervous systems). In addition to derivatives of ectoderm (skin and nervous system) and endoderm (gut and its derivatives), triploblastic animals have mesodermal derivatives—which include musculature, circulatory systems, excretory systems, and the somatic portions of the gonads. Bilateral symmetry gives these animals two axes of polarity (anteroposterior and dorsoventral) along a single plane that divides the body into two symmetrically opposed parts—the left and right sides. The evolution of bilaterality also resulted in cephalization: the concentration of sensory and feeding structures at the anterior end, thus forming a "head." And, except in Xenacoelomorpha, bilaterians further evolved a complete gut (or through gut), with a mouth and an anus, and excretory organs in the form of protonephridia and metanephridia (i.e., the clade Nephrozoa). The origin of the Bilateria was probably in the Ediacaran, around 630–600 million years ago, although some dated phylogenies have estimated the origin was even earlier.

** Molecular phylogenetic support for a monophyletic Scalidophora is ambivalent
*** Paraphyletic (excludes Hexapoda)

The Basal Bilaterian

Phylogenetic research strongly suggests that the Xenacoelomorpha split early from the remaining bilaterian lineage. All members of this phylum share a number of characteristics, including a soft flattened body, mesodermally derived musculature, absence of a coelom or excretory or circulatory systems, a completely ciliated epidermis, and

BOX 9A Characteristics of the Phylum Xenacoelomorpha

1. Soft-bodied, dorsoventrally flattened, acoelomate; almost exclusively marine worms
2. Epidermis with unique pulsatile bodies, found in no other metazoan phylum
3. Cilia of epidermis with distinctive arrangement of microfilaments: the standard 9+2 arrangement extending for most of the shaft but microfilament doublets 4–6 failing to reach the end of the cilium (the "xenacoelomorph cilia")
4. Mouth, when present, ventral; with an incomplete gut (i.e., lacking an anus)
5. Largely lacking discrete organs (e.g., no discrete circulatory system, protonephridia or nephridia, or organized gonads)
6. Cerebral ganglion with a small neuropil; with anterior statocyst and a diffuse intraepithelial nervous system
7. With a frontal organ (Acoelomorpha) or frontal pore (Xenoturbellida), possibly homologous
8. With circular and longitudinal muscles
9. Hox and ParaHox genes present (but fewer in number than in other metazoans)
10. With direct development (no larval forms)

direct development (no larval stage). These features resemble a hypothetical creature known as the **Urbilateria**, the putative first bilaterian or triploblastic animal with anterior–posterior and dorsal–ventral axes. These soft-bodied worms also have a centralized nervous system, with multiple parallel longitudinal nerve cords, although the "brain" is little developed and the main sensory structure appears to be a statocyst. Importantly, research suggests that their mouth—the single gut opening—does not derive from the blastopore (i.e., they are deuterostomous in their development). Thus, the origin of the Bilateria may have been accompanied by an embryological shift in the origin of the mouth from the blastopore (as seen in Cnidaria and Ctenophora) to elsewhere.

Phylum Xenacoelomorpha

The phylum Xenacoelomorpha (Box 9A) comprises three clades of acoelomate worms (Acoela, Nemertodermatida, and Xenoturbellida) that are sometimes recognized as two or three separate phyla. Evidence from both molecular and morphological data suggests that Acoela and Nemertodermatida are sister groups (the Acoelomorpha), and these are a sister group to Xenoturbellida; thus we include them here in a single phylum (see Figure 9.26). In addition to molecular support, xenacoelomorphs also have a suite of unique features that define them among the Bilateria: they lack a through gut (also seen in the phylum Platyhelminthes, but presumably secondarily derived), have unique pulsatile bodies, have ciliated epidermal cells with a distinctive arrangement of microfilaments, and possess a frontal organ (Acoelomorpha) or frontal pore (Xenoturbellida). Xenacoelomorpha currently contains about 400 species, 6 in the subphylum Xenoturbellida (all in the genus *Xenoturbella*) and the rest in the subphylum Acoelomorpha (mostly in the class Acoela). No fossils have been identified. All described species are small, flattened, unsegmented worms without an anus or discrete excretory organs. Almost all are microscopic, but a few reach several centimeters in length. All but a few are free-living; at least two species are endosymbionts in holothuroids. Almost all are marine, although two species of Acoela inhabit fresh waters.

The xenacoelomorph clades have had long taxonomic journeys. Initially Nemertodermatida and Acoela were viewed as the most primitive living Platyhelminthes, due to their simple anatomy. As ultrastructural work revealed increasing complexity, opinion shifted, and from the 1960s to the turn of the century these worms were widely regarded not as primitive, but as secondarily reduced platyhelminths. However, as multigene phylogenetic analyses began to explore these small worms, it became apparent that they were actually very early bilaterians, probably diverging even before the protostome-deuterostome split. All three groups also have unique epidermal bodies that represent degenerating ciliated cells that are resorbed into the body and called **pulsatile bodies** or "restitution cells." In Acoela, the cilia are retained in vacuoles prior to digestion, whereas in nemertodermatids the cilia appear to be lost before resorption begins. A type of pulsatile body also occurs in the xenoturbellids (which may or may not be homologous with those of Acoelomorpha). Pulsatile bodies are unknown from any other metazoan phylum. All Xenacoelomorpha lack discrete excretory systems, the presence of which unites all other Bilateria as the clade Nephrozoa, and their cerebral ganglion has a very small neuropil, although it can be considered a true brain. Furthermore, xenacoelomorphs share a unique pattern of neurotransmitter activity, body wall musculature, and mode of embryonic development.

A close relationship between the acoel and nemertodermatid worms is supported by their unique ciliary rootlet system, frontal organ, perhaps their cleavage pattern (i.e., the horizontal orientation of the second, asymmetric cleavage plane), and several other features. The musculature of acoels and nemertodermatids is also strikingly similar, yet different in some key aspects; acoels have a grid of orthogonal musculature with mainly ventral diagonal musculature and, in some species, a muscular pharynx. More derived acoels have more complex layers of diagonal muscles. Nemertodermatids

for more ebook/ testbank/ solution manuals requests: email 9601267344@qq.com

have an orthogonal grid and well-developed diagonal muscles throughout the body, and little evidence of a muscular pharynx.

Although *Xenoturbella bocki* was initially considered to be a free-living flatworm, its unusual anatomy quickly came to distinguish it from platyhelminths, as well as from the Acoelomorpha. Phylogenetic (and even some morphological) studies initially linked *Xenoturbella* to deuterostomes. Sequences of Hox genes in *X. bocki* also suggested it could be a basal deuterostome with a reduced Hox gene complement, and lack of typical deuterostome characteristics suggested that *Xenoturbella* might belong at the very base of the deuterostome tree. Some earlier phylogenetic analyses suggested that *Xenoturbella* might be closely tied to the clade known as Ambulacraria (Echinodermata and Hemichordata). However, no developmental evidence has been found of structures common to other Ambulacraria, such as gill slits, endostyle, and enterocoelic coelom formation.

By 2009, large-scale molecular phylogenetic studies had begun suggesting *Xenoturbella* is the sister group of Acoelomorpha, at the base of the Bilateria as the sister group to Nephrozoa. The anatomical data seemed to agree with this linking, and it was eventually suggested that together they warranted phylum status as Xenacoelomorpha. Acoels have only three Hox genes (one each of the anterior, central, and posterior groups). Nemertodermatids have only two (a central and a posterior group). *Xenoturbella* has one anterior, two (or three) central, and one posterior gene. Platyhelminths, on the other hand, as most nephrozoans, have a nearly complete Hox cluster. We discuss each of the three curious worm groups in the class Acoela, class Nemertodermatida, and subphylum Xenoturbellida sections below. There is no fossil record attributed to any xenacoelomorphs.

CLASSIFICATION OF PHYLUM XENACOELOMORPHA

Generally small, flattened or semicylindrical, acoelomate marine worms with anterior statocyst; diffuse intraepithelial nervous system, an intraepithelial or basiepidermal nerve net (sometimes condensed into basiepidermal neurite bundles with a condensed brain and submuscular cords); midventral mouth and incomplete gut (i.e., lacking an anus); unique pulsatile bodies (unknown from any other Bilateria). Largely lacking discrete organs (e.g., without a discrete excretory or circulatory system, or organized gonads). Cilia of epidermal cells with distinctive arrangement of microfilaments wherein the standard 9+2 arrangement extends for most of the ciliary shaft, but toward the end, microfilament doublets 4 through 7 end, leaving doublets 1–3 and 8–9, which continue to the end of the cilium. These **xenacoelomorph cilia** are not known in any other animal phylum (although similar cilia have been described from the pharynx of some enteropneust hemichordates). With both circular and longitudinal muscles. With direct development and no distinct larval forms. Two subphyla, Acoelomorpha and Xenoturbellida.

SUBPHYLUM ACOELOMORPHA With small cerebral ganglia with a neuropil, a unique pattern of neurotransmitter activity, and unique body wall musculature; with a distinctive mode of embryonic development. Acoelomorphs lack a well-developed basement membrane (basal lamina), but they do have small islands of extracellular material between the epidermal cells and underlying muscle that might be homologous with the basement membrane of other bilaterians. Hox and ParaHox genes are present in both classes, although these are not strictly similar.

CLASS ACOELA About 400 species. Gut a digestive syncytium, lacking a permanent digestive cavity or with a small transient gut lumen; with unique anterior statocyst containing one statolith; parenchyma may contain chordoid vacuoles; biflagellate sperm, each flagellum with axonemes incorporated into the sperm cell; endolecithal ova; without epithelial basal lamina. Small (1–5 mm) worms, common in marine sediments (a few in fresh water); some are planktonic or symbiotic. (e.g., *Amphiscolops, Antigonaria, Conaperta, Convoluta, Convolutriloba, Daku, Diopisthoporus, Eumecynostomum, Haplogonaria, Hofstenia, Isodiametra, Myopea, Oligochaerus* [with freshwater species], *Paratomella, Polychoerus, Praesagittifera, Proporus, Solenofilomorpha, Symsagittifera, Thalassoanaperus, Waminoa*)

CLASS NEMERTODERMATIDA About 20 species of interstitial or endosymbiotic marine worms possessing a ciliated, glandular epidermis and an anterior statocyst containing 1 to 4 statoliths; parenchyma without chordoid vacuoles; mouth may be present or absent; with small transient or permanent gut cavity; a proboscis with extensible filaments is present in some species; with true epithelium and gland cells; uniflagellate sperm; with endolecithal ova; with limited basal lamina beneath the epidermis. One genus (*Meara*) contains species that are symbionts in sea cucumbers. (e.g., *Ascoparia, Flagellophora, Meara, Nemertinoides, Nemertoderma, Sterreria*)

SUBPHYLUM XENOTURBELLIDA Six species, all in the genus *Xenoturbella*; fleshy pink worms, a few millimeters to over 20 cm in length. Xenoturbellids have a humplike structure in the anterior third of the body but lack other structural organs (other than a statocyst) and possess a diffuse nervous system. A thick basement membrane (the "subepidermal membrane complex") is present beneath the epidermis. An anterior frontal pore, which is continuous with a ventral glandular network, may be homologous with the frontal organ of acoelomorphs. These worms live in holes on sandy coastlines or deeper offshore muds and many appear to be specialized to eat bivalves.

Subphylum Acoelomorpha

These soft, flattened or subcylindrical, acoelomate worms have the body completely covered by locomotory cilia on multiciliated epidermal cells. The cilia form a unique network of interconnecting rootlets, and the epidermal cells have a unique mode of withdrawing and being resorbed. The space between the gut and body is filled with parenchymal cells. The digestive system (and digestive cavity) may be permanent or transient but always lack an anus. There is a weakly ganglionated brain and well-developed subepidermal or intraepidermal nerve plexus. There is an anterior statocyst and frontal organ opening at the anterior tip, some with simple ocelli. All have direct development, and there are no discrete or organized gonads. About 420 species have been described.

Class Acoela

Acoels are mostly minute, sediment- or surface-dwelling worms in marine or brackish water. They range in size from less than a millimeter to about 4–5 cm in length. Those inhabiting interstitial habitats are generally long and slender, whereas those inhabiting surfaces tend to be more disc shaped, broad, and flat. Swimming species are cylindrical with tapered ends or occasionally enrolled sides. Epiphytic species are usually cone shaped with ventrally enrolled sides that may give the appearance of trailing "fins." A few species of acoels have also been found in the guts of echinoderms, in fresh water, and at hydrothermal vent sites (Figure 9.1A–H).

Acoels lack a structural gut. Instead, they possess a multinucleated mass (a syncytium) that phagocytizes ingested food particles (Figure 9.2). Larger species often supplement their nutritional requirements with endosymbiotic algal partnerships, which can contribute to the bright coloration seen in many (Figure 9.3A). Acoels living in the guts of other animals often have symbiotic bacteria inhabiting their epidermis.

Acoels possess both circular and longitudinal muscles. Their nervous system consists of an array of paired longitudinal nerve cords with a concentration of anterior sensory cells and a cerebral commissure (the brain) (Figure 9.4). The anterior statocyst with a single statolith is distinctive in acoels and (along with simple, light-sensitive eyes in some species) appears to assist in maintaining the animal's orientation (Figure 9.1). Acoels lack sclerotized structures other than those associated with genitalia, although some species manufacture crystalline spicules in the parenchyma. They also possess aberrant, complex, biflagellate sperm that vary in the structure of the usual 9+2 arrangement of microtubules possessed by many metazoans. They have direct development and exhibit no distinct larval forms.

FIGURE 9.1 Acoela. (A) *Diopisthoporus lofolitis* (Diopisthoporidae). st = statocyst, e = egg, ph = pharynx simplex. (B) *Paratomella rubra* (Paratomellidae). (C) Color variation in 33 specimens of *Hofstenia miamia* (Hofsteniidae) from the Caribbean. (D) *Philactinoposthia novaecaledoniae*, living specimen (Dakuidae). (E) *Waminoa* sp. (Convolutidae) on bubble coral (*Plerogyra sinuosa*). (F) *Daku riegeri* (Dakuidae). (G) *Eumecynostomum evelinae* (Mecynostomidae). (H) *Paramecynostomum diversicolor* (Mecynostomidae).

Acoels were first described at the turn of the nineteenth century from northeast Atlantic coastlines. These and other early descriptions placed them among the free-living Platyhelminthes and distinguished major subtaxa on the basis of the female reproductive system. Later revisions in the middle of the twentieth century established over 20 families, and most of the nearly 400 described species were based primarily on details of male copulatory structures. Similarities in internal anatomy, epidermal ciliation, and the appearance of epidermal "pulsatile bodies" led to combining Acoela with another group, Nemertodermatida, as the Acoelomorpha.

The lack of hard anatomical features in these worms led workers to studies of microscopic ultrastructure using scanning and transmission electron microscopy, including investigations of muscle fiber orientation and structure (which distinguished several major lineages), sperm morphology, and spermatogenesis (which identified biflagellate sperm and unusual patterns of microtubules within sperm acrosomes), as well as neuroanatomy. Studies increased in number near the end of the twentieth century as the diversity of habitats investigated increased, including anoxic sulfide sands. Further systematic refinements within major acoel clades (notably the polyphyletic family Convolutidae), and developmental analyses, corroborated genetic results that place acoels outside the Platyhelminthes. In addition, 18S and 28S rRNA, mitochondrial DNA, and myosin heavy chain type II nucleotide sequences have all placed acoels outside the Platyhelminthes, as do all recent genomic and transcriptomic analyses. Much taxonomic revision is still under way, and about 9 to 20 families are currently recognized, depending on whose schema is followed.

Both molecular phylogenetics and EvoDevo research provide evidence that acoels likely split off near the base of the bilaterian tree. For example, the pattern of expression of *ClEvx* (a gene responsible for sensory specificity brain neurons) anterior and posterior to the statocyst in hatchling acoels is more similar to that found in cnidarians than it is to more derived bilaterians. Other studies indicate that *brachyury* (*bra*) and *goosecoid* (*gsc*), genes associated with the formation of the acoel mouth, are also expressed during mouth development in protostomes as well as deuterostomes, suggesting that acoel and bilaterian mouths are homologous. neural development and structure in the acoel *Symsagittifera roscoffensis* show that genes associated with brain-like structures are present, suggesting that such genetic machinery was in place in the urbilaterian ancestor (if indeed acoels reflect such an ancestor). The overall "primitiveness" of Acoela is also seen in their lack of a clearly differentiated gut or excretory system, unencapsulated gonads, absence of ciliary or rhabdomeric eyes, lack of a well-developed basal lamina under the epidermis, and absence of a larval stage.

The Acoel Body Plan

Body Wall and External Appearance

Most acoels are tiny, just a few millimeters long. The smallest species tend to be interstitial, feeding on bacteria and organic particulates available on the surfaces or between the spaces of the sediments they inhabit. Infaunal species tend to be more elongate (Figure 9.1A,B,F,H). Larger species usually inhabit the surfaces of rocks, large algae, or cnidarians (Figure 9.1C–E,G). These faster-moving species are often predatory, gliding quickly on their ciliated surfaces and capturing prey with a raptorial "hood" that consists of lateral extensions of the body.

Large-bodied species, reaching lengths of 4–5 cm, in some families (e.g., Convolutidae) have anterior ocelli (Figure 9.1G), whereas small-bodied species tend to lack these. Larger-bodied species also often have photosynthetic endosymbionts under their epidermis (Figures 9.1E and 9.3). The association with endosymbiotic algae probably evolved more than once, and both zoochlorellae and zooxanthellae have been identified among the various species. Algae are usually obtained during feeding by juvenile worms but in some species can also be transmitted within oocytes by parents to their offspring (vertical transmission). In *Heterochaerus langerhansi*, the dinoflagellate *Amphidinium carterae* resides below the epidermis and has been shown, using radioactively labeled carbon and nitrogen, to receive these substances from its host in the forms of CO_2 from respiration and excreted ammonia from protein metabolism. The rate of transfer is light dependent.

It has been suggested that acoel body pigmentation may have several functions. One might be to provide protection from UV radiation for their symbiotic photosynthetic protists. A second might be to provide cryptic coloration, either to make acoels inconspicuous to visual predators, or possibly to make them less visible to their prey. *Hofstenia* species, also known as "panther worms," are highly polymorphic in dorsal pigmentation, with diverse patterns of dappling and striping of brown, yellow, and white colorations (Figure 9.1C).

The acoel body is completely covered with cilia, which may or may not also line the mouth and entrances to reproductive structures. The epithelium lacks a well-defined basal lamina (extracellular matrix, or ECM). Early researchers identified **pulsatile bodies** embedded within the epidermis of acoels (and nemertodermatids), which later proved to be clumps of ciliated cells in the process of being resorbed and replaced by the epidermis.

Mucus-producing **frontal organs**, which superficially resemble those of flatworms but are probably not homologous in structure, occur in most families. These are gland complexes that open at the anterior end of the worm. The ciliated epidermis of acoels also bears **rhabdoid glands** distributed over the body. The **rhabdoids** themselves are composed of mucopolysaccharides and are chemically as well as structurally distinct from the rhabdites of free-living flatworms, although their role in producing mucus to assist ciliary gliding appears to be similar. Some Acoela also have **sagittocysts** (Figure 9.5), complex needle-shaped secretory products (5–50 μm long) that are ejected with force in prey capture or for defense and probably also to assist in sperm transfer during copulation (perhaps

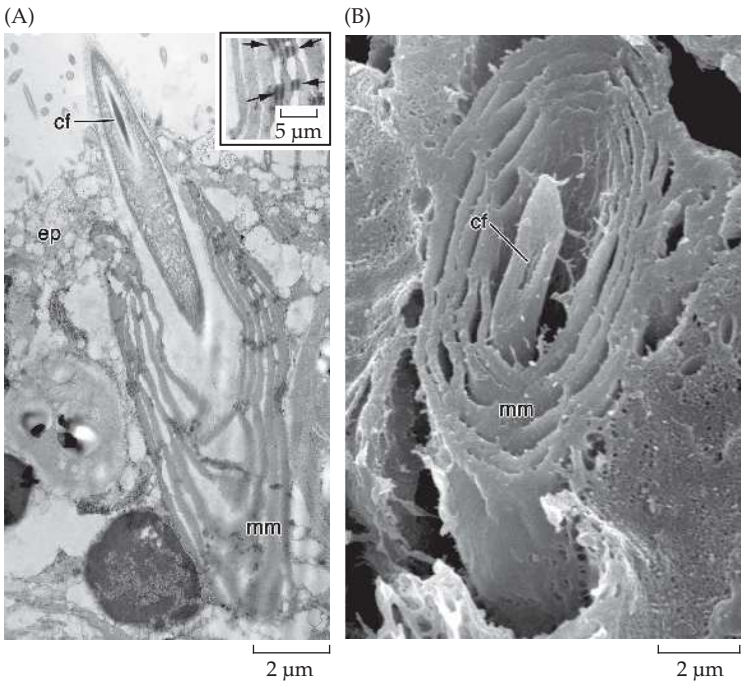

FIGURE 9.5 TEM images of *Convolutriloba longifissura* (Acoela) sagittocysts. (A) A sagittocyst (cf = central filament of sagittocyst) during extrusion from the muscle mantle (mm) and penetration of the epidermis (ep). Inset shows higher magnification of the muscle mantle; arrows indicate the location of desmosomes linking the mantle layers. (B) Close-up of the cut surface of a sagittocyst within the muscle mantle.

by perforating the partner's epidermis). Each sagittocyst arises from a **sagittocyte**, which is surrounded by tightly spiraled muscle filaments that expel the sagittocyst upon contraction (Figure 9.6).

The position of the mouth in acoels is highly variable. In some families, the mouth opens at the posterior end of the animal and leads to a distinct pharynx (Figure 9.1A). Other families have anteroterminal mouths, although most acoel mouths open midventrally (Figures 9.2 and 9.7B). Both a circulatory system and an excretory system, even in the form of protonephridia, are lacking in the Acoela. Male and female reproductive organs are visible through the body wall of smaller acoels (Figure 9.1A,F,H). In larger species they may protrude from the body surface (Figures 9.7D and 9.12B).

Body Musculature, Support, and Movement

The mesodermally derived musculature of acoels provides the primary means of support, whereas the body cilia (assisted by body muscles) provide for their gliding movement. The shape of the cilia is distinctive, having a marked shelf at the tip where doublets 4–7 terminate. The rootlet system that connects the cilia is also unique and plays a role in acoel systematics. Two lateral rootlets project from each cilium and connect to the tips of the adjacent cilia. From a caudal rootlet, two bundles of fibers project to join the kneelike bend of those same adjacent rootlets. Epidermal cilia of acoels beat in a coordinated fashion to create metachronal waves that move from anterior to posterior. The parenchyma between the epidermis and gut sometimes contains chordoid vacuoles (or chordoid cells) that are insunk bodies of epidermal and gland cells.

Abundant dorsoventral muscles serve to flatten the body, and muscles in the body wall generate bending, shortening, and lengthening movements (Figures 9.7 and 9.8). The body wall musculature includes circular, diagonal, longitudinal, crossover, spiral, and even U-shaped muscles. Species lacking a pharynx appear to have specialized, complicated ventral musculature to compensate for the lack of a muscular food-moving structure, and this allows body movements to force food through the mouth.

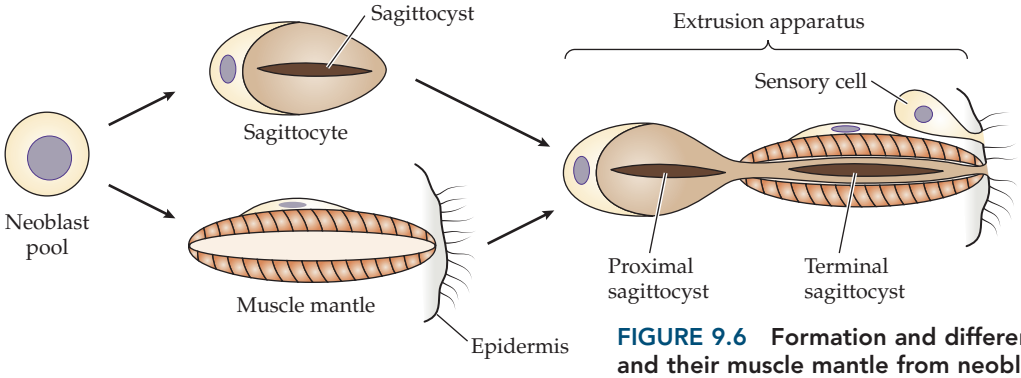

FIGURE 9.6 Formation and differentiation of sagittocytes and their muscle mantle from neoblast cells in Acoela. See text for description.

FIGURE 9.7 Musculature of acoels. (A) Whole mount of living specimen of *Isodiametra earnhardti*. (B) Ventral body-wall musculature of *Haplogonaria amarilla*. (C) Parenchymal musculature of *Isodiametra divae*, showing portions of copulatory organs. (D) Male copulatory organ of *I. divae*, showing musculature of seminal vesicle and invaginated penis. (E) Penis musculature of *Convoluta henseni*. Projections of musculature in whole-mount specimens of acoels stained with Alexa-488-labeled phalloidin and viewed using CLSM. Phalloidin is a naturally occurring toxin in the death cap mushroom (*Amanita phalloides*). Its toxicity is due to its ability to stabilize actin filaments within cells, and this attribute has led to its wide use (fluorescently labeled) in research to visualize filamentous actin, such as muscle fibers. CLSM = confocal laser scanning microscopy.

Nutrition, Excretion, and Gas Exchange

As juveniles, most acoels appear to feed on protists, including unicellular algae such as diatoms. Smaller species may continue this diet throughout their lives, whereas larger species (e.g., *Convoluta convoluta*) are often predaceous, hunting minute crustaceans but also feeding on other worms and larval molluscs. Smaller protists are captured as acoels glide over them with the syncytial gut extruded through the mouth such that it engulfs food with "ameboid"-like action. Larger prey are grasped with the anterior margin of the body and entrapped with mucus before being pressed toward the mouth. Swimming prey may also be rapidly captured and ingested, whereas dead material seems to be actively avoided.

Some acoels possess a pharynx, in some cases known as a **pharynx simplex** (Figure 9.1A), and this structure is variable among the families. In some species the pharynx is a flexible, tube-shaped structure that can be everted from the mouth. In species where no distinct pharynx exists, muscle fibers encircle the mouth to form a sphincter.

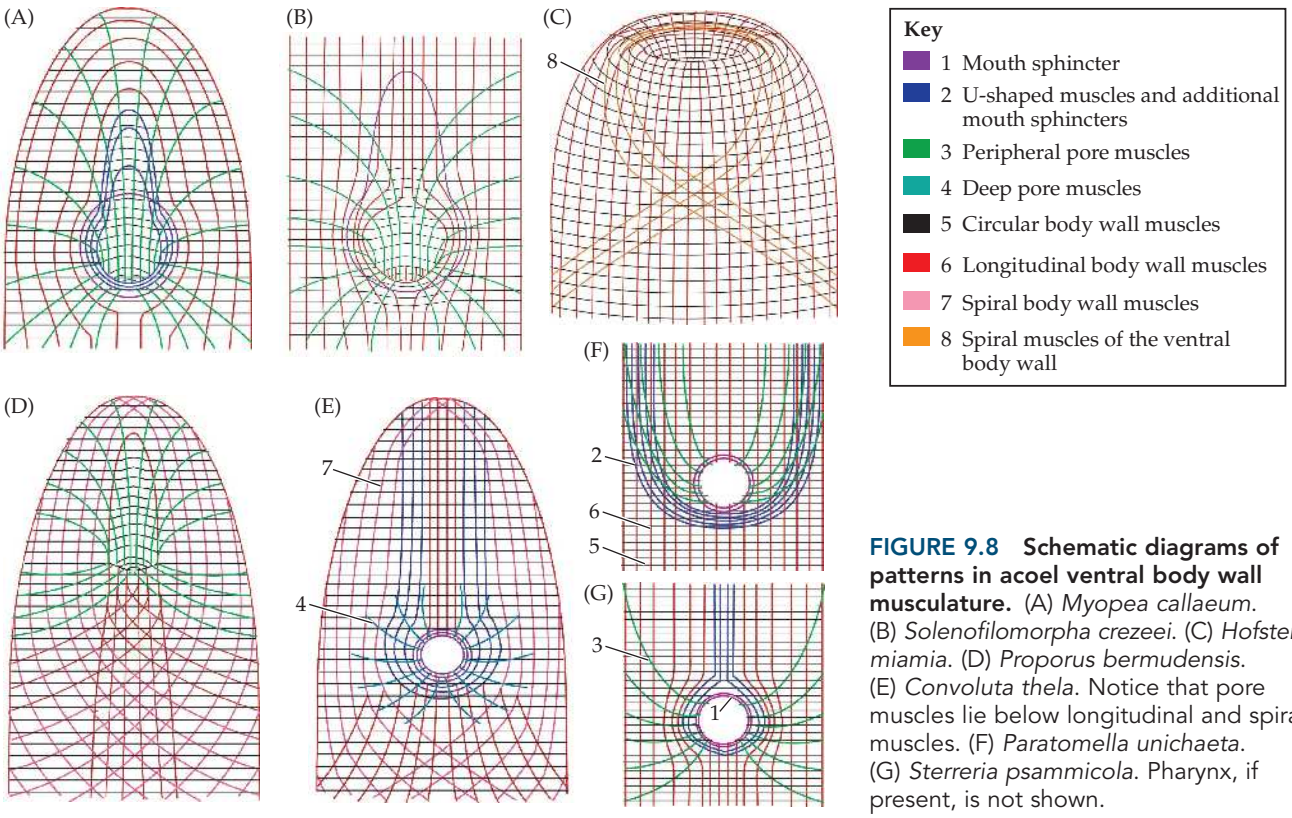

FIGURE 9.8 Schematic diagrams of patterns in acoel ventral body wall musculature. (A) *Myopea callaeum*. (B) *Solenofilomorpha crezeei*. (C) *Hofstenia miamia*. (D) *Proporus bermudensis*. (E) *Convoluta thela*. Notice that pore muscles lie below longitudinal and spiral muscles. (F) *Paratomella unichaeta*. (G) *Sterreria psammicola*. Pharynx, if present, is not shown.

Ingested prey is enclosed within vacuoles that drift within the digestive syncytium, and food is completely absorbed within 18 to 24 hours. A few species, when feeding, develop a small transient gut lumen that is lined with a double layer of cells. The exoskeletons of hard-bodied prey such as crustaceans are voided through the mouth. Fat globules and occasional glycogen vacuoles stored within cells appear to be the primary forms of food reserve. A number of acoel species associate with corals (including *Waminoa* [Figure 9.1E] and several species of *Convolutriloba* [Figure 9.3]). These associations appear to primarily benefit the acoels, which likely feed on mucus produced by these cnidarians. The small size of acoels is sufficient to allow them to eliminate waste nitrogen and carbon dioxide, as well as obtain oxygen from the surrounding water, without a need for specific excretory or circulatory systems.

Nervous Systems and Sense Organs

The central nervous system of acoels usually includes an anteriorly located cluster of large commissures and a few cell bodies that form a paired ganglion system with a minute neuropil (which is quite rudimentary compared with those of other bilaterians). Arising from this are three to five pairs of longitudinal nerve cords connected by an irregular network of transverse fibers (Figure 9.9). Typically there are single or paired dorsal nerve cords and paired lateral and ventral cords. Peripheral neurons connect to epidermal sensory cells and to anterior light-sensitive cells that serve as simple eyes. There is no indication that the eyes have ciliary or rhabdomeric elements, and they are probably simple pigment cells with refractive inclusions and one to several nerve cells to relay the stimulus. This organization contrasts markedly with that of platyhelminths, where the brain consists of a comparatively dense ganglionic mass, the nervous system is primarily developed ventrally, and the nerve cords form an orthogonal nervous system composed of eight orthogons largely developed laterally and ventrally (Figure 9.4). It has been suggested that the bilobed brain of some acoels evolved independently from those found in spiralians and that it may be homologous with the ring-commissural brain seen in nemertodermatids.

The acoel statocyst is a fluid-filled, proteinaceous spherical capsule, 10–30 μm in diameter, surrounding a single retractile statolith (Figure 9.1). The statolith appears to be a single spherical cell. The capsule enclosing the statolith comprises two unciliated cells. Behavioral observations indicate that acoels are capable of precise geotactic orientation, suggesting that movements of the statolith within the statocyst are detectable by the animal. Three pairs of muscle fibers insert into the membrane of the statocyst, evidently assisting in maintaining its position. While the cerebral commissure is closely associated with the statocyst, specific innervation of the structure is difficult to clearly identify, although a small nerve cushion created by two nerve bundles inserting on the capsule, and a cell body located at the ventral

pole, may be responsible for detecting deformation of statocyst fluid. Positional information might also be conveyed by the stretching of muscle fibers surrounding the statocyst. While statocysts appear in other metazoans, including cnidarians, ctenophores, platyhelminths, annelids, and others, statolith movements within the statocyst in these taxa are generally detected by cilia along the internal surface of the statocyst. The lack of these modifications within the Acoela appears to be unique. Acoels (as well as nemertodermatids and xenoturbellids) also have a **frontal organ**, or frontal gland complex, the function of which is not entirely clear. Some acoels have photoreceptive ocelli, the nature of which is still poorly understood. One clade of acoels (the "convolutimorphs") have the unique extrusomes called sagittocysts (Figure 9.6), somewhat like nematocysts of cnidarians and rhabdites of flatworms.

Reproduction and Development

Acoels are all hermaphroditic but capable of both sexual and asexual reproduction. They also have considerable ability to regenerate cells through the actions of multipotent, mesodermally derived, neoblasts. These neoblasts were originally described in the Platyhelminthes, but analogous (or homologous) cells appear in the Acoela. These cells replace damaged or missing body components and appear to have few limitations in how they are able to repair or replace tissues.

Three distinct forms of asexual reproduction have been documented within the Acoela: transverse fission, longitudinal fission, and budding (Figure 9.10). In at least some (e.g., *Paratomella rubra*), chains of smaller animals form from budding at the posterior end of the animal, a process known as **paratomy.**

Most acoels are simultaneous hermaphrodites (Figure 9.11), although some (e.g., all members of the family Solenofilomorphidae) are protandrous. Ovaries and testes may be paired or unpaired, with testes usually dorsal and ovaries more ventral (Figure 9.12A). In some species a single mixed gonad exists. In no cases are the gonads saccate—that is, the germ cell mass is not lined or discretely separated from the surrounding parenchyma.

Genitalia are usually visible near the posterior end of the animal. The penis is a muscular and glandular, or needlelike structure, often with multiple styletlike elements (Figure 9.12B). Male intromittent organs, regardless of form, can be retracted into a seminal vesicle. During copulation the penis is everted through the

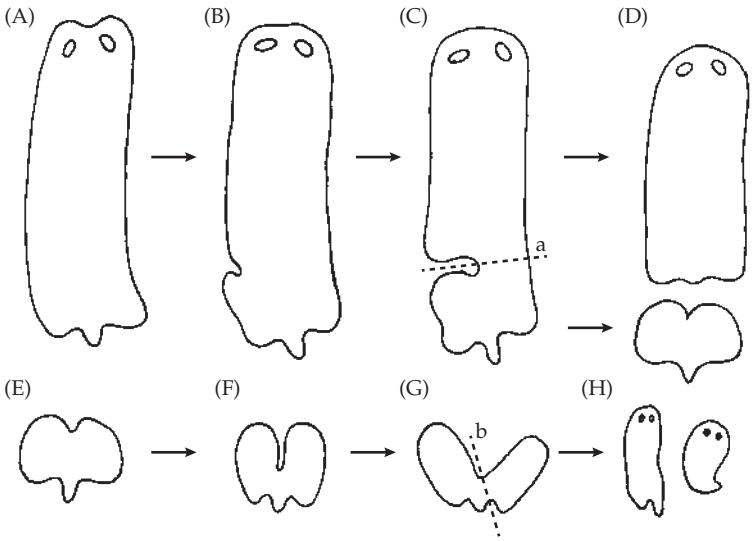

FIGURE 9.10 Modes of asexual reproduction in *Convolutriloba longifissura* (Acoela). (A) Intact animal. (B–D) Transverse fission; lower element of (D) shows "butterfly" stage preceding transverse fission (E–H).

male gonopore that typically lies in a distinct antrum, or vestibule on the body surface. A separate female gonopore exists in some species. In others, the female pore connects directly to the male pore. In still others, no external female opening exists and insemination is hypodermic. Most, but not all, acoels have the vagina positioned anterior to the penis.

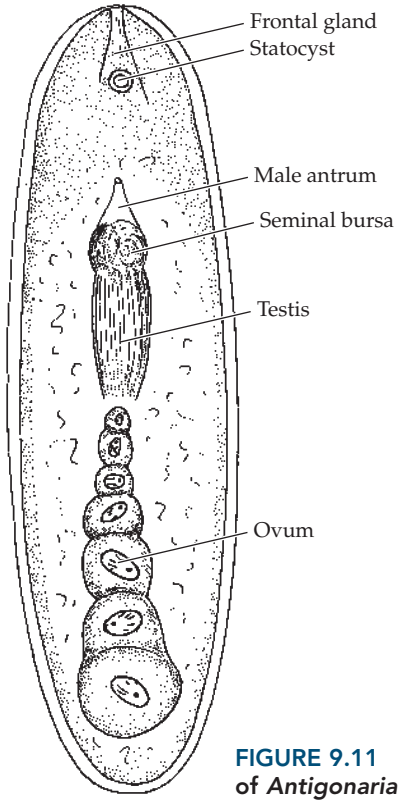

FIGURE 9.11 Internal organization of *Antigonaria arenaria* (Acoela).

A **seminal bursa** may exist that appears to receive sperm from mating partners either during copulation or after hypodermic insemination, and a sclerotized **bursal** or **vaginal nozzle** or sphincter regulates the passage of sperm to eggs. These are among the few sclerotized structures in these soft-bodied worms, and they were considered important in early taxonomic treatments of Acoela. Like many persistent terms in invertebrate zoology, the name "nozzle" was coined by Libbie Hyman, who thought these structures resembled the nozzle of a hose. In certain Convolutidae, multiple bursal nozzles may exist in the same individual (Figure 9.12B). While highly variable in form, seminal bursae and their associated structures appear to be homologous among all acoels.

During copulatory behavior individuals approach one another and exchange quick touches or "nips" of the anterior ends. Larger individuals appear to initiate copulation, which proceeds after both individuals roll into a ball and then unroll with their genitalia firmly engaged. In simultaneous hermaphrodites, each individual can mutually insert its penis into its partner's female gonopore and direct sperm and seminal fluid into the female bursa.

Acoel sperm are filiform and distinctively biflagellate, with the two axonemes of the flagella incorporated into the cell body (a condition also seen in Platyhelminthes) and a 9+2 microtubule pattern. Several well-defined patterns exist in acoel sperm morphology, and these seem to be phylogenetically informative. Combined studies of 18S rRNA sequence data and sperm morphology have revealed remarkable concordance between these two sources of data. Seminal bursae and bursal nozzle complexity also appear to correlate with variation in sperm morphology.

Fertilization is always internal, and zygotes are released either through the mouth, via the female gonopore, or through a rupture created in the epidermis by the growing embryos. Zygotes may be brooded or protected by encapsulation but are usually deposited singly and undergo direct development. Egg clusters appear to be laid primarily at night, in flat gelatinous masses.

Embryonic development is direct, and the cleavage pattern of acoels includes a unique mode called **duet cleavage** that is unlike anything seen in other metazoans. Nemertodermatids, while exhibiting "duet cleavage" in the four-cell stage, do not exhibit the spiral duet pattern seen in acoels. As in spiral quartet cleavage, the first horizontal cleavage in acoels is unequal and so produces micromeres, but it occurs at the two-cell stage instead of the four-cell stage, so the micromeres appear as duets instead of quartets. One

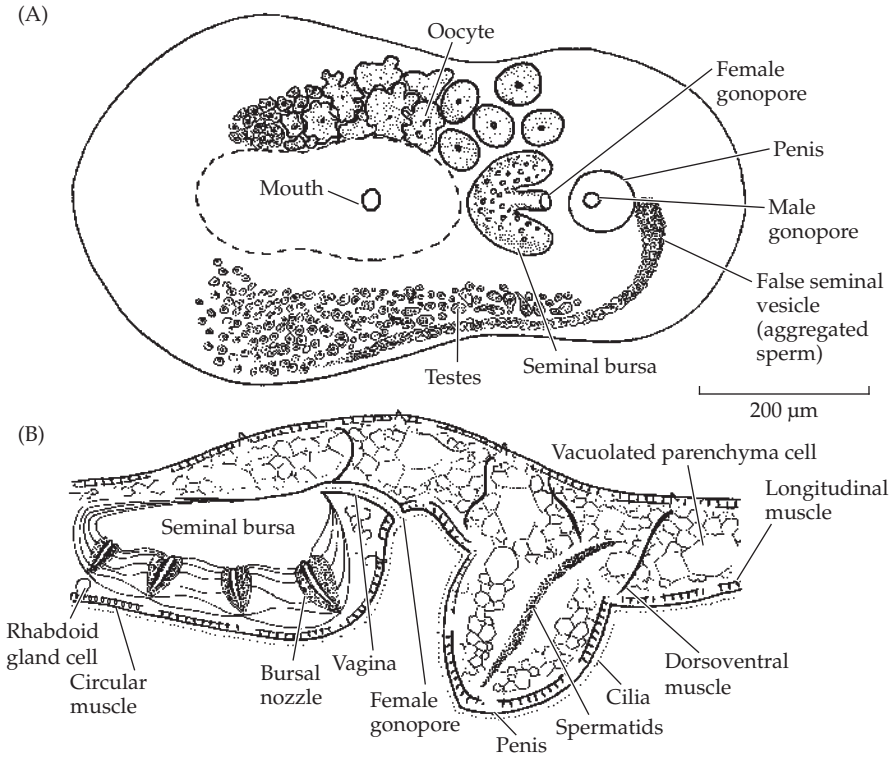

FIGURE 9.12 Acoela: reproductive anatomy of *Polychoerus gordoni*. (A) Dorsal view; note that in this species, as in other Convolutidae, male and female gonads are paired, but they are shown singly here. (B) Sagittal view of female and male reproductive anatomy.

is tempted to call this "bilateral cleavage," rather than spiral cleavage, and it is quite different from that of all other spiral-cleaving Metazoa. So far as is known, acoel embryos generate only endomesoderm, whereas most spiral-cleaving animals tend to also produce some ectomesoderm. Internal tissues arise either by delamination or by immigration of cells that form the ectoderm and mesoderm. By the time gastrulation is complete, the embryo has a layered appearance, with an outer epidermal primordium, and a middle layer of progenitor cells of muscles and neurons, while the innermost cells are those that will develop into the digestive syncytium. Endomesoderm forms from both of the third duet macromeres at the vegetal pole, whereas the mouth forms anteriorly as 1a micromere descendants expand around the posterior pole. Acoels hatch as juvenile worms (direct development) with all major organ systems except the reproductive tract. An anus never forms.

Class Nemertodermatida

Nemertodermatida comprise 18 species of marine worms described mostly from northern Atlantic coastlines. Nearly all known species are free-living, usually in fine sand, mud, or gravel; however, *Meara stichopi* is a symbiont in the foreguts of holothurian echinoderms (sea cucumbers). Nemertodermatids range in length from a few millimeters to nearly a centimeter. They can be leaf shaped or narrow and elongated, and they may creep over the substratum or swim with serpentine movements. Their bodies are densely covered with locomotory cilia, and as a group they are easily recognized by an anterior statocyst containing two statoliths in separate chambers (Figure 9.13A,B)—although a few reports of one to four statoliths also exist. Some species possess an eversible proboscis associated with feeding (oddly, some of these species lack a distinct mouth), with numerous branches that extend anteriorly "like a witch's broom" (Figure 9.14).

The epidermal cells of nemertodermatids lack a true basal lamina but are connected to underlying muscle cells and to each other by a narrow extracellular matrix. Septate junctions between epidermal cells are lacking. As in the acoels, old or damaged ciliated epidermal cells are withdrawn into the body and resorbed, creating temporary structures called pulsatile bodies, although these were called restitution bodies in nemertodermatids (Figure 9.15). Also as in acoels, species living in the guts of other animals often have symbiotic bacteria inhabiting their epidermis (Figure 9.16). The form of the mouth and gut vary among species, from temporary structures to a porelike opening and a narrow intestinal lumen, although a complete gut is lacking (there is no anus, nor is there a discrete pharynx). They lack discrete circulatory or excretory structures. Asexual reproduction has not been reported. Male sexual structures may consist of a simple, ciliated invagination of the epidermis or an eversible penis; seminal vesicles may be present. Where these structures are lacking, sperm appear to simply be ejected from the male antrum. The female gonopore with an

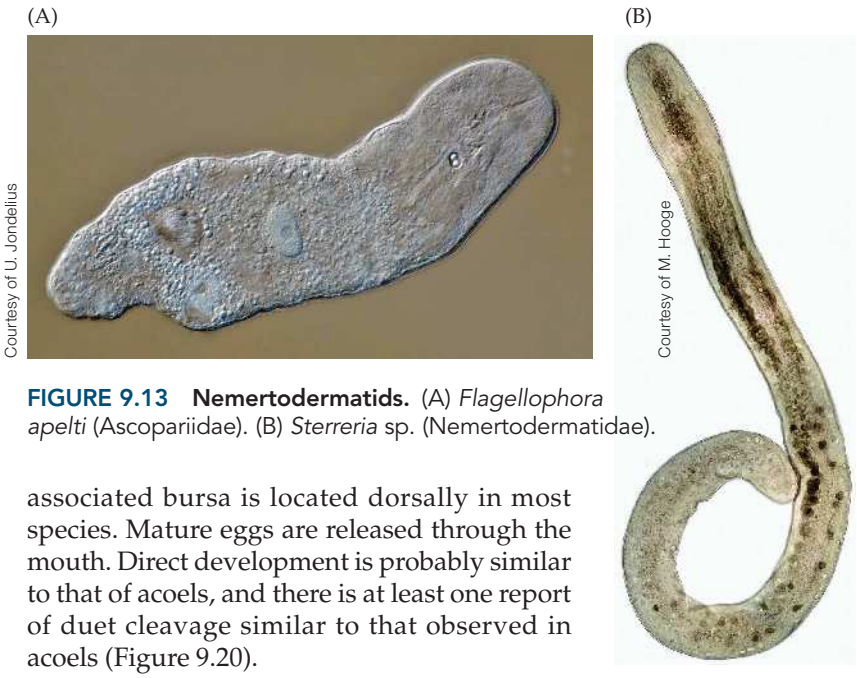

FIGURE 9.13 Nemertodermatids. (A) *Flagellophora apelti* (Ascopariidae). (B) *Sterreria* sp. (Nemertodermatidae).

associated bursa is located dorsally in most species. Mature eggs are released through the mouth. Direct development is probably similar to that of acoels, and there is at least one report of duet cleavage similar to that observed in acoels (Figure 9.20).

The first described nemertodermatid was classified within the acoel Platyhelminthes by Otto Steinböck in 1930. Steinböck, a colorful individual known to express himself in double-spaced capital letters with exclamation marks for emphasis, announced his discovery as "the mother of all turbellarians," possessing a "novel, two-stoned statocyst, an unusually thick and gland-rich epidermis, a peripheral nervous system, and a mixed, lacunar gonad without accessory organs." In 1940 Tor Karling removed the Nemertodermatida from the Acoela because of their well-formed intestinal lumen, a structure lacking in acoels. The Acoela and Nemertodermatida were combined as sister taxa within the Platyhelminthes in 1985 with Ulrich Ehlers' recognition of the taxon Acoelomorpha. Additional work on Nemertodermatida has proceeded slowly because specimens are difficult to come by and because many characters can be highly variable within populations, but the group has seen a sort of revival in the past decades due to realization of their phylogenetic position outside of Platyhelminthes.

The relationship of *Meara stichopi* to its echinoderm hosts is poorly understood but does not appear to be parasitic—hosts do not appear to be harmed by the presence of the worms. In fact, the relationship could be mutualistic, as nematodes have been found within the guts of endosymbiotic *Meara*. Symbiotic species of both *Meara* and *Nemertoderma* are known to possess elongated, Y-shaped symbiotic bacteria (Figure 9.16). In *Meara*,

these symbionts are found primarily on the ventral side of the body. Ultrastructural studies indicate that bacteria occur only on the outside surface of their worm hosts, suggesting that the association between bacteria and host does not represent infection.

The Nemertodermatid Body Plan

Body Structure

In general, nemertodermatids are small. The endosymbiotic *Meara stichopi* is usually less than 2 mm in length, free-living *Nemertoderma* average about 3 mm in length, and a few "giant" nemertodermatids grow to nearly 1 cm. Most individuals are colorless to yellow or red, but pigmentation can be variable within populations. The epidermis of most species appears to contain numerous bottle-shaped mucous glands. Overall, the epidermis resembles that of nemertean worms, which led to the namesake "nemertodermatid." In the genus *Nemertoderma*, these glands are more abundant at the apical pole, forming an anterior gland complex with separated, outwardly directed gland openings or necks. However, these openings are not grouped together in a regular way at an apical pore and thus do not form a "frontal organ" like that described for Platyhelminthes.

Cell and Tissue Organization

The epidermis of nemertodermatids is entirely ciliated. The cells are connected by an intracellular terminal web—a stratified structure composed of a closely woven inner layer of intensely staining fibrils overlain with more loosely packed fibrils, which bulges at the cell borders. Epidermal cells are joined apically by belt-like adherens junctions (belt desmosomes) called **zonula adherens**. Interspersed among the cells are the necks of various glands and sensory receptors, particularly in the anterior region of the animal. The necks of glands appear to have associated muscular rings that may regulate the flow of gland contents (Figure 9.17E).

The ciliary rootlet structure is similar in Acoela and Nemertodermatida, one of the primary reasons workers grouped these two taxa together (as the Acoelomorpha). The rootlets of nemertodermatids include a rostrally oriented rootlet and a caudally oriented rootlet. In its original description, *Meara stichopi* was reported to possess "restitution cells" that appeared to contain ciliary structures in the process of being resorbed. Indeed, these cells represent structures similar to the pulsatile bodies reported in acoels, wherein worn cells are encapsulated and transported to the digestive tract for resorption (Figure 9.15). However, this feature is distinct in the nemertodermatids because the cilia detach from their basal apparatus before encapsulation, eliminating their ability to pulsate, causing some researchers to refer to them as "degenerating epidermal bodies."

Support and Movement

As in most acoels, body musculature in nemertodermatids consists of outer circular and inner longitudinal muscle layers. Diagonal musculature typically is also present and varies among species, with fibers forming connections between layers in some (e.g., *M. stichopi*; Figure 9.17A,B) and forming distinct layers in others (e.g., *Nemertoderma westbladi*; Figure 9.17C,D). Musculature surrounding the mouth also varies, being best developed in species with a permanent mouth. Musculature is also well developed around permanent genital openings (e.g., *M. stichopi*) but is less so in species with transient genital orifices (e.g., *N. westbladi*).

The opening of the male gonopore and its associated antrum appear as an invagination of the entire body wall, and musculature associated with the seminal vesicle consists of a thin layer, present only in individuals with mature male organs (Figure 9.17F). Parenchymal

(F) Posterior body region of *N. westbladi*, with invagination of body wall to form the male antrum; finer musculature of the seminal vesicle is visible in open space. (A–D from I. Meyer-Wachsmuth et al. 2013. *Zoomorphology* 132: 239–252. https://link.springer.com/article/10.1007%2Fs00435-013-0191-6. Courtesy of I. Meyer-Wachsmuth.)

muscles may also be present in individuals in all life stages, forming a three-dimensional network throughout the parenchymal tissue. The statocyst is supported by muscles that attach dorsoposteriorly and anterolaterally to other body wall musculature. Nemertodermatids move by creeping on their ciliated surfaces or, in more elongated species, by undulating their bodies in a serpentine way.

Nutrition, Excretion, Gas Exchange

The gut of nemertodermatids has only a single opening, like that of cnidarians and other xenacoelomorphs. However, unlike in acoels, the gut is not syncytial and instead usually contains a well-defined intestinal lumen. In some nemertodermatid species, a cone of gut tissue has been reported to protrude and retract like a tongue to collect food particles. However, no known

for more ebook/ testbank/ solution manuals requests email 9601267344@qq.com

nemertodermatid possesses a structure recognizable as a muscular pharynx. Other species appear to lack a mouth altogether. In such species (e.g., *Flagellophora apelti*), an anterior **broom organ** is reported, although this structure does not seem to be directly connected to the gut. Instead it seems to consist of a bundle of up to 30 glands whose necks are protrusible through a canal at the anterior end of the body (Figure 9.14B). When opened, the broom organ appears to possess distal ends that are slightly swollen and possibly adhesive. Some researchers have suggested that the mouth of nemertodermatids is a transient structure that appears during a limited part of postembryonic life, with the duration of persistence dependent upon the species.

Meara stichopi inhabits the foregut of the holothurian *Parastichopus tremulus*, a species common on Scandinavian coastlines, and appears to feed on detritus as well as upon nematodes within the gut of its host. Free-living species of Nemertodermatida have been found with comparatively large turbellarians and nematodes within their guts. As in acoels, the small body sizes of nemertodermatids allow them to eliminate waste nitrogen and carbon dioxide, as well as obtain oxygen from the surrounding water, without a need for discrete excretory or circulatory organs.

Nervous System

The nervous system of nemertodermatids is still not well understood. Immunoreactivity studies with the neurotransmitter serotonin (5-hydroxytryptamine; 5-HT) and the regulatory neuropeptide FMRFamide have shown considerable variation in responses in the species examined. In *Meara stichopi*, 5-HT reactivity reveals a subepidermal nerve net and two, loosely organized longitudinal nerve bundles along the length of the animal. In *Nemertoderma westbladi*, 5-HT reactivity shows a two-ringed, anterior commissure, with the rings converging near the statocyst and connected by thin fibers. Two lateral fibers extend longitudinally from the commissure, as does a delicate curtain of evenly spaced finer longitudinal fibers that become indistinct caudally. FMRFamide immunoreactivity follows the same pattern as 5-HT reactivity in *M. stichopi* and *N. westbladi*. These results suggest that the nemertodermatid nervous system is quite distinct from the bilobed ganglionic brain and orthogonal peripheral nervous system of Platyhelminthes (i.e., paired longitudinal ventral nerve cords connected by a regular pattern of transverse commissures). The nemertodermatid central nervous system is also distinct from the commissural brain of acoels (i.e., symmetrical commissural fibers with few cell bodies and three to five pairs of radially arranged longitudinal nerve cords, irregularly connected with transverse fibers). The statocyst may contain one to four statoliths.

Reproduction and Development

The reproductive anatomy and natural history of nemertodermatids is not well studied, and only a few species have been examined in this regard. The male gonopore in nemertodermatids appears to open dorsally (or supraterminally) and is associated with a muscular male antrum. In fully mature specimens, a muscular seminal vesicle and often a male copulatory organ may also evert either posteriorly or slightly dorsally (Figure 9.18). Female genitalia, if present, is located dorsally. *Flagellophora apelti* seems to have a deep, well-defined invagination that may represent a female gonopore (Figure 9.14).

In *M. stichopi*, follicular testicular cells can occupy most of the preoral part of the body. Ovarian cells can occupy the postoral part of the body and the animal often contains one or more large ova within the posterior body region. The male intromittent organ opens terminally to slightly supraterminally in this species.

In general, Nemertodermatida have a 9+2 arrangement of microtubules in their uniflagellate sperm, a condition distinct from the variable microtubule arrangement and biflagellate condition of acoel sperm. Many field-collected nemertodermatids contain two types of sperm. **Autosperm** (sperm produced by the individual in which they are found) in *M. stichopi* are filiform, are about 45–60 μm long, and under phase contrast microscopy show indistinct divisions of individual sperm into head, middle piece, and tail, as is typical of more derived spermatozoan forms within Metazoa (Figure 9.19). Some sperm appear to be coiled, in corkscrew fashion, over half of their length and are nonmotile within the animal producing them. **Allosperm** (sperm not produced by the individual in which they are found) are distinctive because they tend to be uncoiled and motile within the body of recipient individuals.

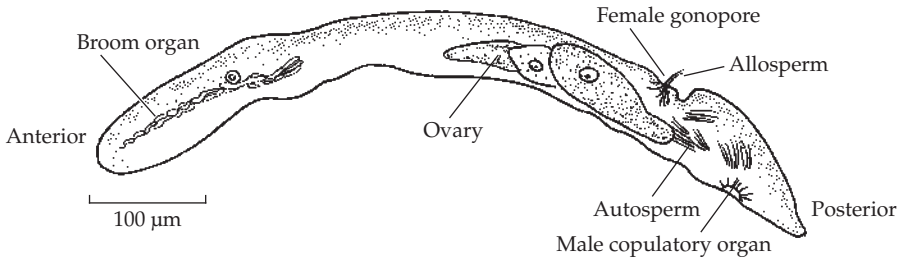

FIGURE 9.18 Nemertodermatida. Diagram of *Ascoparia* sp. showing location of dorsal female gonopore and subterminal male copulatory organ.

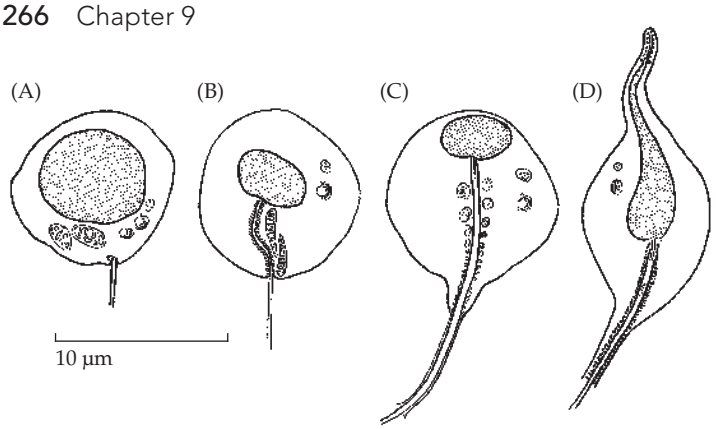

FIGURE 9.19 Nemertodermatida: stages in spermatogenesis in *Meara stichopi*. (A) In early stages of spermatogenesis, the nucleus is large, with heterogeneous electron density; two mitochondria are visible. A single flagellum begins to form from a basal body situated near the cell membrane. (B) The nucleus shrinks and becomes homogenous in density. The mitochondria begin to elongate, and the basal body and associated fibers move into the cytoplasm toward a depression forming in the nucleus. Microtubules coil around the flagellar channel. (C) The mitochondria coil around the flagellar channel, and a sheath grows from the cell to surround the proximal flagellum. (D) The cell and nucleus elongate to form the head of the spermatozoon. The mitochondria form tighter whorls and wander into the length of the flagellar sheath. (After K. Lundin and J. Hendelberg. 1998. *Hydrobiologia* 383: 197–205. https://link.springer.com/article/10.1023%2FA%3A1003439512957)

The pioneering investigator of acoels and nemertodermatids, Einar Westblad, noticed that development of female reproductive structures seemed to precede that of male structures, indicating that some nemertodermatids might be protogynous. On the other hand, other authors have noted that "male maturity seems to precede female maturity," or they have specifically stated that individuals are protandrous. In *N. westbladi*, individuals were found to have matured as males, females, and hermaphrodites, with no clear evidence of either protandry or protogyny. In *Ascoparia neglecta*, an elongate species with no actual mouth in mature individuals (although male and female pores are visible), individuals possess a male copulatory organ, and allosperm have been reported contained in vacuoles near the vagina.

Many species appear to lack female genitalia yet are found to contain both autosperm that are clearly contained within male reproductive structures and allosperm that appear to have been introduced. Individuals bearing allosperm appear to include mature as well as immature individuals, raising the possibility of sperm storage and sperm competition among individuals. Taken together, these findings imply great diversity in reproductive life history among nemertodermatids. Adults in some species appear to be smaller than juveniles, suggesting that maturing individuals may cease to feed and then complete their life history using stored food reserves or other resources.

Copulation has not been observed in any nemertodermatids. However, earlier workers suggested that worms may simply press their posterior ends together long enough for spermatids to get through the epithelium of the recipient worm. Since male structures are located subterminally, this behavior would have to occur with the recipient positioned somewhat dorsally, or an individual transferring sperm would have to undergo dorsiflexion to accomplish impregnation. In species lacking female structures, insemination appears to be hypodermic. Oviposition is accomplished by flexing the body into a dorsiconvex shape, followed by protrusion of the circumoral area of the body to force individual eggs out of the mouth.

Development in nemertodermatids is similar to that of Acoela. The first cleavage division is holoblastic (Figure 9.20). The second division results in the formation of micromeres and macromeres. In later 4-cell stages, the micromeres shift slightly clockwise (dexiotropic), resembling spiral cleavage, but this shift does not occur until well after the division has taken place. Nemertodermatid cleavage starts out radial but then takes place in a duet pattern, the micromeres shifting clockwise to produce a spiral-like pattern. The 4-cell divisions involve both macromeres, resulting in a 6-cell embryo, followed by another division by the micromeres to yield an 8-celled embryo. This alternating pattern is followed until the 16-cell stage, similar to what is known in acoels as "duet cleavage," although in acoels the first division involves a counterclockwise (levotropic)

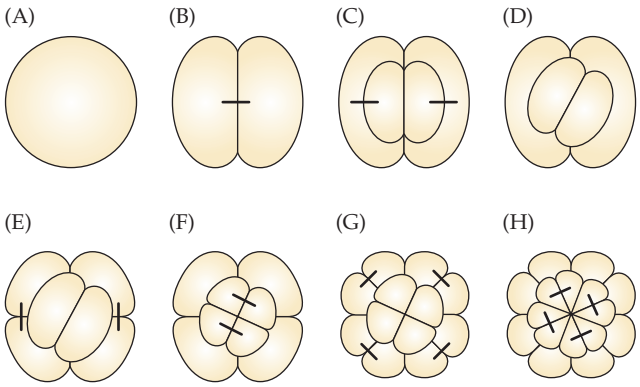

FIGURE 9.20 Diagram of duet cleavage in Nemertodermatida (*Nemertoderma westbladi*), viewed from the animal pole. Lines indicate cleaved relationships among cells. (A) Uncleaved zygote. (B) The 2-cell stage. (C) Early 4-cell stage with micromeres oriented radially. (D) Late 4-cell stage with micromeres shifted. (E) The 6-cell stage. (F) Cleavage of micromeres produces an 8-cell stage. (G) The 12-cell stage with eight macromeres and four micromeres. (H) The 16-cell stage with eight macromeres and eight micromeres. (After U. Jondelius et al. 2004. *Zoomorphology* 123: 221–225. https://link.springer.com/article/10.1007/s00435-004-0105-8)

for more ebook/ testbank/ solution manuals requests: email 9601267342@qq.com

shift of the micromeres rather than the clockwise shift documented for *N. westbladi*. Nevertheless, the form of duet cleavage is similar in both taxa, suggesting to some researchers that this trait is ancestral in the Acoelomorpha.

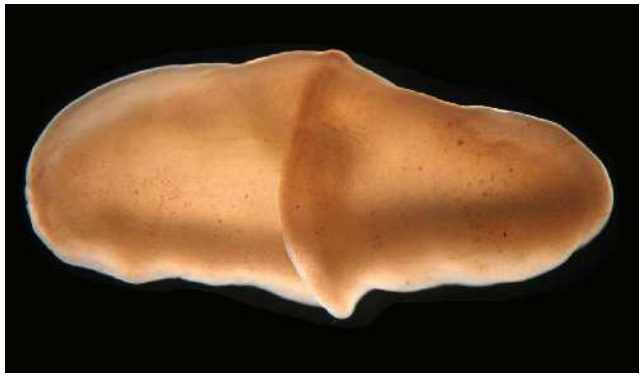
Postembryonic development in *N. westbladi* appears to follow three life history phases. Hatchlings are nearly round, only slightly longer than wide (around 250 × 200 μm). These individuals grow directly into juveniles, which are bottle shaped and may reach nearly 1 mm in length but possess no discernable sexual structures, mouth, or digestive system. Mature specimens may be variable in size (averaging 450 μm in length) and possess a slightly more elongated shape as well as visible male copulatory organs and a small pointed tip at the posterior end formed by the male gonopore.

Subphylum Xenoturbellida

Sixten Bock (1884–1946), the great Swedish platyhelminth specialist, was collecting along the Swedish coast near the Kristineberg Center for Marine Research and Innovation (then known as the Kristineberg Marine Research Station) in 1915 when he came across an odd-looking "flatworm." Bock never got around to identifying the creature, but Einar Westblad, another great platyhelminth specialist, did and initially considered it a free-living archoöphoran platyhelminth, along with similar specimens he had collected near Scotland and Norway. Eventually, in 1949, Westblad described the original specimen as *Xenoturbella bocki*, after its collector (Figure 9.21). The creature caused immediate controversy because of its distinctive appearance. In 1999 a second species was described and named *Xenoturbella westbladi*, but this turned out to be the same species, and thus the name is a junior synonym. The name *Xenoturbella* means "strange turbellarian" because while the creature resembled free-living flatworms overall, its epidermis was reminiscent of hemichordates, and its statocyst seemed similar to that of certain holothuroids.

Since then, five additional species have been discovered and named from the eastern and western Pacific Ocean (Figure 9.22). These worms range in size from a few millimeters to over 20 cm, and they occur in depths from 20 to 3,700 m. Molecular data have shown that xenoturbellids are neither platyhelminths nor closely related to any other nephrozoan phylum, but they are closely related to the Acoelomorpha. Morphological data are in agreement.

Xenoturbella are delicate, free-living, ciliated worms with a very simple body plan. They are easily recognizable by their body furrows: the **horizontal furrows** (= side or anterolateral furrows) and **ring furrow** (= equilateral furrow), the latter nearly crossing the animal's midline (Figure 9.22A). The furrows contain what has been interpreted as high concentrations of sensory cells, so they are presumed to be sensory structures.



Courtesy of G. Rouse

FIGURE 9.21 ***Xenoturbella bocki.*** Live specimen, from 80 m depth, off the west coast of Sweden.

Like acoels and nemertodermatids, xenoturbellids have distinctive epidermal ciliary rootlets and mode of withdrawal of epidermal cells; they possess a diffuse, basi- or intraepithelial nervous system; they use a statocyst for orientation; and they have circular and longitudinal muscles. They possess a midventral mouth, as some acoelomorphs do. Also like acoelomorphs, *Xenoturbella* lack a complete gut, organized gonads, excretory structures, and coelomic cavities, and they have a poorly developed brain. The nervous system is primarily in the form of an intraepidermal nerve net.

However, unlike acoelomorphs, xenoturbellids possess simple spermatozoa, similar to those seen in externally fertilizing species. Also, muscle layers are connected by extensive interdigitations among the layers of cells, and the longitudinal muscles are exceptionally robust. The nervous system, while diffuse, is concentrated along the sensory furrows. Xenoturbellids also are generally larger in size, with some reaching more than 20 cm in length.

As morphological evidence accumulated on *Xenoturbella*, its relationship to flatworms began to be doubted, and by the late 1950s most researchers agreed that *Xenoturbella* was not a flatworm genus. But there was little consensus about what these animals actually were. Opinions on their identity ranged from considering them "among the coelenterates" to placing them in a sister taxon to the enteropneusts. Then, in the late 1990s, analysis of ribosomal RNA from what appeared to be developing oocytes and embryos in some specimens led to the conclusion that *Xenoturbella* was in fact a highly degenerate mollusc, possibly some form of shell-less bivalve. However, subsequent investigations showed that these RNA samples had been contaminated with gut contents containing molluscan DNA. Subsequent DNA studies suggested *Xenoturbella* might be a highly degenerate deuterostome, near the base of the deuterostome line or perhaps closely related to echinoderms and hemichordates. Continued molecular phylogenetic studies have suggested that *Xenoturbella* is closely tied

to acoels and nemertodermatids, and thus the new phylum name Xenacoelomorpha was created to house these three odd, primitive worms.

In 2016 Greg Rouse and colleagues described four new species of xenoturbellids from deep waters of the eastern Pacific (Figure 9.22). A large (>20 cm) species was found in a vesicomyid clam field at 2,890 m depth in Monterey Submarine Canyon (California) and at 1,722 m near a cold-water methane seep in the Gulf of California (Mexico). A second species (~10 cm long) also occurred at 1,722 m in the Gulf of California. A third species (~15 cm long) was found at 3,700 m near a hydrothermal vent in the Gulf of California. The fourth new species was small (~2.5 cm), resembled *X. bocki*, and was found next to the bones of a whale carcass at 631 m in Monterey Canyon. More recently, a sixth species of *Xenoturbella*, *X. japonica*, was added from Japan by Hiroiki Nakano and collaborators (2017), constituting the first finding of the clade in the western Pacific. Whole mitochondrial genome analysis places the three larger species as a sister clade to the smaller Pacific species and *X. bocki*.

The Xenoturbellid Body Plan

General Body Structure

Most specimens of *Xenoturbella* are ovoid in shape, with a flattened ventrum. These worms can be quite active and capable of considerable changes in shape (Figure 9.22B–D). The worms are pink, the anterior region of most individuals being slightly lighter in color, and the horizontal furrows extend posteriorly, on either side, from the head end. Approximately midway down the body, these furrows nearly intersect with a ring furrow. The nervous system appears to be concentrated in these areas, suggesting a sensory function to the structures.

The epidermis of *X. bocki* consists of a layer of tall columnar cells with nuclei situated basally. These cells are densely multiciliated and are interspersed with unciliated or monociliated gland cells and ciliary receptors, the latter being most numerous in the horizontal furrows. The cilia themselves are attached to epidermal cells by several structures (Figure 9.23A). Each cilium ends in a basal body whose protruding **basal foot** has microtubules that extend into the epidermal cell. Two ciliary rootlets project from the basal body deeper into the epidermal cell; the thinner one, located on the same side of the cilium as the basal foot, projects straight into the cell, whereas the thicker rootlet has a kneelike bend. Each cilium has a distinctive arrangement of microfilaments in which the standard 9+2 arrangement extends for most of the ciliary shaft length, but near the end, microfilament doublets 4–7 abruptly end, leaving only doublets 1–3 and 8–9 to continue on to the end of the cilium (Figure 9.23B). This "shelf" arrangement of

for more ebook/ testbank/ solution manuals requests email 9601267344@qq.com

microtubules is also present in Nemertodermatida and Acoela but has not been found in other known metazoan taxa (Figure 9.24).

The basal region of the epidermis houses the cell processes of the multiciliary cells, supporting cells, and a prominent intraepidermal nerve layer. The cell membranes of adjacent epidermal cells intermingle with each other, but tight couplings between the membranes of adjacent extensions do not appear to exist. However, where the cytoplasmic protrusions are shorter, they show a regular arrangement as if the two cells were held together by a zipper, although tight junctions, desmosomes, or gap junctions between cells have yet to be identified.

A number of workers have noted the similarities in both ciliary roots and ciliary tips in *Xenoturbella*, acoels, and nemertodermatids. In all three groups the cilia form a network of interconnecting rootlets. Also as in Acoelomorpha, *Xenoturbella* are capable of withdrawing and resorbing worn-out epithelial cells, although these processes have subtle differences. Whereas nemertodermatids do not withdraw still-motile ciliary cells, the withdrawn epidermal cells in *Xenoturbella* assume an orientation perpendicular to that of the other cells and retain some motility.

(A) Lateral view of the distal shaft showing the "shelf" located approximately 1.5 µm from the cilium tip. (B) Transverse sections of the cilium along its length; a 9+2 arrangement of axonemal fibers begins at the cilium base but microtubule doublets 4–7 end at the shelf.

Support and Movement

Xenoturbella species possess a highly muscular body wall (Figure 9.25A). An outer circular muscle layer surrounds a well-developed inner layer of longitudinal muscles, and radial musculature extends from the gastrodermis to the outer circular layer of muscle cells (Figure 9.25B).

No specialized parenchymal cells exist between the epidermis and the gastrodermis. However, all muscle cells tend to have numerous and well-defined cytoplasmic extensions with extensive mutual interdigitation. Tight attachment of adjacent cell membranes does not appear to exist, but connections resembling the zonula adherens seen in acoels and nemertodermatids are present, as is a fibrous subepidermal layer up to 5 µm thick.

Xenoturbella move by ciliary gliding, without requiring modification of the body profile. The ventral surface is richly supplied with epidermal glands, and

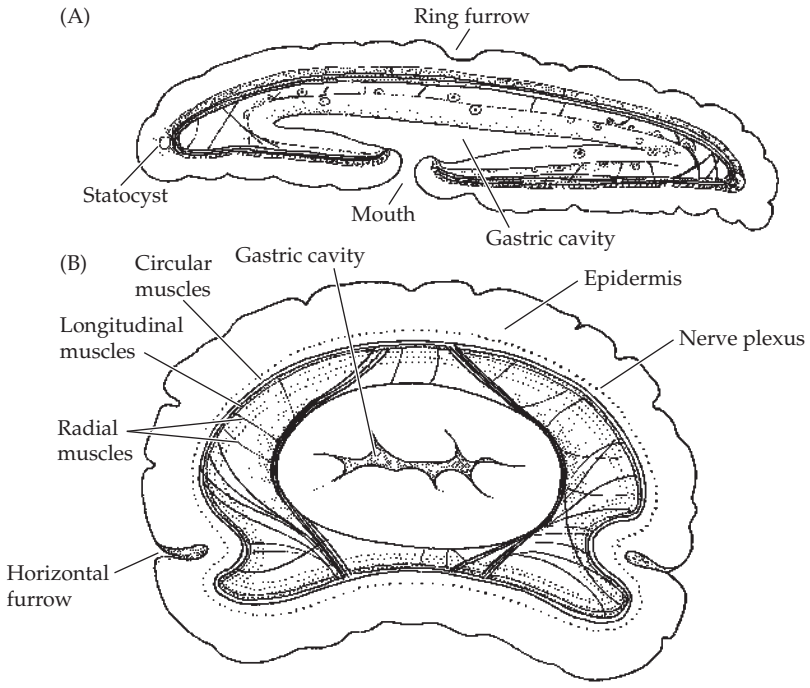

FIGURE 9.25 Internal morphology of *Xenoturbella bocki*. (A) Transverse section anterior to the mouth, showing the gastric cavity. (B) Schematic diagram of longitudinal section anterior to mouth, showing orientation of circular, longitudinal, and radial muscles.

moving animals leave behind a trail of mucus. While they are capable of considerable variation in body configuration due to powerful circular and longitudinal muscles, in most circumstances animals do not require such gymnastics in their basic activities.

Nutrition, Excretion, and Gas Exchange

Feeding by *X. bocki* occurs when individuals open their simple, midventral mouth and protrude their unciliated foregut. Extrusion of this structure appears to take place as a result of contractions of the surrounding body wall musculature, with relaxation of these muscles resulting in foregut retraction. The gut is cellular, but unciliated, and maintains a small cavity. Considerable attention has focused on the gut contents of *Xenoturbella*. Examination of mitochondrial DNA (cytochrome *c* oxidase subunit I sequence data) in the gut contents of *Xenoturbella* suggests that they feed primarily on bivalves, possibly in the form of eggs and benthic larvae. Such specificity suggests that these worms may be specialized predators, a hypothesis supported by the results of stable isotope studies. Two species of endosymbiotic bacteria have been described from the gut of *X. bocki*. Researchers have suggested that these bacteria might assist in nitrogen detoxification (given that excretory organs are lacking) or might supply growth factors or chemical defenses to their hosts. Discrete excretory structures have not been described for *Xenoturbella*.

Nervous System and Sense Organs

The nervous system of *Xenoturbella* is a diffuse intraepithelial (basiepithelial) net with a small anterior concentration forming a small commissural brain. This arrangement is similar to that seen in some acoels and nemertodermatids. The sensory furrows of xenoturbellids appear to have greater concentrations of neurons than other parts of their bodies. Like acoelomorphs, *Xenoturbella* have an anterior statocyst (Figure 9.25A), but the arrangement of muscles and neurons associated with this structure differs in that it appears to be embedded within the nerve net, situated between the epidermis and the muscle layers, rather than specifically supplied with connecting commissures. The statocyst contains motile flagellated cells and a statolith. A frontal pore, continuous with a ventral glandular network, may be homologous with the frontal organ of acoelomorphs.

Reproduction and Development

Xenoturbellids are simultaneous hermaphrodites producing relatively large-diameter, yolky eggs. Neither organized, well-developed ovaries nor testes have been observed in adult individuals. In particular, male gonads appear to consist simply of a layer of male sex cells surrounding the gut. Sperm develop in clumps and appear to be of a "primitive" type, usually associated with external fertilization, wherein spermatids possess a small conical acrosome and a single flagellum. There are no copulatory organs, and gametes appear to be spawned through either the gut or mouth opening. *Xenoturbella* has direct development, as in acoelomorphs, and the hatchlings are elongate/ovoid, swim with a rotating motion with uniform ciliation, and have an apical tuft of cilia. However, no mouth or blastopore has been seen in these juveniles.

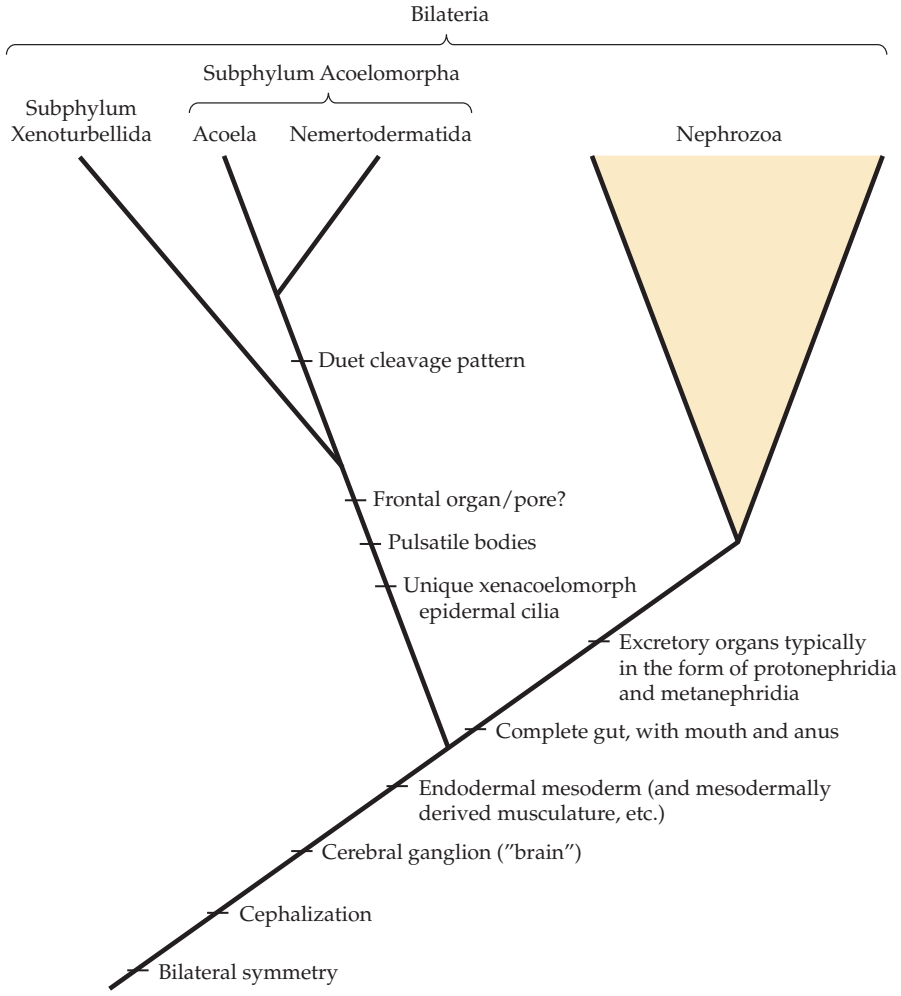

FIGURE 9.26 **The distribution of some important animal features at the base of the bilaterian clade.**

Chapter Summary

This chapter introduced you to one of the most enigmatic animal phyla, composed of relatively simple worms that are now interpreted as the sister group of Nephrozoa and thus often viewed as some of the simplest bilaterians (Figure 9.26). The phylum includes a few hundred species of mostly marine free-living worms (a few inhabit fresh waters, and one is an endosymbiont in sea cucumbers) inhabiting shallow to deep waters. Acoela, with more than 400 known species, is the largest group and a recently established model to study whole-body regeneration. Nemertodermatida has 18 described species, and Xenoturbellida has just 6 species (5 of which were described after 2015). These simple, acoelomate bilaterians have few organs and a largely nonganglionated nervous system. Some lack a true digestive cavity, and all lack an anus and excretory organs. Their development is known only for a few species; all appear to have direct development, and the Acoelomorpha have a unique "duet cleavage" pattern (not reported for xenoturbellids). Important areas of future research for xenacoelomorphs are related to their phylogenetic position (some analyses still support a position within deuterostomes), evo-devo studies of regeneration and body patterning, and better understanding of development (especially in Xenoturbellida).

CHAPTER 10

Protostomia, Spiralia, and the Phylum Dicyemida

This and the following 14 chapters cover an enormous clade of bilaterian animals called Protostomia, and the next 7 chapters treat a subclade of those known as the Spiralia (Box 10A). Early in the evolution of bilaterians the split into two major lineages, which have long been called Protostomia and Deuterostomia, occurred. These groups were named over a century ago, and they were long defined on the basis of embryological principles. In protostomes, the blastopore (the portion in the embryo that typically gives rise to endodermal tissues) was said to give rise to the mouth ("protostome" = mouth first). Typically, in deuterostomes, the blastopore gives rise to the adult anus, the mouth thus forming secondarily at a different location ("deuterostome" = mouth second).

Protostomes and Deuterostomes

As twenty-first-century molecular phylogenetic discoveries began reshuffling animal phyla among the protostome and deuterostome lineages, new views of embryological patterns also emerged. In Deuterostomia (a small group of around 100,000 species in just three phyla—Echinodermata, Hemichordata, and Chordata), the blastopore *does* consistently give rise to the anus, and the mouth forms secondarily. But among the Protostomia, gastrulation is now known to be much more variable than originally thought. In fact, we have learned that in protostomes, while the anus usually does form secondarily, the blastopore does not always give rise to the mouth, especially among animals in the large clade known as Spiralia (annelids, molluscs, nemerteans, and others). And even within Spiralia's sister clade Ecdysozoa, we now know that deuterostomy can occur. For example, both nematomorphs and priapulans appear to have deuterostomous development, with the blastopore giving rise to the anus (at the vegetal pole) and the mouth arising at the animal pole. Gene expression studies have shown that in *Priapulus caudatus*, typical metazoan foregut and hindgut gene expression accompanies this development, and the hindgut/posterior markers *brachyury* (*bra*) and *caudal* (*cdx*) are expressed as the anus emerges from the blastopore. Furthermore, continuing developmental work is revealing that many species of crustaceans also express a form of deuterostomy. And in Chaetognatha gastrulation occurs by invagination of the presumptive endoderm, leaving no blastocoel—the blastopore marks the eventual posterior end of the animal, and both mouth and anus form secondarily, thus also a deuterostomous-like development. In fact, evidence is accumulating that mouth formation from oral ectoderm (in the animal hemisphere), typical of deuterostomy, may be ancestral in both protostomes and deuterostomes, and perhaps in Bilateria itself.

BOX 10A Classification of Bilateria Used in This Book

BILATERIA

Phylum Xenacoelomorpha

NEPHROZOA

PROTOSTOMIA

Spiralia

Phylum Dicyemida (= Rhombozoa)

*Annelida includes Sipuncula, Echiura, and Orthonectida
**Molecular phylogenetic support for a monophyletic Scalidophora is ambivalent
***Paraphyletic (excludes Hexapoda)

So, we see that although the names Protostomia and Deuterostomia are still used for the two clades of Bilateria, the names themselves are no longer perfectly descriptive—they are **legacy names**. It has been suggested that new names should be coined for these two large groups, but as yet there has been no agreement on what those names might be. The 23 phyla belonging to Protostomia include the largest—Arthropoda (over a million described living species) and Mollusca (nearly 80,000 described living species)—and the smallest animal phyla (Micrognathozoa and Cycliophora; one and two described species each, although several undescribed species are known to exist in these small phyla).

Today, the groups Protostomia and Deuterostomia constitute clades based mostly on molecular phylogenetic evidence, and morphological and developmental synapomorphies defining them remain rather ambiguous. A likely ancestral trait of the Protostomia, as it is now constituted, is a central nervous system with a dorsal cerebral ganglion that usually has circumesophageal connectives to a pair of ventral nerve cords. However, there are deviations in this nervous system pattern likely linked to other changes in body morphology that have evolved over the past 500+ million years, especially in sessile and burrowing animals. Probable synapomorphies of Deuterostomia are a trimeric body coelom condition and pharyngeal gill slits, at least primitively (trimery is lacking in the phylum Chordata, and gill slits are absent in extant echinoderms but may have been present in some extinct, stem-group echinoderms). Although still somewhat controversial, the position of the phylum Xenacoelomorpha (acoels, nemertodermatids, and *Xenoturbella*) appears to be basal within Bilateria, this group not aligning strongly with either protostomes or deuterostomes (Box 10A), although some studies have placed xenacoelomorphans within deuterostomes. Protostomes and deuterostomes are viewed as sister groups comprising a clade called Nephrozoa.

Spiralia and Ecdysozoa

Protostomes are composed of two subclades—Spiralia (15 phyla) and Ecdysozoa (8 phyla). Like Protostomia, these clades

for more ebook/ testbank/ solution manuals requests, email 9601267345@qq.com

are based primarily on molecular phylogenetics. However, it is likely that spiral cleavage is an ancestral trait for the Spiralia even though it has been lost or modified in some phyla (e.g., the three lophophorate phyla). Spiral cleavage does not occur outside Spiralia, and it does occur in at least some members of the three main spiralian subclades: Gnathifera, Rouphozoa, and Lophotrochozoa. Although not all members of the clade Spiralia demonstrate clear spiral cleavage, we retain the term as a well-known legacy name. Spiral cleavage was described in Chapter 4, but to remind you—it is a highly stereotyped embryo cleavage pattern in which the 4d cell (the "mesentoblast") gives rise to most of the mesoderm of the adult individual. A caveat of gnathiferan development is that no one has yet been able to determine cell fates, and only a superficial report of spiralian development for a species of gnathostomulid is available. Many spiralians also generate some mesoderm from micromeres of the second or third quartet that are primarily responsible for ectoderm formation (thus it is called ectomesoderm) and this commonly gives rise to larval musculature. Also, in spiral cleavage the embryonic cell divisions shift between dextral and sinistral cleavages in an alternating chirality pattern of development. Spiralia is an ancient clade, and fossils from the Ediacaran Period Doushantuo Formation (China) have even been interpreted as spiral-cleaving embryos.

Some spiral-cleaving animals have a unique larval type, called the trochophore larva (e.g., Mollusca, Annelida, and possibly some others), and the clade name "Trochozoa" has been proposed for those phyla, although this clade gets very mixed support in molecular trees and appears not to be monophyletic. The phylogenetic relationships of the spiralian phyla remain to be sorted out, and so far their deep ancestry has defied clear resolution. However, several clades within Spiralia do seem to be well supported, and we recognize these (see Box 10A). Thus, we identify two main subclades of spiralians (excluding Dicyemida)—Gnathifera (4 phyla; see Chapter 11) and Platytrochozoa (10 phyla; covered in Chapters 12–17). Ecdysozoans are covered in Chapters 18–24.

The Phylum Dicyemida (= Rhombozoa)

Dicyemidans were first described by A. Krohn in Germany in 1839.[1] But it was not until 1876 that a careful study of these unusual creatures was published by the Belgian zoologist Edouard van Beneden. He was convinced that these odd symbionts represented a "link" between the protists and the Metazoa, and it was van Beneden who coined the name "Mesozoa" (= middle animals) to emphasize this point of view, although that name and concept have no phylogenetic basis. Stunkard (1982) considered the phylum (which he called Rhombozoa, to avoid confusion with the order Dicyemida) as a class of "Mesozoa" comprising the orders Dicyemida and Heterocyemida. Most workers today no longer use these two orders and, instead, recognize three families: Conocyemidae, Dicyemidae, and Kantharellidae.

Dicyemidans have a simple, solid body construction—there are no body cavities or differentiated organs. No symmetry exists. An outer layer of somatic/nutritive cells surrounds an inner reproductive cell. Species that have been examined lack a layered extracellular matrix (EMC) and basement membrane, although type IV collagen (localized intracellularly) has been shown by immunolabeling and further studies are needed. All are obligate symbionts in the renal sacs of cephalopod molluscs. Over 120 species have been described, from about 40 species of cephalopods. However, based on the number of known cephalopod species yet to be examined for these symbionts, it is likely that a great many dicyemidans remain undescribed. Infection rates of cephalopods are higher in temperate seas than in the tropics/subtropics. Most of the described dicyemidans live in benthic octopuses, but *Dicyemennea gracile* is a symbiont in cuttlefish of the genus *Sepia*.

The current protocols for recognizing species of dicyemidans, based on morphological traits, appear inadequate. Using molecular methods, Eshragh and Leander (2015) showed that multiple "species" of dicyemidans, from three species of cephalopods, were actually a single polymorphic species in each host. This suggests that the ~120 described morphospecies (based largely on the anatomy of the polar cap) could be a considerable overestimate, and most hosts may harbor only a single species of dicyemidan.

Recent molecular studies—including sequencing of 18S rRNA and other genes, the presence of the *Dox*C gene (which encodes a spiralian peptide), and patterns of Hox (and other genes) expression—all suggest that dicyemidans are probably highly reduced and specialized symbionts in the protostome clade Spiralia. Beyond that, however, their phylogenetic ties remain uncertain. It is quite possible that by the fifth edition of *Invertebrates*, we will have discovered that these odd little creatures are highly specialized symbionts belonging to another spiralian phylum.

Anatomy and Biology of Dicyemidans

Adult dicyemidans are very small, just 0.5 to 3 mm long (see Box 10B). They have from about 9 to 41 body

[1]We use the diminutives "dicyemidan" for the phylum name, and "dicyemid" for the family name.

BOX 10B Characteristics of the Phylum Dicyemida

1. Small (0.5–3 mm), poorly understood, obligate symbionts that live in the renal sacs of cephalopods (octopuses, squids, and cuttlefish); life outside cephalopod hosts is unknown
2. Body simple, asymmetrical, and with a solid construction; without body cavities or differentiated organs
3. Young dicyemidans swim in the host's urine by ciliary action, but when they mature they attach to the inner lining of the nephridia by their polar caps; feed by consuming particulate and molecular nutrients from the host's urine
4. An outer layer of somatic/nutritive cells surrounds a large inner reproductive cell (the axial cell), in which there are smaller cells called axoblasts that float in the cytoplasm
5. Two adult forms known: nematogens produce vermiform embryos asexually from an agamete in the axoblasts of the axial cell; sexually motivated vermiforms are rhombogens, which produce two distinct types of infusoriform embryos (sometimes called larvae) from fertilized eggs
6. Molecular studies suggest dicyemidans may be highly reduced and specialized symbionts in the clade Spiralia

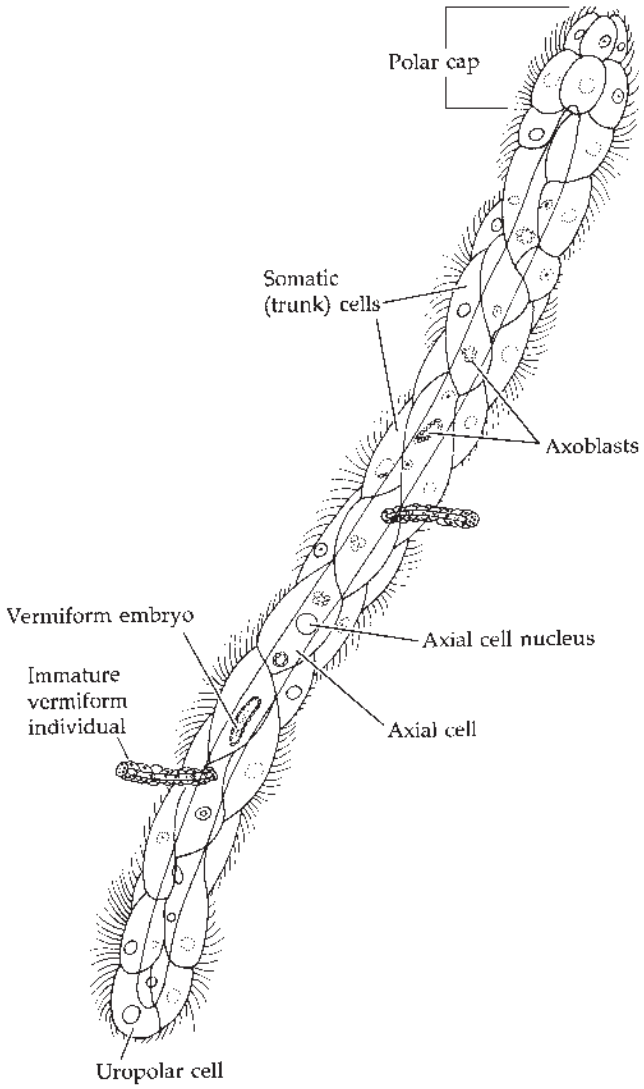

FIGURE 10.1 Nematogen of *Dicyema* (Dicyemida).

cells, depending on the species—one of the smallest cell counts among the Metazoa. As in other Bilateria, dicyemidans have been shown to have three types of cell-cell junctions: septate, adherens, and gap junctions. There are two adult forms, **nematogens** and **rhombogens** that have nearly the same organization but that produce two distinct types of embryos (which are sometimes called "larvae").[2] Nematogens produce **vermiform embryos** asexually from an agamete in the axoblast (see the Life Cycles section), whereas rhombogens sexually produce **infusoriform embryos** from fertilized eggs.

The body of a nematogen consists of an outer sheath of 8–40 ciliated **somatic cells**, the number of which has been constant for most, but not all, species that have been examined, and a single long, interior **axial cell** which is covered by the outer somatic cells (Figure 10.1).[3] The axial cell contains a large polypoid nucleus and intracellular stem cells called **axoblasts**. Eight or nine somatic cells at the anterior end form a distinctive **polar cap** (or **calotte**). Immediately behind the polar cap are two **parapolar cells**. The rest of the somatic cells are sometimes called "trunk cells"; the two posterior-most cells are the **uropolar cells**.

Young dicyemidans are motile and swim about in the host cephalopod's urine by ciliary action. The adults, however, attach to the inner lining of the nephridia by their polar caps. There is no conclusive evidence that these animals cause damage to their hosts, but when present in very high numbers they may interfere with the normal flow of fluids through the nephridia. They attach by inserting the polar cap into renal tubules or crypts of the host's kidney. Nematogens consume particulate and molecular nutrients from the host's urine by phagocytotic and pinocytotic action of their somatic cells. Once the adult has attached to the host, the somatic cilia might serve to keep fluids moving over the body, bringing nutrients

[2]Because the reported differences between rhombogens and nematogens are not consistently found, some workers prefer to simply call them sexual and asexual vermiform adults, respectively.

[3]Constancy in the number of cells (in a given organ, or in the entire body of an animal) is called "eutely," and it is a feature of certain microscopic or near-microscopic animals.

for more ebook/ testbank/ solution manuals requests Email: 9601267384@qq.com

in contact with the surface cells. Although in nature dicyemidans appear to be obligatorily associated with cephalopods, they have been successfully maintained in experimental nutrient media.

Life Cycles

What we know so far about dicyemidan life history is rather bizarre, and the stages of the dicyemidan life cycle that occur outside the host are still incompletely known. The host-dwelling portion of the life cycle includes both asexual and sexual processes, but without a regular alternation between them. Adult dicyemidans thus produce two kinds of offspring. The name "dicyemid" derives from the presence of these two different types of embryos during their life cycle. The nematogen stage produces the vermiform embryo formed asexually as axoblasts develop into **agamete cells**; these grow to become new worms (the nematogens and rhombogens) in the renal sac of the host. Vermiform stages consist of an axial cell and a single layer of 8 to 30 ciliated peripheral cells (a number that is constant for a species). The rhombogen stage produces the **infusoriform embryos**, which develop from fertilized eggs produced around hermaphroditic "gonads" called **infusorigens**, and these eventually escape the host to enter the sea. Infusoriforms consist of 37 to 39 cells, including 4 large internal cells known as urn cells, each containing a germinal cell. There is evidence that a high population density in the renal sac may cause the shift from asexual to sexual reproduction, the infusoriform embryos escaping from the renal sac in search of a new host. How they find their new hosts is unknown. Notably, in sexual reproduction, both fertilization and embryonic development occur within the worm's body.

Asexual reproduction is curious indeed. The cytoplasm of the single axial cell of the nematogen contains numerous tiny cells called **axoblasts**. Immature vermiform organisms are produced asexually by an embryogeny-like process of these individual axoblast cells within the parent axial cell (see Figures 10.2 and 10.3). The first division of an axoblast is unequal and produces a large presumptive axial cell and a small

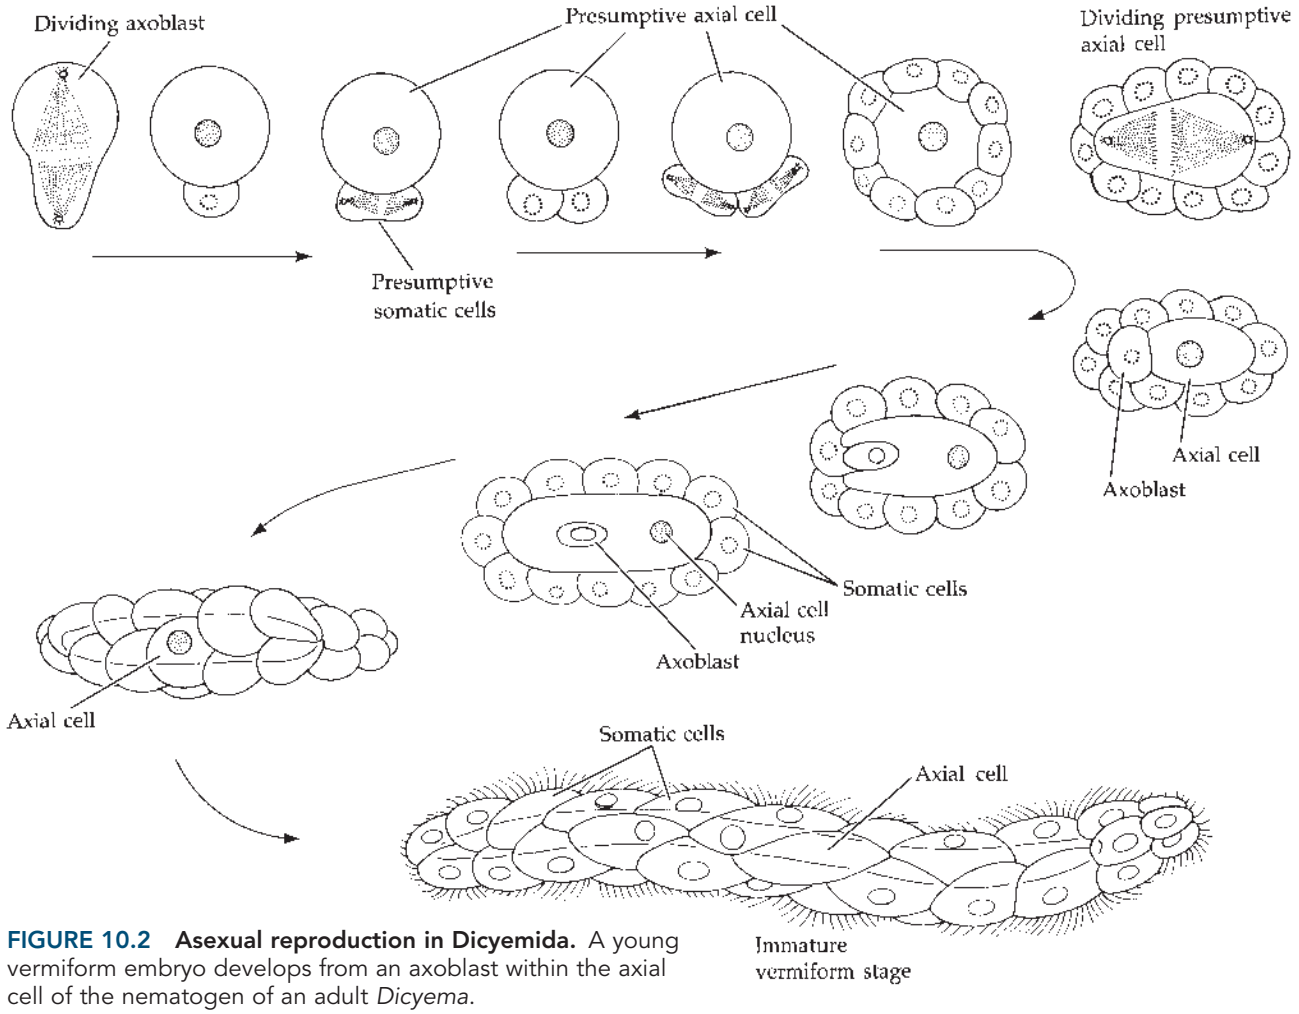

FIGURE 10.2 Asexual reproduction in Dicyemida. A young vermiform embryo develops from an axoblast within the axial cell of the nematogen of an adult *Dicyema*.

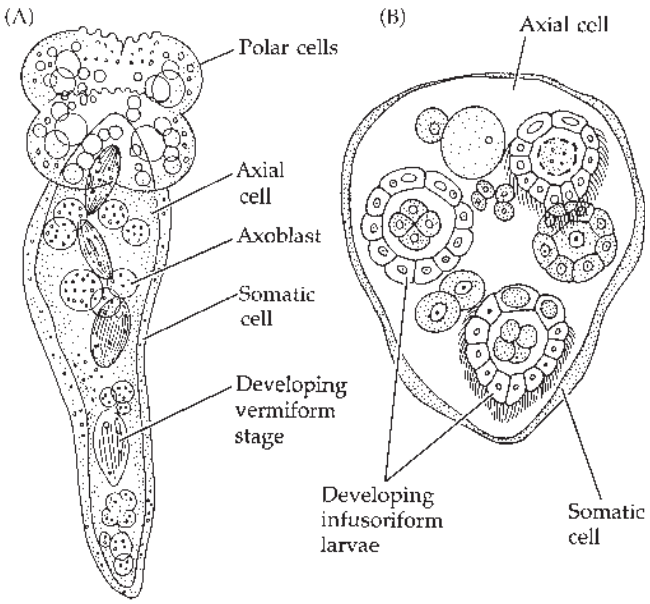

FIGURE 10.3 The dicyemidan *Conocyema*.

presumptive somatic cell. The presumptive somatic cell divides repeatedly, and its daughter cells move by an epiboly-like process (rapid growth of animal pole ectodermal cells to from a sheetlike covering to the vegetal cells) to enclose the presumptive axial cell, which has not yet divided. When this inner cell finally does divide, it does so unequally, and the smaller daughter cell is then engulfed by the larger one! The larger cell becomes the progeny's axial cell proper with its single nucleus, and the smaller engulfed cell becomes the progenitor of all future axoblasts within that axial cell. The "embryo," which now consists of its own central axial cell surrounded by somatic cells, elongates, and the somatic cells develop cilia. The resulting structure is a miniature vermiform organism. The immature vermiform organism leaves the parent nematogen and swims about in the nephridial fluids. Eventually it attaches to the host and enters the adult stage of the life cycle.

Once the vermiform adults become sexually "motivated," they are called rhombogens, and their somatic cells usually enlarge as they become filled with yolky material (Figure 10.4 and chapter opener photo). The axoblast of a rhombogen develops into multicellular structures called **infusorigens**, each consisting of an outer layer of ova and an inner mass of sperm (Figure 10.4B). The infusorigens are retained within a vacuole of the parent's axial cell, and they are functionally hermaphroditic gonads. In each infusorigen, the centrally located sperm fertilize the peripherally arranged ova, each zygote then developing into a ciliated infusoriform larva (Figure 10.4C). This embryo has a fixed number of cells; the two anterior-most cells—called apical cells—contain high-density substances within their cytoplasm. The rest of the surface cells are ciliated and form a sheath around a ring of capsule cells, which in turn enclose four central cells. The number of infusorigens, and the embryos they produce, seems to be related to the size of the adult rhombogen. The infusoriform embryos escape from the parent vermiform adult and pass out of the host's body with the urine.

The development of several species has been studied, and there is no clear evidence of germ-layer formation

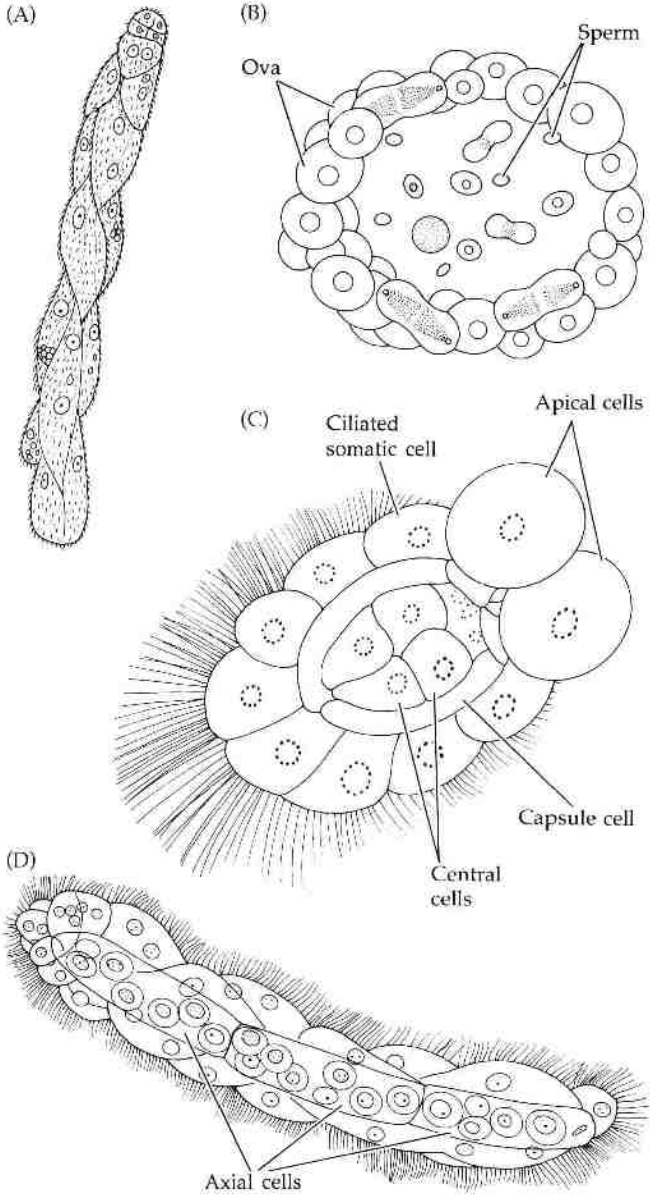

FIGURE 10.4 Sexual reproduction in Dicyemida.

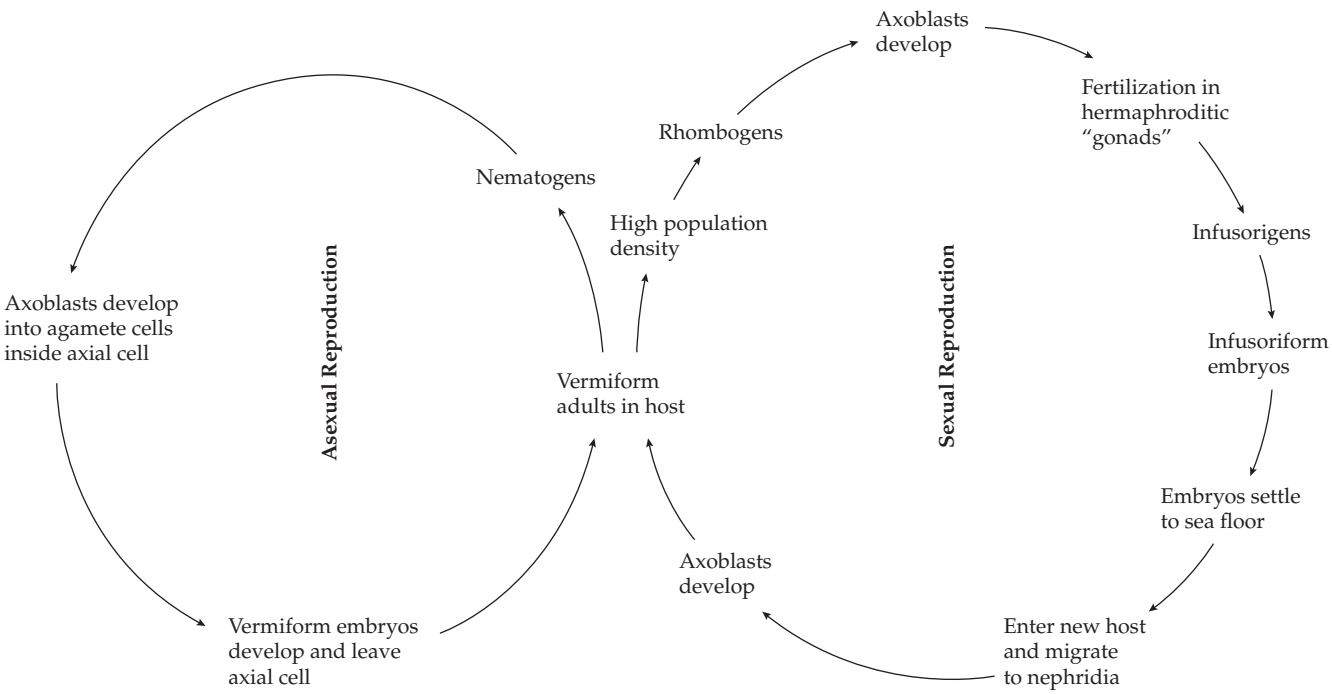

FIGURE 10.5 **Life cycle of a dicyemidan, illustrating the two pathways of sexual and asexual reproduction.**

in the development of the infusoriform embryo, with a rough distinction only as outer and inner cells. The outer cells occupy the dorsal and caudal surfaces of the embryo, and the inner cells are derived from the blastomeres of the vegetal hemisphere. The innermost germinal cells are derived from the cells that form the vegetal pole. The cleavage pattern of sexually produced embryos in *Dicyema japonicum* has been described as holoblastic and spiral, although it is not a typical kind of spiral cleavage. A cavity (the urn cavity) appears among the ventral internal cells, but this small space is interpreted to appear secondarily and not to be a blastocoel.

The events of the dicyemidan life cycle that occur outside the cephalopod host remain a mystery. Some workers have held to the view that the infusoriform embryo enters an intermediate host (presumably some benthic invertebrate), but most of the evidence to date suggests that this is not the case. While much remains to be learned, the following scenario seems plausible. After leaving the host, the infusoriform embryo sinks to the bottom of the ocean—the dense contents of the apical cells serving as ballast. The embryo, or some persisting part of the embryo (perhaps the innermost four cells), enters another cephalopod host. This infectious individual travels through the host, probably via the circulatory system, and enters the nephridia, where it becomes a so-called stem nematogen (Figure 10.4D). The stem nematogen is similar to the vermiform adult except that the former has three axial cells rather than one. Axoblasts within the axial cells of the stem nematogen give rise to more vermiform adults, just as the axoblasts within the adults described earlier did. The vermiform adults produce more individuals like themselves until the onset of sexual reproduction is triggered again, presumably by the high population density. This putative life cycle is schematically represented in Figure 10.5.

Chapter Summary

This chapter introduced you to large and important clades within the Bilateria (i.e., Protostomia and Spiralia) and to the enigmatic phylum Dicyemida (= Rhombozoa). In protostomes, while the anus usually forms secondarily, the blastopore does not always give rise to the mouth, especially among animals in the large clade known as Spiralia. Thus, the clade Protostomia is based primarily on molecular phylogenetic evidence, and morphological and developmental synapomorphies are rather ambiguous. A likely ancestral trait of the Protostomia is a central nervous system with a dorsal cerebral ganglion that usually has circumesophageal connectives to a pair of ventral nerve cords. However, there are deviations in this nervous system pattern likely linked to other changes in body morphology that have evolved over the past 500+ million years. Protostomes

(*Continued*)

Chapter Summary (*continued*)

are composed of two subclades—Spiralia (15 phyla) and Ecdysozoa (8 phyla). Like Protostomia, these clades are also based primarily on molecular phylogenetics, although several synapomorphies may be present in Ecdysozoa, especially in relation to the molting of the cuticle and the lack of locomotory cilia. However, it is likely that spiral cleavage is an ancestral trait for the Spiralia even though it has been lost or modified in many spiralian phyla (e.g., rotifers, chaetognaths, gastrotrichs, and the three lophophorate phyla). Important future research areas are the resolution of phylogenetic relationships within Protostomia and Spiralia.

The spiralian phylum Dicyemida has a simple, solid body construction, without symmetry, body cavities, or differentiated organs. An outer layer of somatic/nutritive cells surrounds an inner reproductive cell. All dicyemidans are obligate symbionts in the renal sacs of cephalopod molluscs, with over 120 species described. Future research should address the phylogenetic relationship of Dicyemida among the other spiralians and unravel the full life history of dicyemidans, especially outside the body of the host cephalopods.

CHAPTER 11

Gnathifera

The Phyla Gnathostomulida, Rotifera (including Acanthocephala), Micrognathozoa, and Chaetognatha

The spiralian protostome clade Gnathifera includes four phyla: Gnathostomulida, Rotifera (including the Acanthocephala), Micrognathozoa, and Chaetognatha. The name is derived from the Greek *gnathos*, "jaw," and the Latin *fera*, "to bear," and it refers to the presence of pharyngeal hard parts or "jaws." While jaws are present in most gnathiferan species, some derived lineages lack them, the assumption being they have been lost secondarily. Despite the small size of many (e.g., gnathostomulids, rotifers, and micrognathozoans), gnathiferans show a remarkable complexity of anatomy, especially in their jaw structures. Although the relationships of the four phyla among themselves are yet to be fully resolved, the composition of the jaws, built of translucent rods with an electron-dense core, and the jaws having pincers caudally articulating into unpaired pedicles (absent in chaetognaths), are unifying features of the clade. The organization of the muscular and nervous systems of gnathiferans is also very similar.

Until the mid-1990s, the Gnathostomulida and Rotifera were pooled together with other microscopic taxa in artificial groups such as "Aschelminthes" or "Nemathelminthes"—catchall categories that were more or less solely characterized by being microscopic taxa with uncertain phylogenetic positions. At that time the Acanthocephala was treated as a distinct phylum; but despite their macroscopic size and endoparasitic biology, they were already considered closely related to the Rotifera based on ultrastructural similarities in their integument. During the 1990s, a number of researchers began to

The sections on Gnathostomulida and Rotifera were revised by Martin Vinther Sørensen. The section on Micrognathozoa was revised by Katrine Worsaae and Reinhardt Møbjerg Kristensen. The section on Chaetognatha was revised by George Shinn.

investigate the phylogenetic positions of the aschelminth phyla. In 1995, two important papers (by W. H. Ahlrichs, R. M. Rieger, and S. Tyler) suggested a sister-group relationship between Gnathostomulida and Rotifera, based on a proposed homology between the jaws in the two groups. The homology was supported by ultrastructural data from transmission electron microscopy that demonstrated jaws in both taxa that were composed of rodlike elements that in cross section appear as translucent areas with a central, electron-dense core. Ahlrichs referred to this grouping as Gnathifera, and he further suggested that the endoparasitic acanthocephalans were actually highly modified rotifers.

At the same time that Gnathifera was taking its shape, a new kind of animal was discovered in mosses from a cold spring in Greenland. It was a tiny, microscopic invertebrate that in some respects resembled a rotifer, and in other ways a gnathostomulid, but also possessed several characteristics that were not found in any other groups. Transmission electron microscopy showed that the ultrastructure of the jaws was nearly identical with that of Rotifera and Gnathostomulida. But the new creatures' jaws were even more complex and had more elements than those found in the two other gnathiferan phyla. In 2000, six years after its discovery, R. M. Kristensen and P. Funch named the animal *Limnognathia maerski* and assigned it to a new animal group, Micrognathozoa, which three years later was recognized as a third gnathiferan phylum.

Molecular phylogenetics strongly suggests Rotifera is the sister group to Micrognathozoa, and they also share similarities in the ultrastructure of their integuments. Both free-living rotifers and acanthocephalans have a syncytial epidermis in which the outer cuticle has been replaced by an intracellular protein lamina in the epidermal cells. Micrognathozoa has a regular nonsyncytial epidermis, but a similar intracellular protein lamina is found in its dorsal epidermal plates, and the presence of this lamina is considered synapomorphic for Micrognathozoa and Rotifera. In addition, the sister-group relationship of rotifers and micrognathozoans is supported by a large array of neuroanatomical characters and by the presence of a skeletal lamina in rotifers and in the dorsal epithelium of micrognathozoans.

Based on ultrastructural similarities in their integuments, the microscopic rotifers and the macroscopic acanthocephalans had long been considered as likely sister taxa. However, evidence from molecular studies shows that Acanthocephala is not the sister group of Rotifera, but actually evolved from within the Rotifera—presumably as a clade that became obligately endoparasitic and subsequently went through a series of dramatic morphological modifications and changes. Modern acanthocephalans are so modified and adapted to their endoparasitic lifestyle that it is hard to find comparative morphological characters that would place them inside Rotifera, but the molecular support is strong and includes studies based on selected target loci and transcriptomes, as well as the complete mitochondrial genomes. Indeed, the sister group of Acanthocephala appears to be Seisonidea, also parasitic, and the two in turn comprise the sister group to Bdelloidea.

The first record of an arrow worm was by the Dutch naturalist Martinus Slabber in 1775, but the name Chaetognatha was not proposed until 80 years later by the German zoologist Rudolf Leuckart (in 1854). The systematic position of the group has been hotly debated ever since. Arrow worms have been at times allied with molluscs, arthropods, and certain blastocoelomates (particularly nematodes). For many years chaetognaths were considered deuterostomes, based on developmental features and their tripartite body coelom. But their placement among the deuterostomes never seemed a fully comfortable match. Even the American zoologist Libbie Hyman, while treating them as deuterostomes, found it a less-than-perfect fit. Modern research is beginning to resolve some long-standing issues. For example, arrow worms are, without doubt, coelomate animals (other gnathiferans are acoelomate or blastocoelomate), and molecular phylogenetics has clearly shown them to be protostomes. The coelomate nature of arrow worms was revealed by early embryological studies, but it took transmission electron microscopy to demonstrate that the adult body cavities are completely lined by mesodermally derived tissues.

In the late 1990s morphological arguments were made that chaetognaths are gnathiferans, based partly upon the proposed homology between their movable grasping spines and the buccal apparatus of rotifers, gnathostomulids, and micrognathozoans. An analysis of Hox genes (in 2017) also identified similarities between Chaetognatha and Rotifera (although gnathostomulids and micrognathozoans were not included in that analysis). In 2019, two phylogenomic analyses using large data sets also suggested they are part of the Gnathifera clade, perhaps even the sister group to the remaining gnathiferans. In addition, it has been proposed that the high chitin content of the spines and teeth, and the structures of the chitinous cuticle of the chaetognath head could be homologous with the chitinous parts and membranes of the pharynx in gnathiferans. Although we include Chaetognatha in the clade Gnathifera, the exact position of this phylum is still not fully resolved, and we look forward to new information and ideas on their relationships over the coming years. Chaetognaths, of course, exhibit classical deuterostome embryological features such as formation of the mesoderm from the gut (enterocoely) and secondary opening of the mouth, although they are

for more ebook/testbank/solution manuals requests, email 9601267344@qq.com

now regarded as members of the Protostomia. The sister group of Gnathifera remains unclear.

In 1911, the American paleontologist Charles Walcott described *Amiskwia sagittiformis* from the middle Cambrian Burgess Shale as a chaetognath. The 7–31 mm creature had a conspicuous head with tentacles, hard gnathiferan-like jaws with 8 to 10 teeth, an elongate trunk, and lateral and caudal fins. It was later claimed to be a nemertean worm or perhaps a mollusc, and then still later deemed "unassignable" to any modern phylum. Quite recently, *Amiskwia* was again reassigned to Chaetognatha, based in part upon its bilaterally arranged set of head structures that have been interpreted as jaws situated within an expanded pharyngeal complex (said to be homologous with those of gnathiferans). However, a reevaluation in 2019 examined Walcott's original 5 specimens and 21 previously unpublished specimens from the same locality and concluded that while *Amiskwia* is a gnathiferan, it may not be a chaetognath. Arguing against it being a crown chaetognath, *Amiskwia* possessed cephalic tentacles and lacked the external grasping spines diagnostic of modern chaetognaths. Although the precise assignment of *Amiskwia* remains elusive, it seems reasonably certain that it belongs to the clade Gnathifera, either as a stem chaetognath or as some other gnathiferan creature. A second species, *Amiskwia sinica*, has been described from the lower Cambrian of China. Importantly, these and other fossils show that lower and middle Cambrian fauna of >500 million years ago included large coelomate spiralians.

Phylum Gnathostomulida: The Gnathostomulids

The phylum Gnathostomulida (Greek, *gnathos*, "jaw"; *stoma*, "mouth") includes about 100 species of minute vermiform hermaphroditic animals (Figure 11.1). These meiofaunal creatures were first described by Peter Ax in 1956 as free-living platyhelminths (then referred to as turbellarians) but given their own phylum rank by Rupert Riedl in 1969. Gnathostomulids are found worldwide, interstitially in marine sands mixed with detritus, from the intertidal zone to depths of hundreds of meters. These interstitial worms vary in body length, from 320 µm in *Problognathia minima* and up to typically 2 mm in the long and slender filospermoids. The longest, *Haplognathia belizensis*, reaches a body length of 3.6 mm! The gnathostomulid body is usually divisible into head, trunk, and in some species a narrow tail region. Distinguishing features of this phylum include a unique jawed pharyngeal apparatus and monociliated epidermal cells (Box 11A). The currently described 100 species and 26 genera are divided into two orders.

GNATHOSTOMULIDA CLASSIFICATION

ORDER FILOSPERMOIDEA Body usually very elongate, with slender rostrum; jaws relatively simple; male parts without injectory penis; sperm filiform (with one 9+2 flagellum); female parts without vagina and bursa. (3 genera: *Cosmognathia*, *Haplognathia*, and *Pterognathia*)

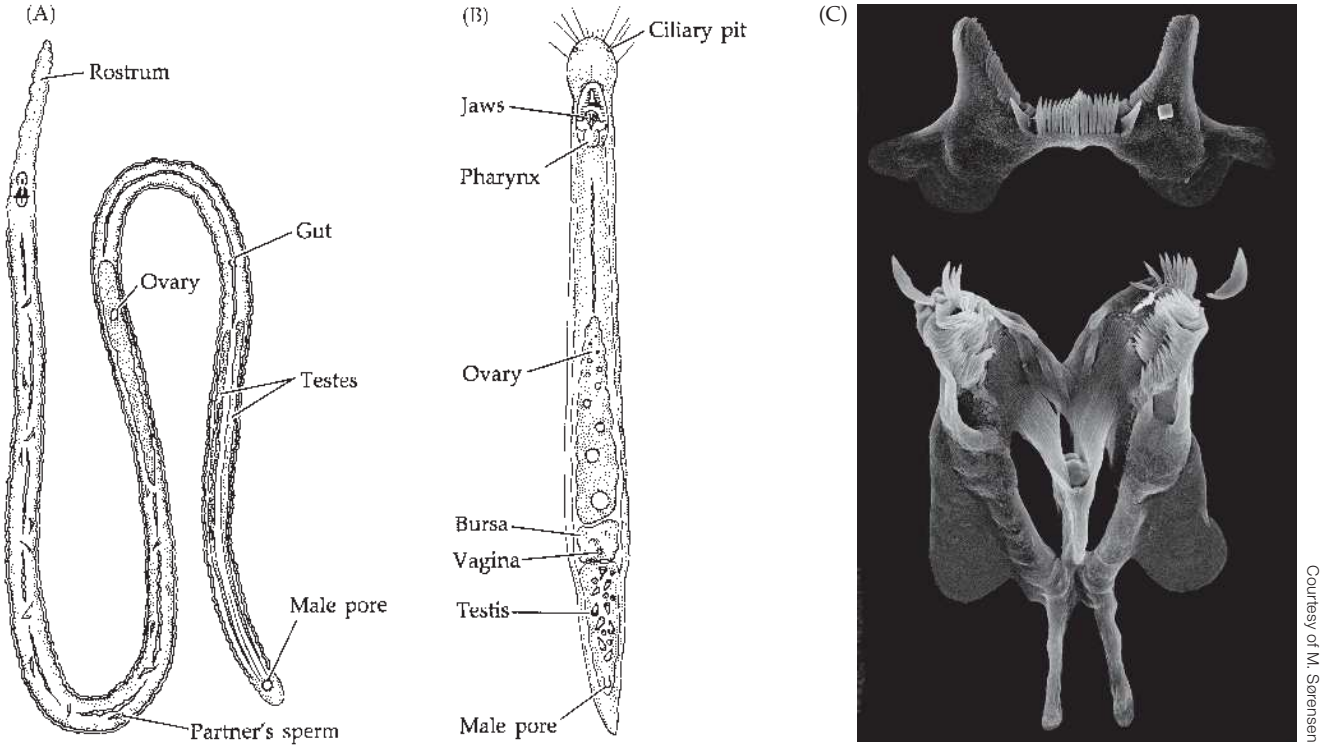

FIGURE 11.1 Representative Gnathostomulida. (A) *Haplognathia simplex*. (B) *Austrognatharia kirsteueri*. (C) Basal plate and jaws of *Gnathostomula armata*. (A,B after W. E. Sterrer. 1972. *Syst Zool* 21: 151–173.)

BOX 11A Characteristics of the Phylum Gnathostomulida

1. Triploblastic, bilateral, unsegmented, vermiform acoelomates
2. Epidermis monolayered; all epithelial cells monociliated
3. Gut incomplete (anus rudimentary, vestigial, or absent)
4. Pharynx with unique, complex jaw apparatus
5. Without circulatory system or special gas exchange structures
6. Excretion through protonephridia with monociliated terminal cells
7. Hermaphroditic
8. Cleavage spiral and development direct
9. Found in marine, interstitial environments

ORDER BURSOVAGINOIDEA Body usually not extremely elongate relative to width; head with shorter rostrum and often a constriction in the neck area; jaws complex; male parts with penis, with or without a stylet; sperm cells aflagellate, either dwarf cells or giant conuli; female parts with bursa and usually a vagina. (23 genera, including *Agnathiella*, *Austrognatharia*, *Gnathostomula*, and *Onychognathia*)

The Gnathostomulid Body Plan

Body Wall, Support, and Locomotion

Each outer epithelial cell bears a single cilium by which the animal moves in a gliding motion. This condition has received special attention, as it is not common among protostomes. Movement is aided by body contortions produced by the contraction of thin strands of subepidermal (cross-striated) muscle fibers. These actions, plus reversible ciliary beating, facilitate twisting, turning, and crawling among sand grains and allow limited swimming in some species. Mucous gland cells occur in the epidermis of at least some species. The body is supported by its more or less solid construction, with a loose mesenchyme filling the area between the internal organs.

Nutrition, Circulation, Excretion, and Gas Exchange

The mouth is located on the ventral surface at the "head-trunk" junction and leads inward to a complex muscular pharynx armed with pincerlike jaws and in some species an unpaired anterior basal plate (Figure 11.1). Curiously, the two known species of the genus *Agnathiella* have no jaws at all. Gnathostomulids ingest bacteria and fungi by snapping actions made by the jaws or by scraping with the basal plate. The pharynx connects with a simple, elongate, saclike gut. A permanent, functional anus is not present, but in a few gnathostomulids a tissue connection between the posterior end of the gut and the overlying epidermis has been observed. This enigmatic feature has been variously interpreted as either a temporary anal connection to the exterior, as the remnant of an anus that has been evolutionarily lost, or as an incipient anus that has yet to fully develop.

Gnathostomulids depend largely on diffusion for circulation and gas exchange. The excretory system is composed of serially arranged protonephridia that stretch from the pharyngeal region to the terminal end of the body. Like the epithelial cells, the protonephridial terminal cells are monociliated.

Nervous System

The nervous system is intraepidermal and unsegmented. It consists of a brain, a buccal ganglion, and up to four dorsal and five ventral longitudinal nerve cords, connected by up to three commissures. Various sensory organs, such as sensory ciliary pits and stiff sensoria formed by groups of joined cilia from monociliated cells, are concentrated in the head region. Gnathostomulid specialists have attached a formidable array of names to these structures, which are of major taxonomic significance.

Reproduction and Development

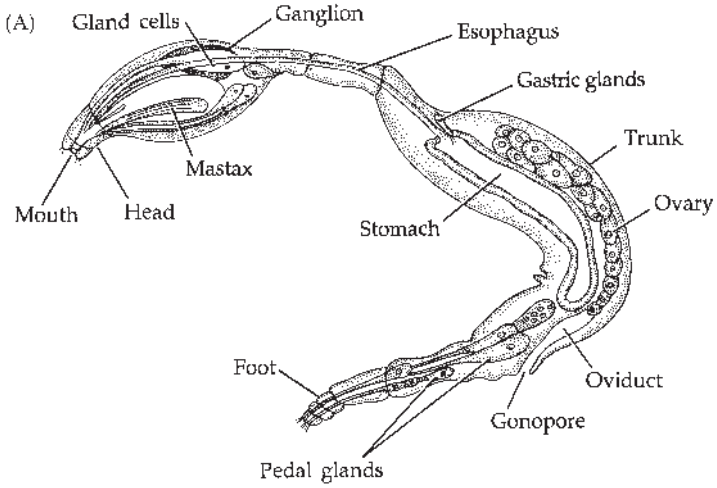
Gnathostomulids are hermaphrodites. The male reproductive system includes one or two testes generally located in the posterior part of the trunk and tail; the female system consists of a single large ovary (Figure 11.1). Members of the order Bursovaginoidea possess a vaginal orifice and a sperm-storage bursa, both associated with the female gonopore, and a penis in the male system; members of the order Filospermoidea lack these structures.

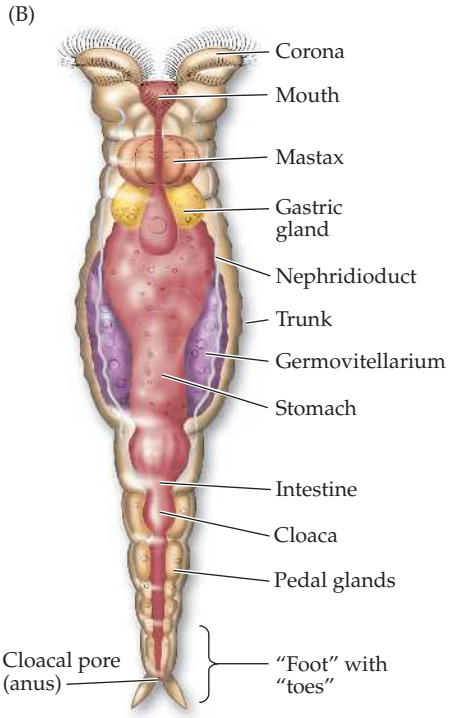
Mating has been only superficially studied in gnathostomulids. Although the method of sperm transfer is not certain, suggestions include filiform sperm of filospermoid gnathostomulids boring through the body wall. Among some bursovaginoid gnathostomulids, sperm is transferred directly to the mating partner's bursa by hypodermic impregnation via the sclerotized penis stylet. In any case, these animals appear to be gregarious, to rely on internal fertilization, and to deposit zygotes singly in their habitat. Cleavage is reported as spiral, and development is direct, but clear details on embryonic and juvenile development are scarce.

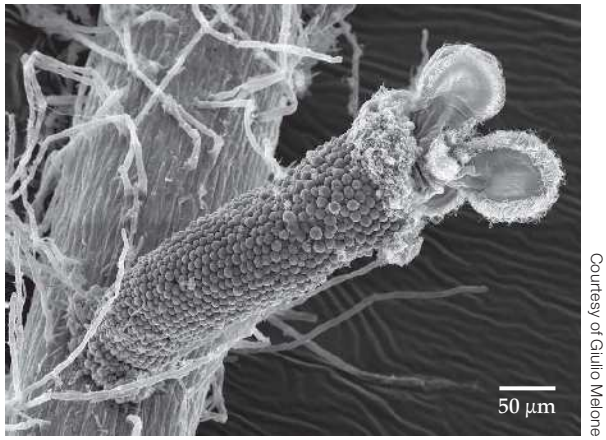
Phylum Rotifera: The Free-Living Rotifers

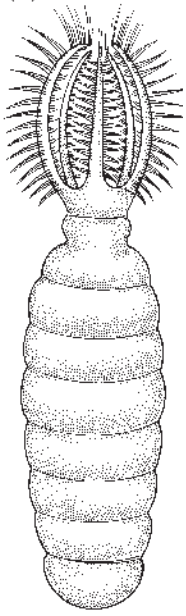
The phylum Rotifera (Latin *rota*, "wheel"; *fera*, "to bear") includes around 2,150 described species, most of which are microscopic (100 to 1,000 μm long) and

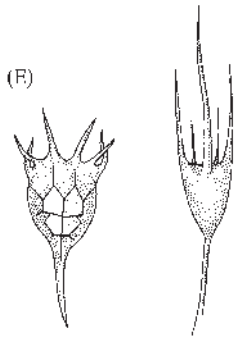
for more ebook/testbank/solution manuals requests, email 9601267344@qq.com











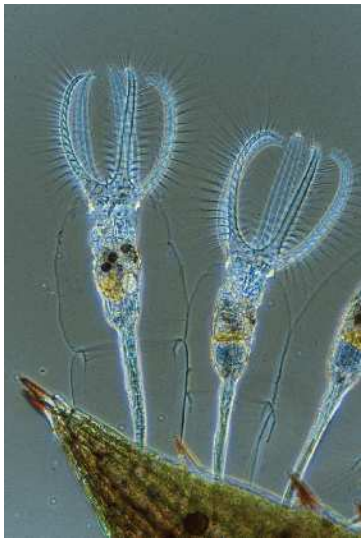


FIGURE 11.2 Representative rotifers. (A) *Paraseison annulatus* (subclass Seisonidea), a marine ectoparasitic rotifer from the gills of *Nebalia*. (B) *Philodina roseola* (subclass Bdelloidea). (C–F) Members of the subclass Monogononta. (C) SEM of a sessile rotifer (*Floscularia*) that lives inside a tube that it constructs from small pellets composed of bacteria and detritus. (D) *Stephanoceros*, one of the strange collothecacean rotifers with the corona modified as a trap. (E) The loricae of two loricate rotifers. (F) Live specimens of *Stephanoceros*.

free-living, and about 1,200 parasitic acanthocephalans. The macroscopic acanthocephalan worms represent a rotifer ingroup, but due to their considerable differences in biology and morphology, they will be discussed separately. Thus, in this first section the name Rotifera refers to the microscopic, free-living rotifers only. The name "Syndermata" was proposed some time ago for a clade of Rotifera + Acanthocephala, but with the current understanding that these are not sister groups (the latter arose as a clade from within the former), that name is no longer useful.

Rotifers were known to early microscopists, such as Antony van Leeuwenhoek in the late seventeenth century; at that time they were lumped with the protists as "animalcules" (mainly because of their small size). Besides the 2,000 or so known, morphologically recognizable species, complexes of cryptic species have been demonstrated for several morphospecies. For example, *Brachionus plicatilis* has been subject to intensive studies, and at least 22 putative cryptic species have been identified within this species complex. As a whole, rotifers remain poorly characterized systematically, and many named species have ambiguous descriptions and have not been rediscovered since their original discovery.

Despite their small size, rotifers are actually quite complex and display a variety of body forms (Figure 11.2). Most are solitary, but some sessile forms are colonial, a few of which secrete gelatinous casings into

which the individuals can retract. They are most common in fresh water, but many species are also known from marine or brackish habitats and from damp soil or the water film on mosses. A few species are even ecto- or endoparasites in other invertebrates. They often comprise an important component of the plankton of fresh and brackish waters.

The body comprises three general regions—the head, trunk, and foot. The head bears a ciliary organ called the **corona**. When active, the coronal cilia often give the impression of a pair of rotating wheels, hence the derivation of the phylum name; in fact, rotifers were historically called "wheel animalcules." Members of this phylum are further characterized by being blastocoelomate and having an integument without an outer cuticle, but instead with a supportive intracellular protein lamina. They usually show a tendency to eutely and have a complete gut, protonephridia, and often syncytial tissues or organs (Box 11B). The pharynx is modified as a **mastax** comprising sets of internal jaws called **trophi**. The morphology of the trophi is of considerable systematic importance and often the main character to identify species and genera.

A highly surprising discovery about rotifers was made in 2008, when it was found that bdelloid rotifers have incorporated large numbers of genes from diverse foreign sources into their genomes, including bacteria, fungi, and plants. These foreign genes have accumulated mainly in the telomeric regions at the ends of chromosomes, and at least most of them seem to retain their functional integrity. Bdelloids also are prone to infection by an aggressive fungus, *Rotirephthora angustispora*, that eats them from the inside out. Experiments have shown that the longer the rotifers remain dry and in a state of dormancy, the more likely they are to avoid infection by *R. angustispora*, suggesting that their adaptation for quiescence may also be an adaptation to avoid fungal predation.

BOX 11B Characteristics of the Phylum Rotifera

1. Triploblastic, bilateral, unsegmented blastocoelomates
2. Gut complete and regionally specialized
3. Pharynx modified as a mastax, containing jawlike elements called "trophi"
4. Anterior end bearing variable ciliated fields as a corona
5. Posterior end often bearing toes and adhesive glands
6. Epidermis syncytial, with fixed number of nuclei; secreting extracellular glycocalyx and intracellular skeletal lamina (the latter forming a lorica in some species)
7. With protonephridia, but no special circulatory or gas exchange structures
8. With unique retrocerebral organ
9. Males generally reduced or absent; parthenogenesis common
10. With modified spiral cleavage
11. Found in marine, freshwater, or semiterrestrial environments; sessile or free-swimming
12. Cryptobiosis present in many species

CLASSIFICATION OF PHYLUM ROTIFERA

CLASS HEMIROTIFERA

Endoparasites, ectoparasites, or free-living; this group is recognized only by molecular data.

SUBCLASS ACANTHOCEPHALA Macroscopic endoparasites; see the Phylum Rotifera, Subclass Acanthocephala section.

SUBCLASS BDELLOIDEA (Figure 11.2B) Free-living, found mostly in fresh water, moist soils, and foliage (also marine, and terrestrial); corona typically well developed; trophi ramate (grinding). (20 genera, all asexual, e.g., *Adineta*, *Embata*, *Habrotrocha*, *Philodina*, *Rotaria*, and *Zelinkiella*)

SUBCLASS SEISONIDEA (Figure 11.2A) Epizoic on the marine leptostracan crustacean *Nebalia*; corona reduced to bristles; trophi fulcrate (piercing); males fully developed and considered to have diploid chromosome numbers; sexual females produce only mictic ova. (2 genera: *Paraseison* and *Seison*)

CLASS EUROTIFERA

SUBCLASS MONOGONONTA (Figure 11.2C–F) Predominately freshwater, some are marine; swimmers, creepers, or sessile; corona and trophi variable; males typically short-lived, haploid, and reduced in size and complexity; sexual reproduction probably occurs at some point in the life history of all species; mictic and amictic ova produced in many species; single germovitellarium. (121 genera, e.g., *Asplanchna*, *Brachionus*, *Collotheca*, *Dicranophorus*, *Encentrum*, *Epiphanes*, *Euchlanis*, *Floscularia*, *Lecane*, *Notommata*, *Proales*, *Synchaeta*, *Testudinella*)

The Rotifer Body Plan

Body Wall, General External Anatomy, and the Corona

Most rotifers have a soft, gelatinous glycocalyx outside their epidermis, but unlike many other invertebrates, they have no external cuticle. Instead they have an intracellular protein lamina located inside the epidermis, for protection and stabilization of the body. This protein lamina may vary considerably in thickness and flexibility among the genera and families. Species with a very thin protein lamina are called "illoricate

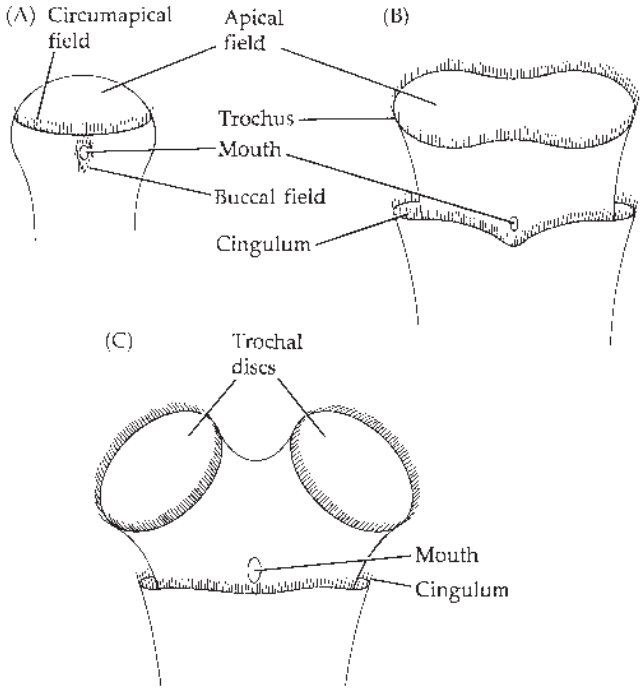

FIGURE 11.3 Modifications of the corona among selected rotifer types. (A) The presumed plesiomorphic condition has buccal and circumapical fields. (B) The circumapical field is separated into trochus and cingulum. The trochus is lobed, like that of *Floscularia*. (C) The trochus is separated into two trochal discs, as found in many bdelloid rotifers.

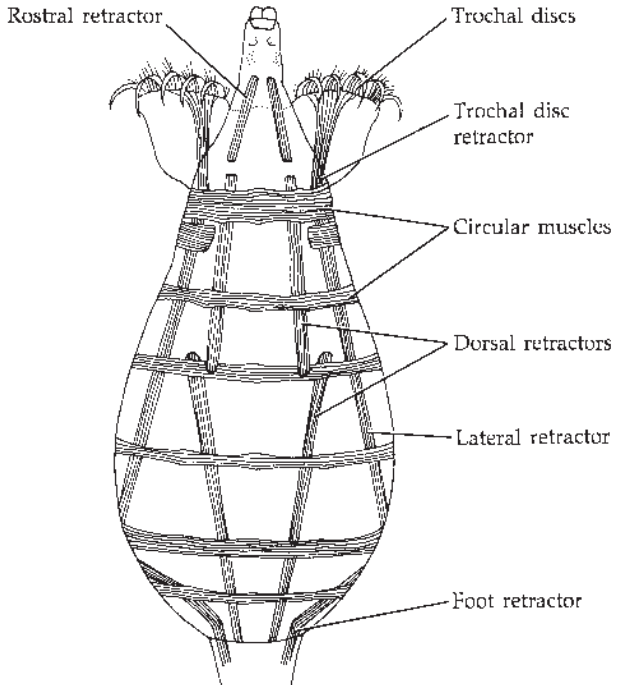

FIGURE 11.4 Major muscle bands of the bdelloid rotifer, *Rotaria* (dorsal view).

rotifers," and they often appear as very flexible and hyaline animals that contract completely when disturbed. In other species, the intracellular protein lamina is much thicker and forms a body armor, called a **lorica**, and these species are referred to as "loricate rotifers." Another special condition of the rotifer epidermis is the absence of walls between the epidermal cells, meaning that the epidermis is a syncytium with about 900 to 1,000 nuclei.

The body surface of many illoricate rotifers is annulated, allowing flexibility. The surface of loricate species often bears spines, tubercles, or other sculpturing (Figure 11.2E). Many rotifers bear single dorsal and paired lateral sensory antennae arising from various regions of the body. A **foot** is not present in all species, but when present it is often elongate, with cuticular annuli that permit a telescoping action. The distal portion of the foot often bears spines, or a pair of "toes" through which ducts from the pedal glands pass. The secretion from the pedal glands enables the rotifer to attach temporarily to the substratum. The foot is absent in some swimming forms (e.g., *Asplanchna*) and is modified for permanent attachment in sessile types (e.g., *Floscularia*).

The **corona** is the most characteristic external feature of rotifers. Its morphology varies greatly, and in some groups, the corona is an important taxonomic character. The presumed primitive condition is shown in Figure 11.3A. A well-developed patch of cilia surrounds the anteroventral mouth. This patch is the buccal field, or circumoral field, and it extends dorsally around the head as a ciliary ring called the circumapical field. The extreme anterior part of the head bordered by this ciliary ring is the apical field. The corona has evolved to a variety of modified forms in different rotifer taxa. In some species, the buccal field is quite reduced, and the circumapical field is separated into two ciliary rings, one slightly anterior to the other (Figure 11.3B). The anterior-most ring is called the trochus, the other the cingulum. In many bdelloid rotifers the trochus is a pair of well-defined anterolateral rings of cilia called trochal discs (Figure 11.4C), which may be retracted or extended for locomotion and feeding. It is the metachronal ciliary waves along these trochal discs that impart the impression of rotating wheels.

Many organs and tissues of rotifers display eutely: cell or nuclear number constancy. This condition is established during development, and there are no mitotic cell divisions in the body following ontogeny.

Body Cavity, Support, and Locomotion

Beneath the epidermis are various circular and longitudinal muscle bands (Figure 11.4); there are no sheets or layers of body wall muscles. The internal organs lie within a typically spacious, fluid-filled blastocoelom.

In the absence of a thick, muscular body wall, body support and shape are maintained by the intraepidermal skeletal lamina and the hydrostatic skeleton provided by the body cavity. In loricate species the integument is only flexible enough to allow slight changes in shape, so increases in hydrostatic pressure within the body cavity can be used to protrude body parts (e.g., foot, head, and corona). These parts are also protracted and retracted by various muscles (Figure 11.4), each consisting of only one or two cells.

Although a few rotifers are sessile, most are motile and quite active, moving about by swimming or creeping like an inchworm. Some are exclusively either swimmers or crawlers, but many are capable of both methods of locomotion. Swimming is accomplished by beating the coronal cilia, forcing water posteriorly along the body, and driving the animal forward, sometimes in a spiral path. When creeping, a rotifer attaches its foot with secretions from the pedal glands, then elongates its body and extends forward. It attaches the extended anterior end to the substratum, releases its foot, and draws its body forward by muscular contraction.

Feeding and Digestion

Rotifers display a variety of feeding methods, depending upon the structure of the corona (Figure 11.3), the mastax, and the trophi (Figure 11.5). Ciliary suspension feeders have well-developed coronal ciliation and a grinding mastax. These forms include the bdelloids, which have trochal discs and ramate trophi (Figure 11.5A), and a number of monogonont rotifers, which have a separate trochus and cingulum and a malleate trophus (Figure 11.5B). These forms typically feed on organic detritus or minute organisms. The feeding current is produced by the action of the cilia of the trochus (or trochal discs), which beat in a direction opposite to that of the cilia of the cingulum. Particles are drawn into a ciliated food groove that lies between these opposing ciliary bands and are carried to the buccal field and mouth.

Raptorial feeding is common in many species of Monogononta. Coronal ciliation in these rotifers is often reduced or used exclusively for locomotion. Raptorial feeders obtain food by grasping it with protrusible, pincerlike mastax jaws; most possess either forcipate

trophi (nonrotating) (Figure 11.5C) or incudate trophi (rotating 90°–180° during protrusion). Raptorial rotifers feed mainly on small animals but are known to ingest plant material as well. They may ingest their prey whole and subsequently grind it to smaller particles within the mastax, or they may pierce the body of the plant, protist, or animal with the tips of the mastax jaws and suck fluid from the prey (Figure 11.5D).

Some monogonont rotifers have adopted a trapping method of predation. In such cases the corona usually bears spines or setae arranged as a funnel-shaped trap (Figure 11.2D,F). The mouth in these trappers is located more or less in the middle of the ring of spines (rather than in the more typical anteroventral position); thus, captured prey is drawn to it by contraction of the trap elements. The mastax in trapping rotifers is often reduced.

A few rotifers have adopted symbiotic lifestyles. As noted in the classification scheme, seisonids live on marine leptostracan crustaceans of the genus *Nebalia*. These rotifers (*Seison* and *Paraseison*) crawl around the base of the legs and gills of their host, feeding on detritus and on the host's brooded eggs. It has been suggested that species of the predatory *Paraseison* may use the anterior tip of the fulcrum of their fulcrate trophi (Figure 11.5E) to pinch the cuticle of the leptostracan host and feed on its hemolymph. Some bdelloids (e.g., *Embata*) also live on the gills of crustaceans, particularly amphipods and decapods, and *Zelinkiella synaptae* lives on the integument of certain sea cucumbers and terebellid annelids. There are isolated examples of endoparasitic rotifers inhabiting hosts such as *Volvox* (a colonial protist), freshwater algae, snail egg cases, and the body cavities of certain annelids and terrestrial slugs. Little is known about nutrition in most of these species.

The digestive tract of most rotifers is complete and more or less straight (Figure 11.6A). (The anus has been secondarily lost in a few species, and some have a moderately coiled gut.) The mouth leads inward to the pharynx (mastax) either directly or via a short, ciliated buccal tube. Depending on the feeding method and food sources, swallowing is accomplished by various means, including ciliary action of the buccal field and buccal tube, or a pistonlike pumping action of certain elements of the mastax apparatus. The mastax is ectodermal in origin. Opening into the gut lumen just posterior to the mastax are ducts of the salivary glands. There are usually two to seven such glands; they are presumed to secrete digestive enzymes and perhaps lubricants aiding the movement of the trophi.

A short esophagus connects the mastax and stomach. A pair of gastric glands opens into the posterior end of the esophagus; these glands apparently secrete digestive enzymes. The walls of the esophagus and gastric glands are often syncytial. The stomach is generally thick walled and may be cellular or syncytial, usually comprising a specific number of cells or nuclei in each species (Figure 11.6B). The intestine is short and leads to the anus, which is located dorsally near the posterior end of the trunk. Except for *Asplanchna*, which lacks a hindgut, an expanded cloaca connects the intestine and anus. The oviduct and usually the nephridioducts also empty into this cloaca.

Digestion probably begins in the lumen of the mastax and is completed extracellularly in the stomach, where absorption occurs. In one large and enigmatic group of bdelloids the stomach lacks a lumen. Although much remains to be learned about the digestive physiology of rotifers, some experimental work indicates that diet has multiple and important effects on various aspects of their biology, including the size and shape of individuals as well as some life cycle activities.

Circulation, Gas Exchange, Excretion, and Osmoregulation

Rotifers have no special organs for internal transport or for the exchange of gases between tissues and the environment. The blastocoelomic fluid provides

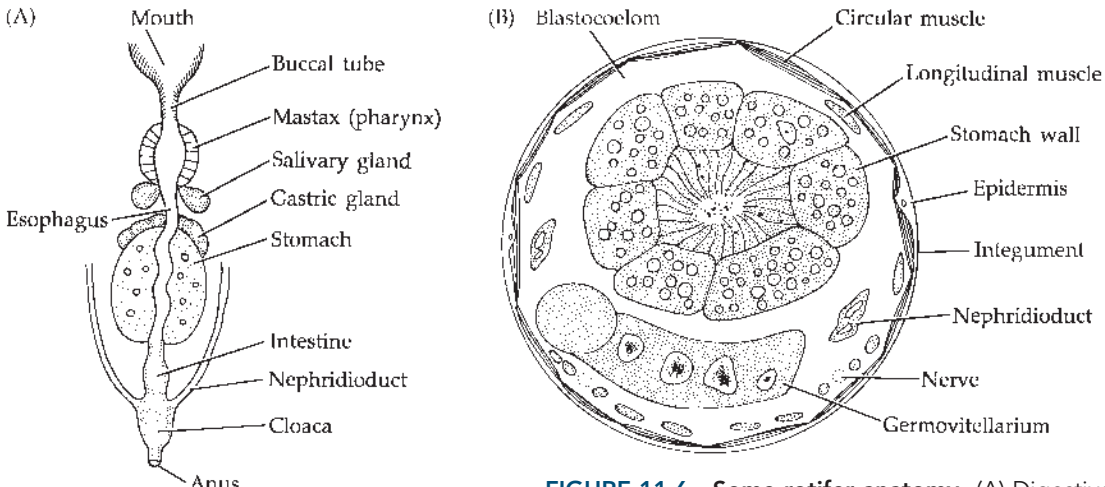

FIGURE 11.6 Some rotifer anatomy. (A) Digestive system of a rotifer. (B) Cross section through the trunk.

a medium for circulation within the body, which is aided by general movement and muscular activity. Small body size reduces diffusion distances and facilitates the transport and exchange of gases, nutrients, and wastes. These activities are further enhanced by the absence of linings and partitions within the body cavity, so the exchanges occur directly between the organ tissues and the body fluid. Gas exchange probably occurs over the general body surface wherever the integument is sufficiently thin.

Most rotifers possess one or several pairs of flame bulb protonephridia, located far forward in the body. A nephridioduct leads from each flame bulb to a collecting bladder, which in turn empties into the cloaca via a ventral pore. In some forms, especially the bdelloids, the ducts open directly into the cloaca, which is enlarged to act as a bladder (Figure 11.6A). The protonephridial system of rotifers is primarily osmoregulatory in function, and it is most active in freshwater forms. Excess water from the body cavity and probably from digestion is also pumped out via the anus by muscular contractions of the bladder. This "urine" is significantly hypotonic relative to the body fluids. It is likely that the protonephridia also remove nitrogenous excretory products from the body. This form of waste removal is probably supplemented by simple diffusion of wastes across permeable body wall surfaces.

Some rotifers (especially the freshwater and semiterrestrial bdelloids) are able to withstand extreme environmental stresses by entering a state of metabolic dormancy. They have been experimentally desiccated and kept in a dormant condition for as long as four years—reviving upon the addition of water. Some have survived freezing in liquid helium at –272°C and other severe stresses dreamed up by biologists.

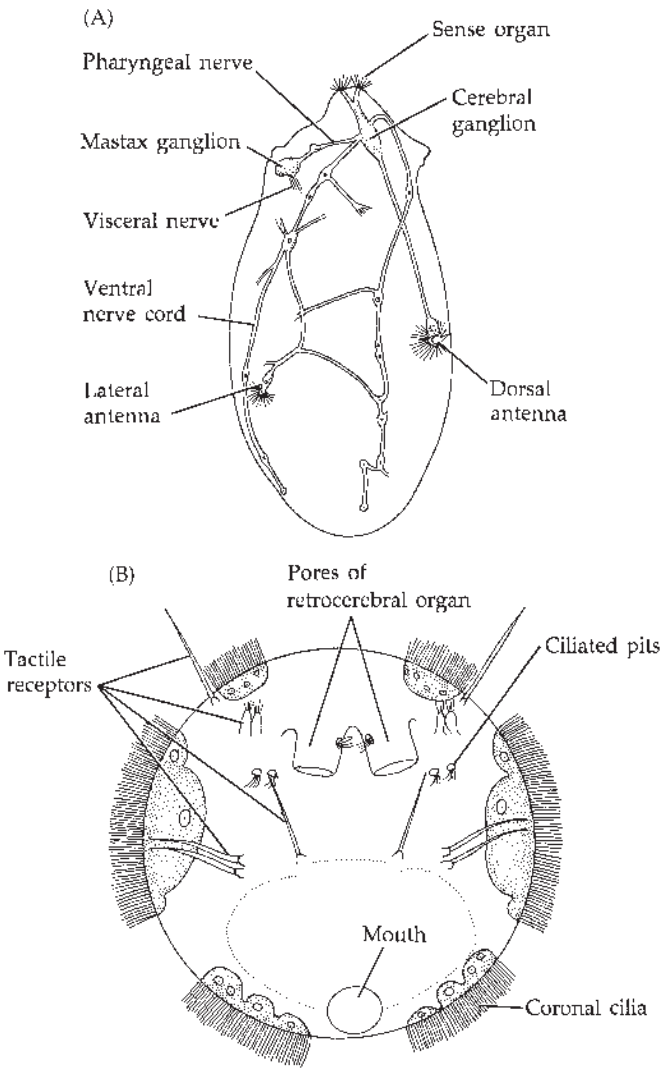

FIGURE 11.7 More rotifer anatomy. (A) The nervous system of *Asplanchna*. (B) The coronal area of *Euchlanis* (apical view). Note the various sense organs.

Nervous System and Sense Organs

The cerebral ganglion of rotifers is located dorsal to the mastax, in the neck region of the body. Several nerve tracts arise from the cerebral ganglion, some of which bear additional small ganglionic swellings (Figure 11.7A). There are usually two major longitudinal nerves, either both ventrolateral or one dorsal and one ventral.

The coronal area generally bears a variety of touch-sensitive bristles or spines and often a pair of ciliated pits thought to be chemoreceptors (Figure 11.7B). The dorsal and lateral antennae are probably tactile. Some rotifers bear sensory organs, which are arranged as a cluster of micropapillae encircling a pore. These organs may be tactile or chemosensory. Most of the errant rotifers possess at least one simple ocellus embedded in the cerebral ganglion. In some, this cerebral ocellus is accompanied by one or two pairs of lateral ocelli on the coronal surface, and sometimes by a pair of apical ocelli in the apical field. The lateral and apical ocelli are multicellular epidermal patches of photosensitive cells. In 1977 Pierre Clément described possible baro- or chemoreceptors in the body cavity that may help regulate internal pressure or fluid composition.

Associated with the cerebral ganglion is the so-called **retrocerebral organ**. This curious glandular structure gives rise to ducts that lead to the body surface in the apical field (Figure 11.7B). Though it was once thought to be sensory in function, more recent work suggests that it may secrete mucus to aid in crawling.

Reproduction and Development

Parthenogenesis is probably the most common method of reproduction among rotifers. Other forms of asexual reproduction are unknown, and most groups show only very weak powers of regeneration. Most rotifers are gonochoristic. However, other than the Seisonidea,

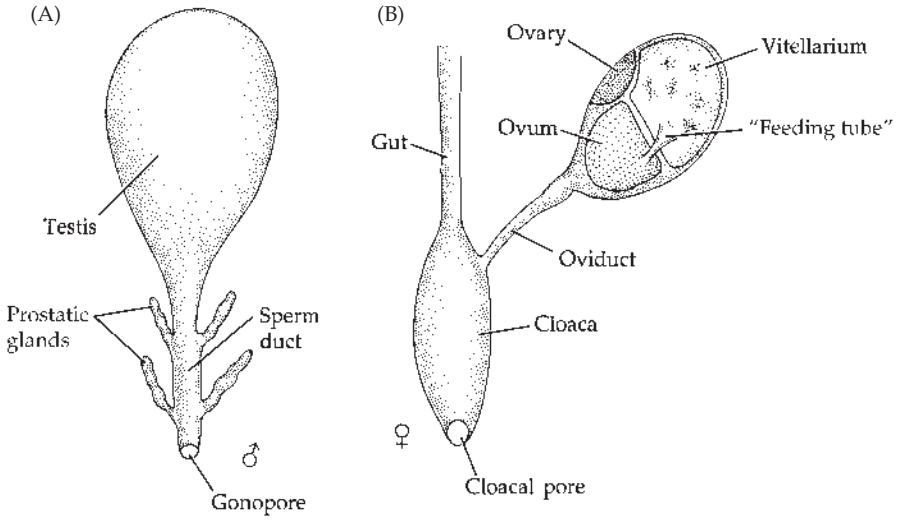

FIGURE 11.8 Reproductive systems from a generalized monogonont rotifer. (A) Male. (B) Female.

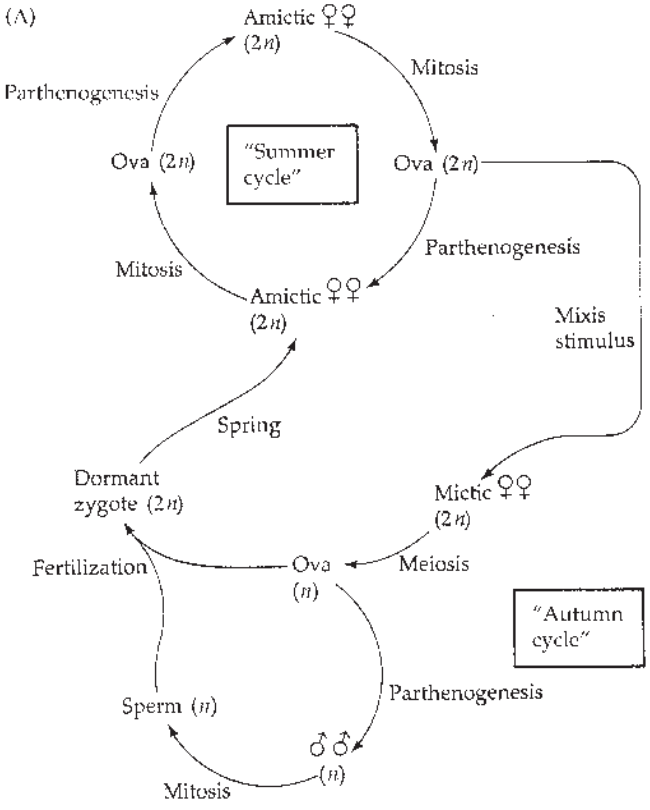
males either are reduced in abundance, size, and complexity and have haploid chromosome numbers (Monogononta) or do not exist (Bdelloidea). If you find a rotifer, the chances are good that it is a female.

The male reproductive system (Figure 11.8A) includes a single testis (paired in Seisonidea), a sperm duct, and a posterior gonopore whose wall is usually folded to produce a copulatory organ. Prostatic glands are sometimes present in the wall of the sperm duct. The males are short-lived and possess a reduced gut unconnected to the reproductive tract.

The female system includes paired (Bdelloidea) or single (Monogononta) syncytial germovitellaria (Figure 11.8B). Eggs are produced in the ovary and receive yolk directly from the vitellarium before passing along the oviduct to the cloaca; in those forms that have lost the intestinal portion of the gut (e.g., *Asplanchna*), the oviduct passes directly to the outside via a gonopore. There are no yolk glands in Seisonidea.

In rotifers with a male form, copulation occurs either by insertion of the male copulatory organ into the cloacal area of the female or by hypodermic impregnation. In the latter case, males attach to females at various points on the body and apparently inject sperm directly into the blastocoelom (through the body wall). The sperm somehow find their way to the female reproductive tract, where fertilization takes place. The number of eggs produced by an individual female is determined by the original, fixed number of ovarian nuclei—usually 20 or fewer, depending on the species. Once fertilized, the ova produce a series of encapsulating membranes and are then either attached to the substratum or carried externally or internally by the brooding female.

Parthenogenesis is generally the rule among bdelloids, but it is also a common and usually seasonal occurrence in monogononts, where it tends to alternate with sexual reproduction. This cycle (Figure 11.9A) is an adaptation to freshwater habitats that are subject to severe seasonal changes. During favorable conditions, females reproduce parthenogenetically through the production of mitotically derived diploid ova (amictic ova). These eggs develop into more females without fertilization.



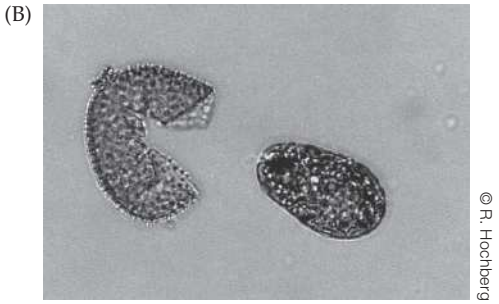


FIGURE 11.9 Life cycle of a monogonont rotifer. (A) Mictic/amictic alternation in the life cycle of a monogonont rotifer. (B) Micrograph of an amictic female hatching from an overwintering phase.

However, when ova from amictic females are subjected to particular environmental conditions (so-called mixis stimuli), they develop into mictic females, which then produce mictic (haploid) ova by meiosis. The exact stimulus apparently varies among different species and may include such factors as changes in day length, temperature, or food resources or increases in population density. Although these cycles are commonly termed summer and autumn cycles, this is a bit misleading because mixis can also occur during warm weather and many populations have several periods of mixis each year. Mictic ova require fertilization by male gametes to develop a new female individual, but if no males are present, the unfertilized mictic ova will instead develop into haploid males, which produce sperm by mitosis. These sperm fertilize other mictic ova, producing diploid, thick-walled, resting zygotes. The resting zygotic form is extremely resistant to low temperatures, desiccation, and other adverse environmental conditions. When favorable conditions return, the zygotes develop and hatch as amictic females (Figure 11.9B), completing the cycle.

Only a few studies have been conducted on the embryology of rotifers (see especially Pray 1965). In spite of the paucity of data, and some conflicting interpretations in the literature, it is generally thought that rotifers have modified spiral cleavage. However, detailed analyses of cell lineages are still needed to determine if the typical spiral pattern persists past the first couple of cell divisions, especially with regard to the origin of the mesoderm. The isolecithal ova undergo unequal holoblastic early cleavage to produce a stereoblastula. Gastrulation is by epiboly of the presumptive ectoderm and involution of the endoderm and mesoderm; the gastrula gradually hollows to produce the blastocoel, which persists as the adult body cavity. The mouth forms in the area of the blastopore. Definitive nuclear numbers are reached early in development for those organs and tissues displaying eutely.

Errant rotifers undergo direct development, hatching as mature or nearly mature individuals. Sessile forms pass through a short dispersal phase, sometimes called a larva, which resembles a typical swimming rotifer. The "larva" eventually settles and attaches to the substratum. In all cases, there is a total absence of cell division during postembryonic life (i.e., they are eutelic).

Many rotifers exhibit developmental polymorphism, a phenomenon also seen in some protists, arachnids, and insects. This is the expression of alternative morphotypes under different ecological conditions by organisms of a given genetic constitution (the differentiation of certain castes in social insects is one of the most remarkable examples of developmental polymorphism). In all such animals studied to date, the alternative adult morphotypes appear to be products of flexible developmental pathways, triggered by environmental cues and often mediated by internal mechanisms such as hormonal activities. In one well-studied genus of rotifers (*Asplanchna*), the environmental stimulus regulating which of several adult morphologies is produced is the presence of a specific molecular form of vitamin E, α-tocopherol. *Asplanchna* obtains tocopherol from its diet of algae or other plant material or when it preys on other herbivores (animals do not synthesize tocopherol). The chemical acts directly on the rotifer's developing tissues, where it stimulates differential growth of the syncytial hypodermis after cell division has ceased. Predator-induced morphologies also occur among rotifers. *Keratella slacki* eggs, in the presence of the predator *Asplanchna* (both are rotifers), are stimulated to develop into larger-bodied adults with a very long anterior spine, thus rendering them more difficult to eat.

Phylum Rotifera, Subclass Acanthocephala: The Acanthocephalans

As adults, the 1,200 or so described species of acanthocephalans are obligate intestinal parasites in vertebrates, particularly in birds and freshwater fishes. Larval development takes place in various arthropod intermediate hosts. The name Acanthocephala (Greek *acanthias*, "prickly"; *cephalo*, "head") derives from the presence of recurved hooks located on an eversible proboscis at the anterior end. The rest of the body forms a cylindrical or flattened trunk, often bearing rings of small spines. Most acanthocephalans are less than 20 cm long, although a

BOX 11C Characteristics of the Subclass Acanthocephala (Phylum Rotifera)

1. Triploblastic, bilateral, unsegmented blastocoelomates
2. Gut absent
3. Anterior end with hook-bearing proboscis
4. Tegument and muscles contain a unique system of channels called the lacunar system
5. Protonephridia absent except in a few species
6. With unique system of ligaments and ligament sacs partially partitioning the body cavity
7. With unique hydraulic structures called lemnisci that facilitate extension of proboscis
8. Gonochoristic
9. With modified spiral cleavage
10. All are obligate parasites in guts of vertebrates; many have complex life cycles with a so-called acanthor larva.

Oxford University Press, London.)

few species exceed 60 cm in length; females are generally larger than males. The digestive tract has been completely lost, and except for the reproductive organs, there is significant structural and functional reduction of most other systems, a condition related to the parasitic lifestyles of these worms (Box 11C). The persisting organs lie within an open blastocoelom, partially partitioned by mesentery-like ligaments.

The acanthocephalans are usually divided into three groups based on the arrangement of proboscis hooks, the nature of the epidermal nuclei, spination patterns on the trunk, and the nature of the reproductive organs: Palaeacanthocephala (e.g., *Polymorphus, Corynosoma, Plagiorhynchus, Acanthocephalus*), Archiacanthocephala (e.g., *Moniliformis*), and Eoacanthocephala (e.g., *Neoechinorhynchus, Octospiniferoides*) (see Figure 11.10).

The Acanthocephalan Body Plan

Body Wall, Support, Attachment, and Nutrition

Adult acanthocephalans attach to their host's intestinal wall by their proboscis hooks, which are retractable into pockets, like the claws of a cat (Figure 11.10). In nearly all species, the proboscis itself is retractable into a deep proboscis receptacle, enabling the body to be pulled close to the host's intestinal mucosa. Nutrients provided by the host are absorbed through the parasite's body wall, and a gut is absent. The outer body wall is a multilayered,

syncytial, living tegument, which overlies sheets of circular and longitudinal muscles. The tegument includes layers of dense fibers as well as what appear to be sheets of plasma membrane, and an intracellular protein lamina, such as the one found in free-living rotifers. The tegument is perforated by numerous canals that connect to a complex set of unique circulatory channels called the **lacunar system** (Figure 11.10C). The tegumental channels near the body surface may facilitate pinocytosis of nutrients from the host. The body wall organization is such that each species has a distinct external appearance; some even appear to be segmented, but they are not.

At the junction of the proboscis and trunk, the epidermis extends inward as a pair of hydraulic sacs (**lemnisci**) that facilitate extension of the proboscis, as in free-living bdelloid rotifers; the proboscis is withdrawn by retractor muscles. The lemnisci are continuous with each other and with a ring-shaped canal near the anterior end of the body, whereas their distal ends float free in the blastocoelom. This arrangement may help to circulate nutrients and oxygen from the body to the proboscis.

One or two large sacs lined with connective tissue arise from the rear wall of the proboscis receptacle and extend posteriorly in the body. These structures support the reproductive organs and divide the body into dorsal and ventral **ligament sacs** in the archiacanthocephalans and eoacanthocephalans, or they produce a single ligament sac down the center of the body cavity in the palaeacanthocephalans (Figure 11.10D,E). Within the walls of these sacs are strands of fibrous tissue—the ligaments—that may represent remnants of the gut. The space between these internal organs is blastocoelomic.

The body is supported by the fibrous tegument and the hydrostatic qualities of the blastocoelom and lacunar system. The muscles and ligament sacs add some structural integrity to this support system, and canals of the lacunar system penetrate most of the muscles.

Circulation, Gas Exchange, and Excretion

Exchanges of nutrients, gases, and waste products occur by diffusion across the body wall, although some Archiacanthocephala possess a pair of protonephridia and a small bladder. Internal transport is by diffusion within the body cavity and by the lacunar system, the latter functioning as a unique sort of circulatory system, which permeates most body tissues. The lacunar fluid is moved about by action of the body wall muscles.

Nervous System

As in many obligate endoparasites, the nervous system and the sense organs of acanthocephalans are greatly reduced. A cerebral ganglion lies within the proboscis receptacle (Figure 11.10C) and gives rise to nerves to the body wall muscles, the proboscis, and the genital regions. Males possess a pair of genital ganglia. The proboscis bears several structures that are presumed to be tactile receptors, and small sensory pores occur at the tip and base of the proboscis. Males have what appear to be sense organs in the genital area, especially on the penis.

Reproduction and Development

Acanthocephalans are gonochoristic, and females are generally somewhat larger than males. In both sexes, the reproductive system is associated with the ligament sacs (Figure 11.10E). In males, paired testes (usually arranged in tandem) lie within a ligament sac and are drained by sperm ducts to a common seminal vesicle. Entering the seminal vesicle or the sperm ducts are six or eight cement glands, whose secretions serve to plug the female genital pore following copulation. When nephridia are present, they also drain into this system. The seminal vesicle leads to an eversible penis, which lies within a genital bursa connected to the gonopore. This gonopore is often called a cloacal pore because the bursa appears to be a remnant of the hindgut.

In females, a single mass of ovarian tissue forms within a ligament sac. Clumps of immature ova are released from this transient ovary and enter the body cavity, where they mature and are eventually fertilized. The female reproductive system comprises a gonopore, a vagina, and an elongate uterus that terminates internally in a complex open funnel called the **uterine bell** (Figure 11.10E). During mating the male everts the copulatory bursa and attaches it to the female gonopore. The penis is inserted into the vagina, sperm are transferred, and the vagina is neatly capped with cement. Sperm then travel up the female system, enter the body cavity through the uterine bell, and fertilize the eggs.

Much of the early development of acanthocephalans takes place within the body cavity of the female. Cleavage is holoblastic, unequal, and likened to a highly modified spiral pattern. A stereoblastula is produced, at which time the cell membranes break down to yield a syncytial condition. Eventually, a shelled **acanthor larva** is formed (Figure 11.11). The embryo leaves the mother's body at this (or an earlier) stage. Remarkably, the uterine bell "sorts" through the developing embryos by manipulating them with its muscular funnel; it accepts only the appropriate embryos into the uterus. Embryos in earlier stages are rejected and pushed back into the body cavity, where they continue development. The selected embryos pass through the uterus and out the genital pore and are eventually released with the host's feces.

Once outside the definitive host, the developing acanthocephalan must be ingested by an arthropod intermediate host—usually an insect or a crustacean—to continue its life cycle. The acanthor larva penetrates the gut wall of the intermediate host and enters the body cavity, where it develops into an **acanthella** and then into an

for more ebook/testbank/solution manuals requests, email 9601267344@qq.com

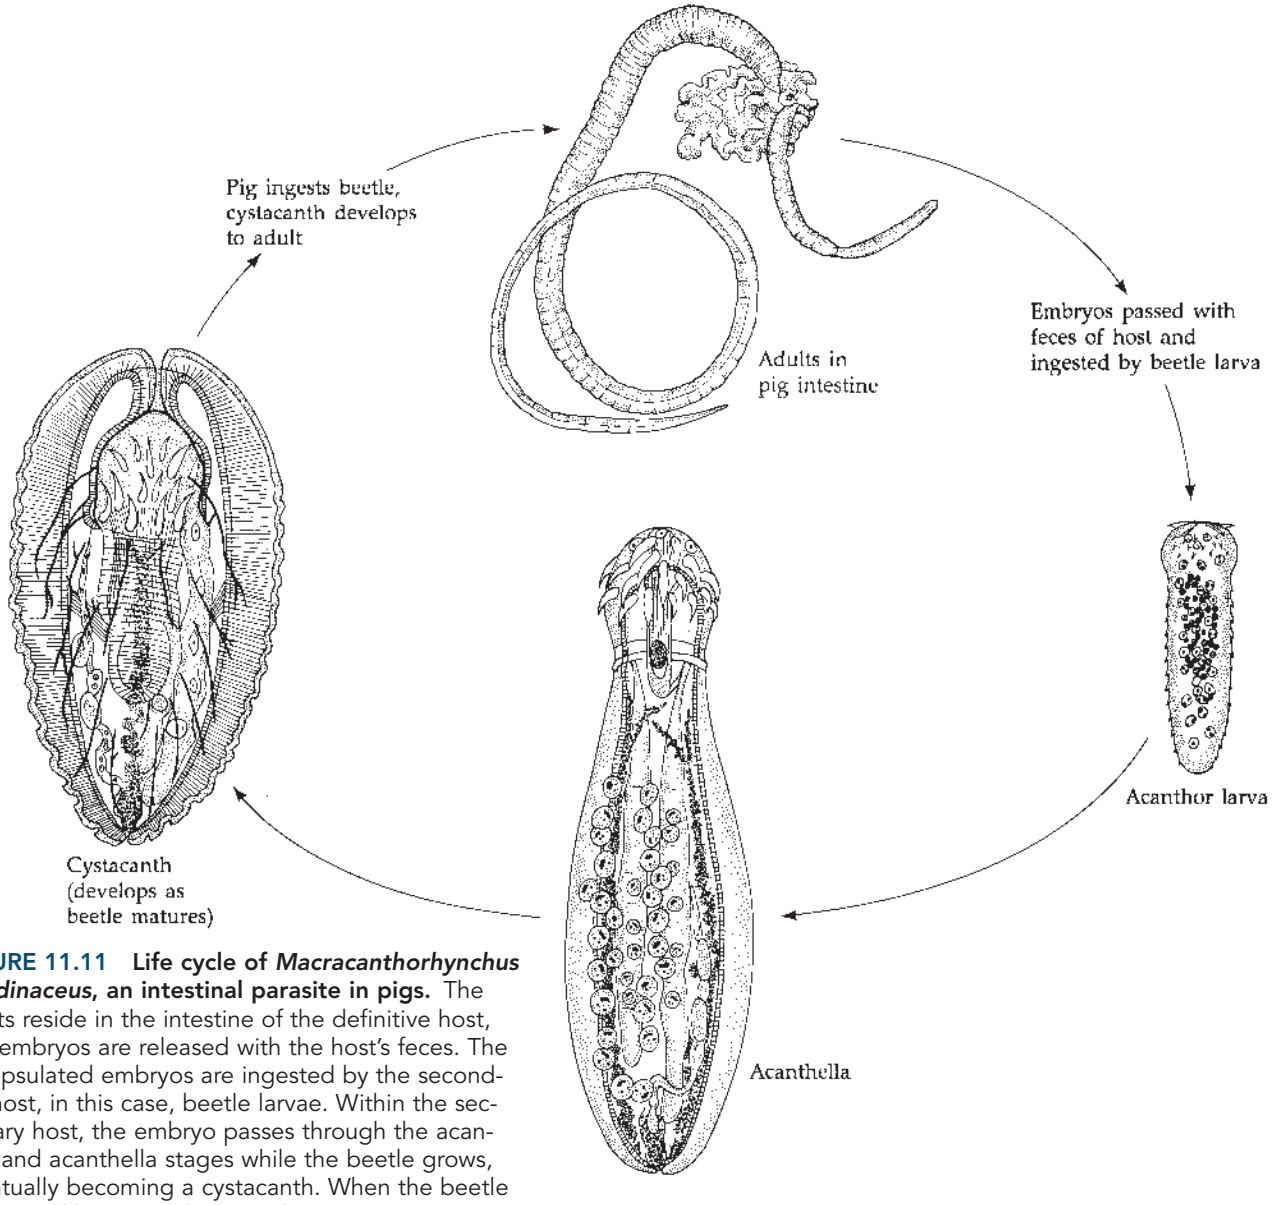

FIGURE 11.11 Life cycle of *Macracanthorhynchus hirudinaceus*, an intestinal parasite in pigs. The adults reside in the intestine of the definitive host, and embryos are released with the host's feces. The encapsulated embryos are ingested by the secondary host, in this case, beetle larvae. Within the secondary host, the embryo passes through the acanthor and acanthella stages while the beetle grows, eventually becoming a cystacanth. When the beetle is ingested by a pig, the juvenile matures into an adult, thereby completing the cycle.

encapsulated form called a **cystacanth** (Figure 11.11). When the intermediate host is eaten by an appropriate definitive host, the cystacanth attaches to the intestinal wall of the host and matures into an adult.

Phylum Micrognathozoa: The Micrognathozoans

A new microscopic animal, *Limnognathia maerski*, was described in 2000 by Reinhardt Kristensen and Peter Funch from a cold spring at Disko Island, West Greenland. Due to the numerous unique features of this new microscopic animal, a new monotypic class, Micrognathozoa (Greek, *micro*, "small"; *gnathos*, "jaw"; *zoa*, "animal"), was erected. Although *L. maerski* shows a superficial resemblance to microscopic annelids, its affiliation with Gnathostomulida and Rotifera was quickly established based on ultrastructural similarities of the epidermis and jaws. Jawlike structures are also found in other protostome taxa, such as in the kalyptorhynch turbellarians with their proboscises, in dorvilleid annelids, and in aplacophoran molluscs, but studies of their ultrastructure show that none of these jaws are homologous with those of *L. maerski*. Early molecular phylogenetic studies showed that Micrognathozoa did not nest within either of the two other gnathiferan phyla (Gnathostomulida and Rotifera), but next to them. For this reason, Micrognathozoa was given phylum status (Giribet et al. 2004). A later phylogenetic analysis based on transcriptomic data (Laumer et al. 2015) placed Micrognathozoa as the sister group to Rotifera (including Acanthocephala), with these

two comprising the sister clade to Gnathostomulida. Micrognathozoa still includes only the single described species from Greenland, but two later records of morphologically similar micrognathozoans from freshwater creeks in widely separated geographical areas (southern Indian Ocean and Great Britain) will most likely prove to be distinct species when DNA analyses have been completed. In the southern Indian Ocean, on Île de la Possession (Crozet Islands), micrognathozoans were found in low densities in both stagnant and running waters during the subantarctic summer (De Smet 2002), whereas in the United Kingdom only a few animals have been found from a stream in southern Wales (and only in winter) and a single animal was found on a sand grain of river sediment in Lambourn Parish, Berkshire (J. Schmid-Araya and P. E. Schmid pers. comm.). Finally, Giribet and Edgecombe (2020) reported on micrognathozoan environmental DNA in several peat bogs of the Pyrenees (O. Wangersteen unpubl. data). Micrognathozoa is thus the only animal phylum known strictly from freshwater habitats.

The Micrognathozoan Body Plan

Limnognathia maerski is an acoelomate animal ranging from about 80 μm to 150 μm in adult length (juveniles measuring 85–107 μm in length). The adult body can be divided into three main regions: a head, an accordion-like thorax, and an abdomen (Figures 11.12 and 11.13); the head contains the prominent jaw apparatus (Box 11D).

Epidermis, Ciliation, and Body Wall Musculature

Despite their small size, micrognathozoans have a complex support system and body musculature. *Limnognathia maerski* has dorsal and lateral **epidermal plates** formed by an intracellular matrix as in rotifers (including acanthocephalans) (Figures 11.12 and 11.13). Ventral plates are lacking, but the "naked" epidermis has a thin extracellular glycocalyx layer and a true cuticular oral plate The animal lacks syncytia, a key character of Rotifera (and Acanthocephala); however, it possesses a unique form of gap junctions showing transverse electron dense bands in a zipper-like pattern (we call these **zip-junctions**) between the dorsal epidermal cells.

The pattern of ventral multiciliated cells is characteristic of Micrognathozoa and has shown to be somewhat more complicated than illustrated in Figure 11.12 (so see also Figure 11.14). These cells comprise on the head a semicircular anterior field and also a posterior arched, ciliary field surrounding the mouth anterolaterally, as well as one anterior and three posterolateral pairs of **ciliophores** (synchronously beating multiciliated cells) surrounding the pharyngeal bulb. The midventral ciliation of the thorax and abdomen consist of about 17 transverse rows of two to four ciliophores, with the four last rows together constituting a posterior adhesive ciliary pad. The ventral paired ciliophores form the locomotory organ and are characterized by very long ciliary roots, originally mistaken for cross-striated muscles. These cells are highly similar to ciliophores found in the interstitial microscopic annelids *Diurodrilus* and *Neotenotrocha*. The posterior ciliary pad is very different from the adhesive toes of rotifers, gastrotrichs, and annelids, and the structure may be a unique synapomorphy for Micrognathozoa.

As in many marine interstitial animals (e.g., gnathostomulids, gastrotrichs, microscopic annelids), special forms of tactile bristles or sensoria are found on the body. A typical tactile bristle may consist of a single sensory cell, the **collar receptor**, with a single cilium in the middle surrounded by eight or nine microvilli that form the "collar" (see apicalia and dorsalia in Figure 11.12). Other sensory cells may have two or three cilia (see frontalia, lateralia and caudalia in Figure 11.12). The sensory cell clusters that form the two **apical ciliary tufts** (which are not collar receptors) are also multiciliary cells. Two large, posterior glands were recently revealed by immunostaining (Figures 11.12 and 11.14), which by their simple configuration and homogenous content resemble mucus-secreting glands. They might have an

adhesive function, together with the ciliary pad, but they do not resemble the more complex adhesive duo gland system found in the posterior end of gastrotrichs and the interstitial annelid *Diurodrilus*. Otherwise, no epidermal glands are known from micrognathozoans.

Limnognathia maerski has an elaborate body wall musculature, comprising 7 main pairs of longitudinal muscles extending from head to abdomen, and 13 pairs of oblique dorsoventral muscles localized in the thoracic and the abdominal regions (Figure 11.15). The musculature further comprises several minor posterior muscles and fine anterior forehead muscle, as well as the prominent pharyngeal muscular apparatus (Figure 11.16B). Cross-striated muscles are found in both the body wall and the jaw musculature. The three main ventral longitudinal pairs and one dorsal pair of muscles (green and blue muscles, Figure 11.15) span the entire length of the body, and some fibers even branch off to continue anteriorly into the head and posteriorly into the abdomen, forming a delicate muscular fencelike

FIGURE 11.13 Micrognathozoa: *Limnognathia maerski*, light micrographs. (A) Adult female with mature egg (length 0.14 mm). (B) Juvenile with relatively large thorax/smaller abdomen and immature oocyte (length 0.09 mm).

structure. These muscles seemingly aid longitudinal contraction and ventral bending of the body. The 13 oblique dorsoventral muscles may function together with the longitudinal muscles as supporting semicircular body wall musculature. Their close approximation to the gut further suggests they may act as gut musculature, thus possibly compensating for the lack of outer or inner circular musculature in Micrognathozoa.

Locomotion

Micrognathozoans swim in a characteristic slow spiral motion when moving freely in the water column. It is a slow movement, very different from that of rotifers. From video recordings, it seems that the trunk ciliophores are used both in swimming and in epibenthic crawling or gliding motions on the substrate. Gliding is accomplished by the rows of motile ciliophores, each with multiple cilia beating in unison, in the same way as is seen in the annelid *Diurodrilus*. However, the preoral ciliary field does not seem to be involved in either swimming or gliding. *Limnognathia maerski* has never been observed moving backward (as is common among gnathostomulids), not even when they reverse the beating of their long cilia. In addition, an escape motion has been observed where contraction of trunk muscles creates rapid jerky movements.

Pharyngeal Apparatus, Feeding, and Digestion

The mouth opens ventrally on the anterior margin of the cuticular, nonciliated oral plate and leads into the pharyngeal cavity, followed by a short esophagus dorsal to the paired jaw apparatus, then continues into the undifferentiated, nonciliated gut. The temporary anus is located dorsally and opens only periodically, as also seen in all gnathostomulids and in some gastrotrichs.

The pharyngeal apparatus, less than 30 μm wide, shows a complexity unseen in any other microscopic taxon, comprising numerous hard jaw parts and intricate musculature (Figure 11.16), as well as a buccal ganglion. The jaw parts comprise four main sets of sclerotized, denticulate, hard elements (sclerites): the large paired **fibularium**, the **main jaws**, the **ventral jaws**, and the **dorsal jaws**. The largest sclerite in each jaw is the fibularium, and it plays a central role in supporting the pharynx. Several subparts of the main sclerites have been described, including the anterior region of the ventral jaws called the **pseudophalangia**. So far, little is known about the functionality of this complex apparatus or the possible independent movement of all these parts, and only the pseudophalangia has been observed protruding from the mouth in fast snapping movements, possibly grasping food. The pharyngeal musculature is similarly complex and includes a major **ventral muscle plate** supporting (and moving) the entire jaw apparatus, as well as several other paired and unpaired striated muscles (Figure 11.16B). The ventral muscle plate is formed by 8–10 longitudinal cross-striated muscle fibers (purple muscles, Figure 11.16B) underlying the fibularium and enveloping the jaws laterally and caudally. This large muscle is unique to the Micrognathozoa, being absent in other gnathiferan phyla. The many paired and unpaired muscles seem mainly related to the fibularium and the main jaws, moving the jaws as well as supplying some of the minor jaw elements such as the accessory sclerites and the pharyngeal lamellae and allowing for the extrusion of the ventral jaws. The feeding biology of micrognathozoans is not well known. The animals are found on mosses or in the sediments, and video recordings have shown the animal eating bacteria on the surfaces of mosses and sand grains.

Circulation, Gas Exchange, and Excretion

Micrognathozoans are acoelomates and thus lack a circulatory system, and gas exchange takes place by diffusion across the epidermis. The paired nephridial system is in each lateroventral side composed of an anterior and a posterior, thoracic nephridium (with 4 and 2 terminal cells, respectively), possibly both opening into the intermediate collecting tubule (Figure 11.12A). The terminal cells are monociliated, in contrast to the multiciliated terminal cells of Rotifera but similar to those found in Gnathostomulida.

Nervous System and Sense Organs

Micrognathozoa possess a simple nervous system consisting of an anterior, slightly bilobed, dorsal brain and two pairs of ventral longitudinal nerves, connected by paired subpharyngeal commissural ganglia and a terminal commissure (Figure 11.14C). A large buccal assembly of somata (possible ganglion) is found caudal to the pharyngeal apparatus, which may control the movement of jaw elements. The numerous nucleated, minute cells found in the ganglia and musculature of the pharynx are in line with the suggested small size of the Micrognathozoa genome. Peripheral nerves extend from the cords, connecting to the sensory cilia (Figure 11.14B,C). Some of these cilia are clearly monociliated collar receptors (one cilium surrounded by eight to nine microvilli), whereas others are more complex with several sensory cells involved. The terms used for the sensory structures are, from anterior to posterior, apicalia, frontalia, lateralia, dorsalia, and caudalia (Figure 11.12). In the anterior end of the animal, a pair of lateral hyaline vesicles is present. They may be unpigmented, inner eyes of the annelid type, the so-called phaosomes, and like these they contain a dense layer of microvilli, but no ciliary structures.

Reproduction and Development

Only the female reproductive system has been found, suggesting that *Limnognathia maerski* is parthenogenetic. The reproductive system is anatomically simple, and it seems that the two ovaries obtain nutrition directly from the midgut, a feature also reported from freshwater chaetonotoid gastrotrichs. A pair of caudal, ciliated oviducts open midventrally (Figure 11.14B), possibly through the midventral pore found in the midst of the posterior ciliated pad. Though collecting has been done year-round in Greenland, the species is only found during the short summer. Two egg types have been found, as in limnic gastrotrichs and rotifers, where the smooth egg may be a quick-developing summer egg, and the strongly sculptured winter egg (Figure 11.17) may be a resting egg, not developing during the 10-month-long Arctic winter.

Phylum Chaetognatha

The chaetognaths (literally, "bristle jaws"), or arrow worms, comprise a small phylum of about 150 species of marine, mainly planktonic, voraciously predatory invertebrates (Figures 11.18 and 11.19). They are of moderate size, ranging from about 0.5 to 12 cm in length. Arrow worms are distributed throughout the world's oceans and occur in some estuaries; they are ecologically important as consumers of copepods and other small zooplankton. Arrow worms often occur in very high numbers and sometimes dominate the biomass in midwater plankton tows. Some species (e.g., *Spadella*) are epibenthic in shallow water. Special collection methods, such as use of submersibles, are turning up new species at great ocean depths, and many of these live just off the deep ocean floor (e.g., *Heterokrohnia* and *Archeterokrohnia*). At least two deep-water species, *Caecosagitta macrocephala* and *Eukrohnia fowleri*, are bioluminescent, releasing luminous particles that form glowing clouds in the water (although their luciferin-and-luciferase-based luminescent organs are located in different parts of the body). Definitive fossil chaetognaths with preserved soft tissues and grasping spines have been described from the middle Cambrian Burgess Shale of Canada (*Capinatator praetermissus*) and early Cambrian Chengjiang biota of China, about 520 million years ago (e.g., *Eognathacantha ercainella, Protosagitta spinosa, Ankalodous sericus*), and it is likely that Cambrian protoconodonts are grasping spines of arrow worms. Most of what we know about the biology of these delicate organisms is based on just a few nearshore species that can be collected without damage and kept alive in laboratory settings.

Comparative morphologists have not yet identified any unambiguous synapomorphies that unite chaetognaths with other protostome phyla, but molecular work, being phylogenetic analysis of genomic data or comparative analysis of Hox genes, places chaetognaths with the members of Gnathifera. Many unique features reveal the phylum status of arrow worms, including the movable cuticular grasping spines on

the head, a multilayered epidermis over most of the body, horizontal fins on the sides and posterior end, and closed seminal vesicles on the tail. Major characteristics of the phylum are listed in Box 11E.

Morphological uniformity within the phylum has resulted in few features that can be used to determine systematic relationships within the group. For many years, two orders were recognized: Phragmophora included all arrow worms having transverse "phragma" muscles, and Aphragmophora included all arrow worms lacking these muscles. The Phragmophora is now thought to be paraphyletic with respect to a monophyletic Aphragmophora. Presence of transverse muscles in both the trunk and tail is generally considered to be a plesiomorphic trait. A comprehensive cladistic analysis (Gasmi et al. 2014) based on both molecular and morphological characters recognized five well-resolved families. The first two families listed here represent a monophyletic group, as do the last three families, but neither of these groups has been given a name. In benthic and deep-sea species, the trunk and tail tend to be similar in length; in pelagic species the trunk tends to be conspicuously longer than the tail. Unless stated otherwise, the families are characterized by one pair of lateral fins and two paired rows of teeth.

CLASSIFICATION OF PHYLUM CHAETOGNATHA

FAMILY HETEROKROHNIIDAE Mostly deep-sea species, some presumably living on or close to the seafloor. Phragma muscles in both trunk and tail (*Archeterokrohnia*, *Heterokrohnia*, *Xenokrohnia*) or just the trunk (*Bathyspadella*). 23 species.

FAMILY EUKROHNIIDAE Pelagic, phragma muscles restricted to anterior trunk; one paired row of posterior teeth. 11 species, in the single genus *Eukrohnia*.

FAMILY SPADELLIDAE Epibenthic in shallow water; small; phragma muscles throughout much of trunk but absent from tail (e.g., *Paraspadella*, *Spadella*). 30 species.

FAMILY KROHNITTIDAE Pelagic, lack phragma muscles, one paired row of anterior teeth. One pair of lateral fins. 4 species, in the single genus *Krohnitta*.

FAMILY SAGITTIDAE Pelagic, a few nearshore species are facultatively epibenthic; lack phragma muscles. Two pairs of lateral fins except in *Pterosagitta* (e.g., *Caecosagitta*, *Ferosagitta*, *Parasagitta*, *Pterosagitta*, *Sagitta*). 60 species in 13 genera.

Three genera (*Bathybelos, Krohnittella, Pterokrohnia*), each belonging to its own family, are known from just

BOX 11E Characteristics of the Phylum Chaetognatha

1. Bilaterally symmetrical protostomes, with streamlined, elongate, trimeric body comprising head, trunk, and tail region; single head coelom, and paired trunk and tail coeloms separated by transverse septa
2. Epidermis mostly stratified, with cuticle on ventral side of head; body with lateral and caudal fins, supported by "rays" consisting of elongate cytoskeleton-rich epidermal cells; nonmolting
3. Mouth surrounded by sets of long moveable grasping spines and short teeth used in prey capture; mouth set in ventral vestibule; anterolateral fold of body wall forms retractable hood that can enclose grasping spines
4. With striated longitudinal muscles, arranged in quadrants; weak circular musculature consists of myoepithelial cells
5. No discrete gas exchange or excretory systems
6. Hemal system restricted to trunk, consisting of narrow peri-intestinal sinuses and larger sinuses in dorsal mesentery and posterior septum
7. Complete gut; anus ventral, at trunk-tail junction
8. Centralized nervous system with large dorsal (cerebral) and ventral (subenteric) ganglia connected by circumenteric connectives; ciliary receptors for detection of waterborne disturbances; anterior ciliary loop (= corona ciliata) of uncertain function (but possibly chemosensory). With inverted pigment-cup ocelli
9. Hermaphroditic, with internal fertilization and direct development. Cleavage equal, holoblastic, and apparently modified spiral. Mesoderm and body cavities form by heterocoely. Despite blastopore denoting posterior end of body, both mouth and anus forming secondarily, subsequent to closure of the blastopore
10. Strictly marine; raptorial carnivores; largely planktonic, but some benthic species known

one or a few poorly preserved specimens and are of uncertain phylogenetic status. *Bathybelos* is especially intriguing because the single known specimen, collected from 2,500 m deep in the Gulf of Mexico, was described as having many unusual features, including a unique dorsal ganglion on the very long head and no ventral ganglion.

The Chaetognath Body Plan

Externally, arrow worms are streamlined, with virtually perfect bilateral symmetry. Internally, transverse septa divide the coelomate body into a head, a trunk, and a tail. The head bears a ventrally placed mouth, set in a depression called the **vestibule**. The entire head region is elegantly adapted to a predatory lifestyle. Lateral to the mouth are long movable **grasping spines**, or "hooks," and in front of the mouth are short **cuticular teeth**—both used in prey capture and ingestion (Figures 11.19E and 11.20). The dorsolateral margins of the head possess a muscularized fold of the body wall called the **hood**. Except during prey capture, this is drawn ventrally around the sides of the head, thereby enclosing the grasping spines and streamlining the head. A pair of small, pigmented photoreceptors lie dorsally on the head. Also dorsally is a distinctive ring of innervated ciliated cells, the **corona ciliata**, which likely functions in chemoreception. The trunk bears one or two pairs of horizontal **lateral fins**, and the tail bears a single **tail fin**. Chaetognath fins are simple epidermal folds enclosing a thick sheet of supportive extracellular matrix; certain elongate epidermal cells form fin rays. The body surface has many multicellular **ciliary receptors**, which bear short rows of nonmotile cilia serving as mechanoreceptors for detecting disturbances in the water. The trunk contains the intestine, which terminates ventrally at the trunk-tail junction, and two ovaries. The female gonopores are located laterally at the posterior end of the trunk. The male reproductive system occupies the tail, which is commonly filled with masses of differentiating sperm. Paired seminal vesicles protrude laterally, between the lateral and caudal fins.

The chaetognath body plan couples structural simplicity with a high degree of specialization. We tend to view the specialized features of arrow worms as adaptations to a planktonic predatory lifestyle, but with nowhere to hide, pelagic arrow worms must also be adept at avoiding their own predators. Most chaetognaths are as transparent as glass and spend much of their time suspended motionlessly in the water—both features that minimize detection by visual predators such as fish. A chaetognath's sensitivity to waterborne disturbances is equally useful for detecting both prey and approaching predators, and the ability to move quickly enables both prey capture and escape from potential predators.

Body Wall, Support, and Movement

Over most of the body, the epidermis is a stratified epithelium. Flattened surface cells produce a thin layer of secretion over the body, much as in fish. Underlying epidermal cells are filled with cytoskeletal tonofilaments (supportive cytoskeletal microfilaments). The epidermis on the ventral and lateral parts of the head consist of a single layer of cuticularized cells. The cuticle is not molted. On all parts of the body, a thick basement membrane joins the epidermis to underlying tissues. Striated longitudinal muscle dominates the body wall of the trunk and tail (Figure 11.19F). On each side of the midline is a large group of dorsal longitudinal muscle and ventral longitudinal muscle (Figure 11.19F). These

for more books/testbank/solution manuals requests, email 9601267344@qq.com

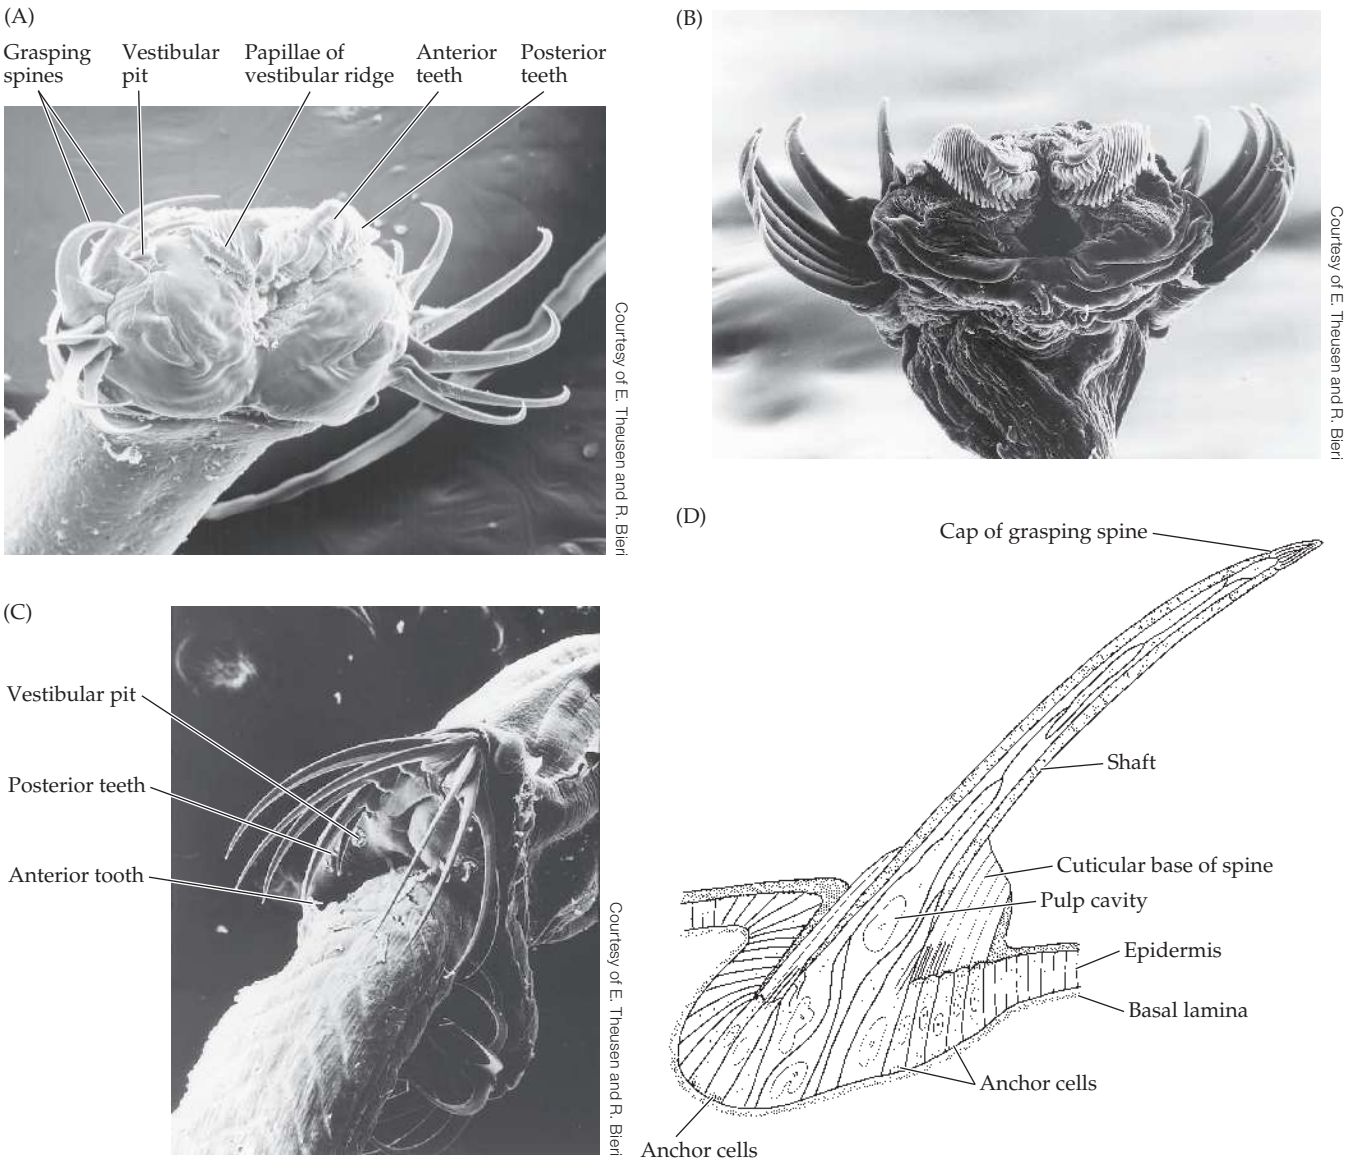

FIGURE 11.20 (A,B) Heads of chaetognaths. (A) *Zonosagitta pulchra*. Note the well-developed raptorial structures. (B) *Zonosagitta bedoti*, from the eastern Pacific. The hooks are clearly visible on either side of the head surrounding the large number (17–20) of long, narrow, posterior teeth. The shorter anterior teeth lie just above the mouth. The vestibular ridge with its pores is partially visible behind the left set of posterior teeth. (C) The chaetognath in this photo, *Flaccisagitta hexaptera*, has partially swallowed a fish larva (probably an anchovy). A single anterior tooth projects down below the second hook on the left side of the photo, and two posterior teeth can be seen between the first and second hooks. The circular organ just below the first hook is the vestibular pit. (D) Diagram of a grasping spine of *Parasagitta elegans*.

are separated from the body cavities by a thin layer of squamous peritoneum (noncontractile peritoneal cells). In addition, a weak circular musculature exists in the form of myoepithelial "lateral field cells" and dorsomedial and ventromedial cells. In some, sheets of transverse **phragma** muscle extend obliquely from the lateral body wall to the ventral midline (Figure 11.19A); their functions remain unknown. In all arrow worms, the head musculature is complex (Figure 11.19E).

The body cavities are true coeloms. The single head cavity is reduced by the elaborate cephalic musculature. In the trunk and tail, longitudinal mesenteries separate the coelomic space into left and right compartments, and in the tail incomplete lateral mesenteries partially subdivide each tail compartment (Figure 11.19F). The coelomic fluid is colorless in life, but it stains intensely, which suggests an abundance of dissolved organic molecules. Circulation of coelomic fluids in both trunk and tail is caused by ciliated cells in the lateral body wall. Coelomocytes are apparently lacking.

Body support in chaetognaths is provided by the hydrostatic quality of the coelom, crossed helical

arrangement of collagen fibers in the basement membrane, and tonus of the body wall musculature. Locomotion of both pelagic and epibenthic species involves forward darting motions caused by rapid alternating contractions of the dorsal- and ventral-longitudinal muscles. The fins are not used as propelling surfaces but are placed so that they slice through the water and serve as stabilizers. In pelagic species, brief swimming bursts alternate with quiescent periods, when the animals may slowly sink. This "hop-sink swimming," common among small planktonic invertebrates, probably constitutes a prey search behavior, and perhaps a depth stabilization measure (the fins also increase resistance to sinking between swimming bursts). Because swimming tends to be upward, it also helps the animals maintain a vertical position in the water column. Species that make pronounced diurnal vertical migrations—up at night and down during the day—are presumably capable of extended bouts of swimming. Some species of arrow worms are neutrally buoyant due to hypertrophied intestinal cells or vacuolated epidermal cells that contain fluids less dense than seawater.

Feeding and Digestion

Chaetognaths prey upon a variety of small pelagic animals, especially copepods. They can consume prey that are nearly as large as themselves, including small fish and other arrow worms! The complex musculature of the head operates the grasping spines and retraction of the hood during feeding. Both planktonic and benthic species are ambush predators, using ciliary receptors scattered over the body to detect movements of nearby prey. A chaetognath can determine both the direction and distance of potential prey at close range (even in the dark). Prey are ingested whole. The release of luminescent clouds in deep-sea species might serve to startle potential prey into movement, which can then be detected by the chaetognaths to facilitate predation. The luminescent cloud might also provide a means of escaping from predators.

Benthic forms, such as *Spadella*, feed while affixed to a substratum by adhesive secretions. As prey swim within reach, the anterior end is raised, and grasping spines are flared. The prey is captured by a quick downward flex of the head while the rest of the body remains firmly attached. The grasping spines close around and manipulate the prey, orienting it for ingestion. Planktonic chaetognaths feed on prey approaching the body from all sides. Laterally positioned prey are captured by rapid flexure of the body, and a short forward hop can be executed to grab prey located in front.

The grasping spines on the left and right sides can be moved simultaneously or alternately, resulting in a surprising degree of dexterity during manipulation of prey. When rigid prey such as small crustaceans are captured, the chaetognath positions the victim longitudinally for swallowing. The spines and teeth contain α-chitin, hardened at their tips by silicon in the two species so far examined closely. While superficially resembling setae of arthropods or chaetae of annelids, each tooth and grasping spine is a complex structure produced by a group of specialized epidermal cells. The grasping spines of some species bear serrations. Teeth are commonly cuspidate, a shape that may aid in the penetration of prey, including the exoskeletons of small crustaceans. A neurotoxin, tetrodotoxin, has been isolated from the heads of some species and may be used to quell prey. The toxin would presumably be incorporated into the sticky secretions produced by the pharynx and vestibular glands. It has been hypothesized that symbiotic bacteria produce the tetrodotoxin, but symbiotic bacteria have not been found during ultrastructural studies of the head or gut of arrow worms.

The gut is a relatively simple straight tube extending from the mouth in the vestibule to the ventral anus at the trunk-tail junction (Figure 11.19A,C,I). The mouth leads into a short pharynx and esophagus, both of which are equipped with gland cells. Swallowing is accomplished by well-developed esophageal muscles. The gut narrows where it passes through the head-trunk septum, and it extends posteriorly as a long intestine. A short rectum joins the posterior intestine to the anus. Most digestion occurs extracellularly in the posterior intestine and can be extremely rapid. Orange carotenoid pigments derived from the prey are incorporated into the otherwise transparent tissues of some deep-water chaetognaths.

Circulation, Gas Exchange, and Excretion

A simple hemal system exists in at least some chaetognaths, but it is easily overlooked because the blood is colorless and transparent. The hemal system consists of thin sinuses situated between the intestinal epithelium and surrounding myoepithelial peritoneum. Larger hemal sinuses exist in the dorsal mesentery, trunk-tail septum, ovaries, and body wall near the ventral ganglion. Transport through the hemal system is probably driven by the intestinal musculature. Even when the gut is empty, posteriorly directed peristalsis alternates with anteriorly directed peristalsis. The nutritive demands of various tissues in the tail are probably met by ultrafiltration across the tail side of the posterior septum, from the hemal sinus in the trunk-tail septum to the tail coelom. Gas exchange and excretion are apparently by diffusion through the body wall.

Nervous System and Sense Organs

Of paramount importance to the success of chaetognaths as active predators are features of the nervous system and associated sensory receptors. As we have

for more eBook/testbank/solution manuals requests, email 9601267344@qq.com

seen in other groups, a body plan that emphasizes cephalization is usually an integral factor in adapting to a predatory lifestyle. The central nervous system of chaetognaths includes a large dorsal cerebral ganglion in the head. From this, paired nerves extend posterodorsally to the eyes and corona ciliata, and small anteriorly directed frontal connectives lead to paired esophageal ganglia and, ultimately, innervate the head muscles and gut, forming a sort of loop. Larger paired circumesophageal main connectives extend posteroventrally to join a large ventral ganglion (also called the **ventral nerve center**) located in the trunk epidermis (Figure 11.19G). From the ventral ganglion, numerous peripheral nerves radiate to all parts of the trunk and tail, branching to form an elaborate intraepidermal nerve plexus having both sensory and motor functions. Via the main connectives and these peripheral nerves, the ventral ganglion receives sensory input from the head and from ciliary receptors on the body. It controls swimming and other behaviors caused by the body wall musculature of the trunk and tail.

Ciliary receptors are short straight rows of nonmotile cilia that project from the body surface. They are stereotypically arranged and oriented either parallel (sometimes called "ciliary fences") or transversely (sometimes called "ciliary tufts") relative to the long axis of the body, such that the entire body functions as an "antenna" for reception of nearby disturbances. The ciliary receptors detect hydrodynamic stimuli and react to close-range mechanosensory input, thus are important for both prey detection and input leading to swimming behavior. Each receptor contains 50–300 cells. Although chemoreceptors have yet to be positively identified in chaetognaths, they almost certainly exist. Candidates include the aforementioned corona ciliata, the pore-bearing vestibular ridges located just behind the teeth, and other tiny pores flanking the mouth.

Most arrow worms possess a pair of eyes on the dorsal surface of the head. Typically, each eye has a large central pigment cell, indented to form seven cups containing the light-sensitive parts of the photoreceptor cells, which are ciliary (not rhabdomeric) (Figure 11.19H). We can infer from their structure that chaetognaths have a nearly uninterrupted visual field enabling them to orient to light direction and intensity. The eyes of deep-water arrow worms are variously modified in ways that presumably increase sensitivity to light. For example, in certain species of *Eukrohnia*, the photoreceptor cells are directed outward, and each is capped by a transparent "lens." The eyes probably do not form images but are used for orientation during vertical migration.

Reproduction and Development

Arrow worms are hermaphroditic, with paired ovaries in the trunk and paired testes in the tail (Figure 11.19I). Groups of spermatogonia are released from the testes to the tail coeloms, where they circulate as the sperm mature. The filiform sperm are picked up by open ciliated funnels and conveyed down the sperm ducts to a pair of seminal vesicles, which bulge from the sides of the tail. In some species, gland cells secrete a spermatophore wall around the enclosed sperm. When filled with sperm, the seminal vesicles are conspicuously white. Release of sperm involves rupture of the seminal vesicles during mating. This can lead to self-fertilization in some species but happens during mating in most species. Each ovary bears along its side an oviduct that leads to a genital pore just in front of the trunk-tail septum. Eggs develop within the ovaries where they are bathed in a nutritive fluid derived from the posterior hemal sinus. Fertilization occurs prior to ovulation as sperm received during mating pass from the oviduct through specialized accessory fertilization cells to the attached eggs. Immediately after fertilization, zygotes move into the oviduct for release to the environment.

Mating has been most extensively studied in some benthic spadellids (e.g., *Spadella cephaloptera*, *Paraspadella gotoi*) and the neritic *Ferosagitta hispida*. After a rather elaborate mating "dance," sperm from a seminal receptacle are deposited as a mass onto the mate's body. In *Paraspadella gotoi*, the sperm mass is precisely placed at the female gonopore, but in the others sperm masses are attached more anteriorly, and columns of sperm stream over the epidermis of the recipient to enter the female gonopores. Benthic chaetognaths (e.g., *Spadella*) tend to deposit fertilized eggs on algae or other suitable substrata. Planktonic species typically shed floating embryos to the sea. *Pterosagitta draco* encloses the embryos in a large floating gelatinous mass, and species of *Eukrohnia* carry developing embryos in gelatinous masses, one on either side of the body near the tail, until the young are ready to swim (Figure 11.18 and Figure 11.21). *Ferosagitta hispida* descends and attaches developing eggs to stationary benthic objects. When food is abundant, new batches of sperm and eggs can be produced in daily succession.

Development is direct, lacking any larval stage or metamorphosis. The transparent eggs contain little yolk, and cleavage is holoblastic and equal. Both classical and modern studies have suggested a modified spiral pattern of cleavage, with unmistakable animal and vegetal cross-furrow cells, but this is easily overlooked because animal-pole cells ("micromeres") and vegetal-pole cells ("macromeres") are similar in size, and cleavage of arrow worms has been incorrectly described in the past as being radial. However, while a spiralian-like tetrahedral four-cell embryo is derived via a levotropic blastomere displacement in the second cleavage, subsequent cleavage stages have not yet been documented, and further research is needed to understand the nature of cleavage in these animals. The coeloblastula consists of pyramidal cells arranged around a small blastocoel (Figure 11.22).

Gastrulation (germ layer formation) occurs by invagination of the presumptive endoderm, leaving no blastocoel. The blastopore marks the eventual posterior end of the animal—both mouth and anus form secondarily, thus giving chaetognaths a deuterostome-like developmental pattern. Starting at the future anterior end, vertical epithelial folds of endoderm grow posteriorly through the archenteron, separating the future lateral coelomic cavities from the medial gut cavity (Figure 11.22). Early formation of the head-trunk septum results in the early isolation of the head coeloms. As development continues, embryos elongate and the body cavities become compressed, but the surrounding mesodermal cells retain their epithelial morphology. The coeloms re-expand later in development and then persist as true coeloms into adulthood. Interestingly, all organs and tissues of mesodermal origin, including body wall musculature, intestinal musculature, and somatic reproductive tissues, derive entirely from the peritoneum of the embryonic coeloms. It seems that coelom and mesoderm formation in chaetognaths is neither fully enterocoelous nor schizocoelous; some have called this a modified enterocoely, whereas Kapp (2000) proposed the name **heterocoely** for the unique mode of coelom formation in this group.

(D) Later gastrula. (E) Production of mesodermal folds from archenteron. (F) Blastopore closure and secondary mouth opening with the formation of a stomodeum. (G) Formation of coelomic pouches.

Development from zygote release to hatching as a juvenile chaetognath is rapid, about 48 hours. Parental investment per embryo is small, the eggs contain little yolk, and they are abandoned soon after fertilization, except in a number of brooding forms (Figures 11.18 and 11.21). The rapid development to a feeding juvenile is essential to the success of this life history strategy.

Chapter Summary

This chapter introduced you to the clade Gnathifera, which contains four phyla: Gnathostomulida, Rotifera, Micrognathozoa, and Chaetognatha. The name "Gnathifera" is derived from the presence of complex, hardened, pharyngeal jaws used for feeding in these four groups. Although differing in details, the jaws in these four phyla are thought to be homologous. Gnathostomulids and chaetognaths are strictly marine; micrognathozoans and most rotifers inhabit fresh waters. The parasitic and highly modified acanthocephalans, once assigned to their own phylum, are now recognized as a clade within Rotifera. Phylogenetic studies strongly support a sister-group relationship between Micrognathozoa and Rotifera, but the relationships of the other gnathiferans have yet to be fully resolved. Gnathostomulids comprise about 100 species of microscopic, vermiform, meiofaunal, hermaphroditic animals. Rotifers include about 2,150 species of mostly microscopic, free-living creatures, plus another 1,200 species of parasitic acanthocephalans that inhabit the guts of various vertebrates (especially birds and freshwater fishes). Free-living rotifers are common in fresh waters, but also occur in brackish and marine environments. Micrognathozoa, the only animal phylum known strictly from freshwater habitats, consists of a single described, microscopic (80 μm to 150 μm adult length) creature from a cold spring in Greenland. Records of micrognathozoans from freshwater creeks in the Indian Ocean region (Crozet Islands), England, and the Pyrenees (Spain) may prove to be distinct species. The chaetognaths, or arrow worms, are a small phylum of about 130 species of marine, mainly planktonic (although a number of benthic species are known), gelatinous animals that reach up to 12 cm in length. Outfitted with powerful jaws, arrow worms are voracious predators and important in oceanic planktonic food webs.

CHAPTER 12

Platytrochozoa and Two Enigmatic Phyla

Entoprocta and Cycliophora

The great protostome clade known as Spiralia contains 15 phyla, 14 of which belong to the two lineages Gnathifera and Platytrochozoa, while the phylogenetic relationship of the phylum Dicyemida remains unclear. The larger clade Platytrochozoa encompasses ten phyla, eight of which belong to the well-supported clades Lophotrochozoa and Rouphozoa (see Chapters 8, 13, and 17). But two platytrochozoan groups remain difficult to place among their spiralian kin: Entoprocta and Cycliophora. This chapter treats these two enigmatic phyla.

Unlike the Gnathifera, which show a relatively conserved body plan, the Platytrochozoa phyla are highly variable, and divergences such as blind versus through guts or the presence versus absence of primary and secondary body cavities seem to have evolved multiple times.

Entoprocts have been known since the nineteenth century, but cycliophorans were not discovered until the 1960s and not described until 1995. Both are small marine phyla, although two freshwater entoproct species are known. Entoprocts resemble minute cnidarian polyps and are often colonial, whereas cycliophorans are solitary microscopic symbionts on the mouthparts of lobsters. Neither is encountered frequently enough to have acquired a generally accepted vernacular name. Although species in these two phyla do not resemble one another superficially, you will recognize some fundamental anatomical similarities as you read about them here. Some morphological work (and early molecular phylogenies) supported a grouping of Entoprocta + Cycliophora + Bryozoa (the "Polyzoa"), but phylogenetic studies over the past decade have removed the bryozoans from this group, leaving just the entoprocts and cycliophorans as a possible sister group buried somewhere deep in the Spiralia lineage.

The section on Entoprocta was revised by Claus Nielsen.

Phylum Entoprocta: The Entoprocts

The phylum Entoprocta (Greek *entos*, "inside"; *proktos*, "anus"), or Kamptozoa (Greek *kamptos*, "bent"), includes about 200 described species of small, sessile, solitary or colonial creatures that superficially resemble cnidarian hydroids (Figure 12.1; Box 12A). All but two species are marine (the freshwater colonial *Urnatella gracilis* and *Loxosomatoides sirindhornae*). Colonial forms live attached to various substrata, including algae, shells, and rock surfaces. Many solitary species are commensal on a variety of hosts—especially sponges (Figure 12.1C), sipunculans, and other annelids—and are typically associated with just one or a few host species. Entoprocts are not uncommon in shallow water; most live shallower than 200 m in the sea, but some species are known from depths as great as 5,220 m. They are often mistaken for tiny cnidarian polyps or otherwise overlooked by the casual tide pool observer because of their small size, but a quick examination through a hand lens reveals both their beauty and their true nature. Certain benthic flatworms and molluscs are known to feed on entoprocts.

The individual zooids of entoprocts are goblet shaped but clearly bilateral, and the crown of feeding tentacles in most of the colonial species is almost circular. Each zooid consists of a cuplike body, the **calyx**, from which arises an almost closed horseshoe of ciliated tentacles (Figure 12.1). The tentacles encircle a concavity, called the **atrium** or vestibule, in which both the protonephridia and the gonoducts open. The

mouth and anus both lie inside the tentacle crown, the mouth being situated on the rim carrying the tentacle crown, and the anus opening on a small anal cone in the atrium (hence the name Entoprocta). The calyx is carried on a stalk, which in solitary forms attaches to the substratum, either directly or via a complicated foot. In colonial forms the stalk attaches to branched stolons or an enlarged basal plate. The phylum is commonly divided into four families. Some specialists recognize orders on the basis of the presence or absence of a septum between the stalk and calyx, or on solitary versus colonial habits. Recent molecular studies, albeit with limited data, have supported a division into two classes: Solitaria (for Loxosomatidae) and Coloniales (for the remaining three families, in which the stalks attach to a common basal plate or to branched stolons).

The phylogenetic position of the entoprocts has been much discussed. Originally, they were treated as bryozoans, but when the larval protonephridium was discovered in 1877 (by Berthold Hatschek), they were placed in the Scolecida, with affinities to the Rotifera. Also, unlike Bryozoa and other lophophorates, entoprocts have spiral cleavage. In the 1920s, R. B. Clark discovered that they lack a coelom, and they were then placed somewhere in

BOX 12A Characteristics of the Phylum Entoprocta

1. Triploblastic, bilateral, unsegmented, probably acoelomate
2. Sessile, solitary, or colonial (with stalks borne on stolons)
3. Cup-shaped calyx body carried on a stalk and housing a U-shaped gut
4. Calyx with a horseshoe-shaped band of ciliated tentacles that surround the mouth, anus, gonoducts, and protonephridia; mouth situated at base of the frontal tentacles and anus at the opposite side of the atrium
5. Hermaphroditic or gonochoristic
6. Cleavage spiral
7. Some with trochophore larvae
8. Nearly all species shallow-water marine animals (two known freshwater species and a few that inhabit brackish waters) attached to stones or algae; many of the solitary species as commensals of annelids, sponges, and other water-current-producing invertebrates

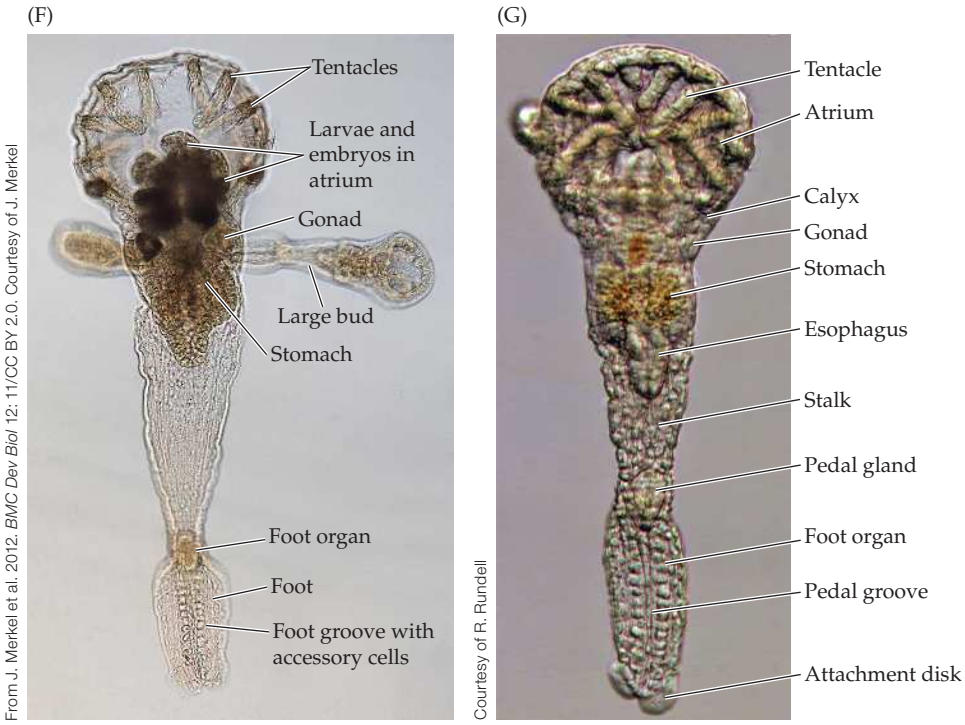

FIGURE 12.1 Entoprocts. (A,B) Diagrams of a solitary (*Loxosomella*) and a colonial (*Pedicellina*) entoproct. (C) Dense growth of an unidentified *Loxosomella* on a sponge; many calyces can be seen rising from their stalks. (D) Two zooids of *Pedicellina cernua*, each showing its calyx and stalk. (E) Zooids of an undescribed Australian species of *Barentsia*. (F) *Loxosomella vancouverensis* from San Juan Island, Washington, with embryos, larvae, and buds. (G) Labeled micrograph of the meiofaunal species *L. vancouverensis*, from British Columbia (Canada). Described in 2012, this is the first free-living entoproct, and only the third entoproct species, reported from the west coast of North America. The other two known west coast species are both symbionts on the mantis shrimp *Pseudosquilla ensigera*. *Loxosomella vancouverensis* is just 440 µm long and has 14 tentacles and two attachment discs at the base of the foot organ. The foot adheres to the substrate (sand grains and shell bits) but can detach and reattach.

the large group Spiralia. Their position among the Spiralia remains enigmatic, but recent work suggests they may be closely allied to Cycliophora.

Crown-group (modern) entoproct fossils are known only from specimens of *Barentsia* in the Late Jurassic of the United Kingdom. An entoproct-looking fossil from the Cambrian Chengjiang biota, *Cotyledion tylodes*, has been descried and has the typical body divisions of a calyx, stalk, and "holdfast."

ENTOPROCT CLASSIFICATION

FAMILY LOXOSOMATIDAE Solitary; without a septum between stalk and calyx; usually commensal on other invertebrates; some are capable of limited movement on a suckered base or a complicated foot; muscles continuous from stalk to calyx (see Figure 12.1A,C). (e.g., *Loxosoma*, *Loxosomella*)

FAMILY LOXOKALYPODIDAE Colonial; without a septum between stalk and calyx; a few zooids attached to a basal plate; muscles continuous from stalk to calyx; ectocommensal on the annelid *Glycera nana* in the northeastern Pacific. Monotypic: *Loxokalypus socialis*

FAMILY PEDICELLINIDAE Colonial; with incomplete stalk-calyx septum; with star-cell complex; muscles extend for the length of the stalk but are not continuous with those of calyx; stalk undifferentiated (see Figure 12.1B,D). (e.g., *Loxosomatoides*, *Myosoma*, *Pedicellina*)

FAMILY BARENTSIIDAE Colonial; with incomplete stalk-calyx septum; with star-cell complex; stalk differentiated into wide, muscular nodes and narrow, nonmuscular rods (see Figure 12.1E). (e.g., *Barentsia*, *Urnatella*)

The Entoproct Body Plan

Body Wall, Support, and Movement

The calyx (body) and stalk are covered by a thin cuticle that does not extend over the ciliated portion of the tentacles or the atrium. Some have described the fine structure of the cuticle as more similar to annelids than it is to either Bryozoa or Cycliophora. The stiff parts of the stalk of barentsiids have a thick cuticle, and cuticular dorsal "shields" are characteristic of some colonial species. The stalk often contains chitin. The epidermis is cellular. All entoprocts have a tentacle musculature with larger outer muscles and thinner inner muscles. These muscles move the tentacles and curl them up when the tentacle crown is retracted; a ring muscle just below the tentacle base constricts the atrium over the retracted tentacles. Other muscle bands compress the calyx to extend the tentacles. Contractions of longitudinal and oblique muscles in the basal part of the calyx and in the stalk make characteristic nodding movements of the zooid possible and also enable more complicated movements of the stalk. The myoanatomy of the so-called entoproct "creeping larva" shows similarities to the foot of some molluscs, as do the paired sets of dorsoventral muscles that intercross ventrally above the foot. Most authors suggest there is no persistent body cavity, and the area between the gut and body wall is filled with mesenchyme (Figure 12.2D). However, others have provided evidence for a primary body cavity separated from all surrounding tissues by a basal lamina, which underlies the ectodermal and endodermal epithelia and covers the excretory system, gonads, muscle cells, and nerves that cross the body cavity, thus suggesting that small remnants of a primary body cavity are retained as a hemocoel—this constituting the basis of the Lacunifera hypothesis that unites Entoprocta with Mollusca. And, at least one recent molecular analysis found a mollusc-entoproct clade.

Feeding and Digestion

Entoprocts are ciliary suspension feeders. They collect food particles, mostly phytoplankton, from currents produced by the lateral cilia on the tentacles (Figure 12.2A,C). The water currents pass between the tentacles and away from the atrium. Food particles are collected on the downstream side of the ciliary band by the "catch-up method" in which the compound lateral cilia—several cilia working together as one unit—cut through the water to contact the particle and push it to the frontal band of separate cilia on the frontal side of the tentacle (Figure 12.2B). The particles are then transported along the tentacle to the horseshoe-shaped ciliary band along the food groove on the atrial ridge and to the mouth (Figure 12.2C).

Food particles are moved into the gut by cilia lining the buccal tube and by muscular contractions of the esophagus (Figure 12.2D). The esophagus leads to a spacious stomach, from which a short intestine extends to the rectum located within the anal cone. Food is moved through the gut by cilia. The stomach lining secretes digestive enzymes and mucus, which are mixed with the food by a tumbling action caused by the ciliary currents. Digestion and absorption occur within the stomach and intestine, where food is held for a time by an intestinal-rectal sphincter muscle.

Circulation, Gas Exchange, and Excretion

The gut also apparently serves as an excretory passage. Cells in the ventral stomach wall accumulate brownish spheres and release them into the stomach lumen, from which they are discharged through the anus. Adult entoprocts also possess a pair of flame bulb protonephridia located between the stomach and the atrium epithelium (Figure 12.1B). The freshwater species *Urnatella gracilis* has additional, more complex protonephridia both in the body and in the joints of the stalk. The protonephridia drain to a short common nephridioduct that leads to a pore on the surface of the atrium. A similar condition is found in another

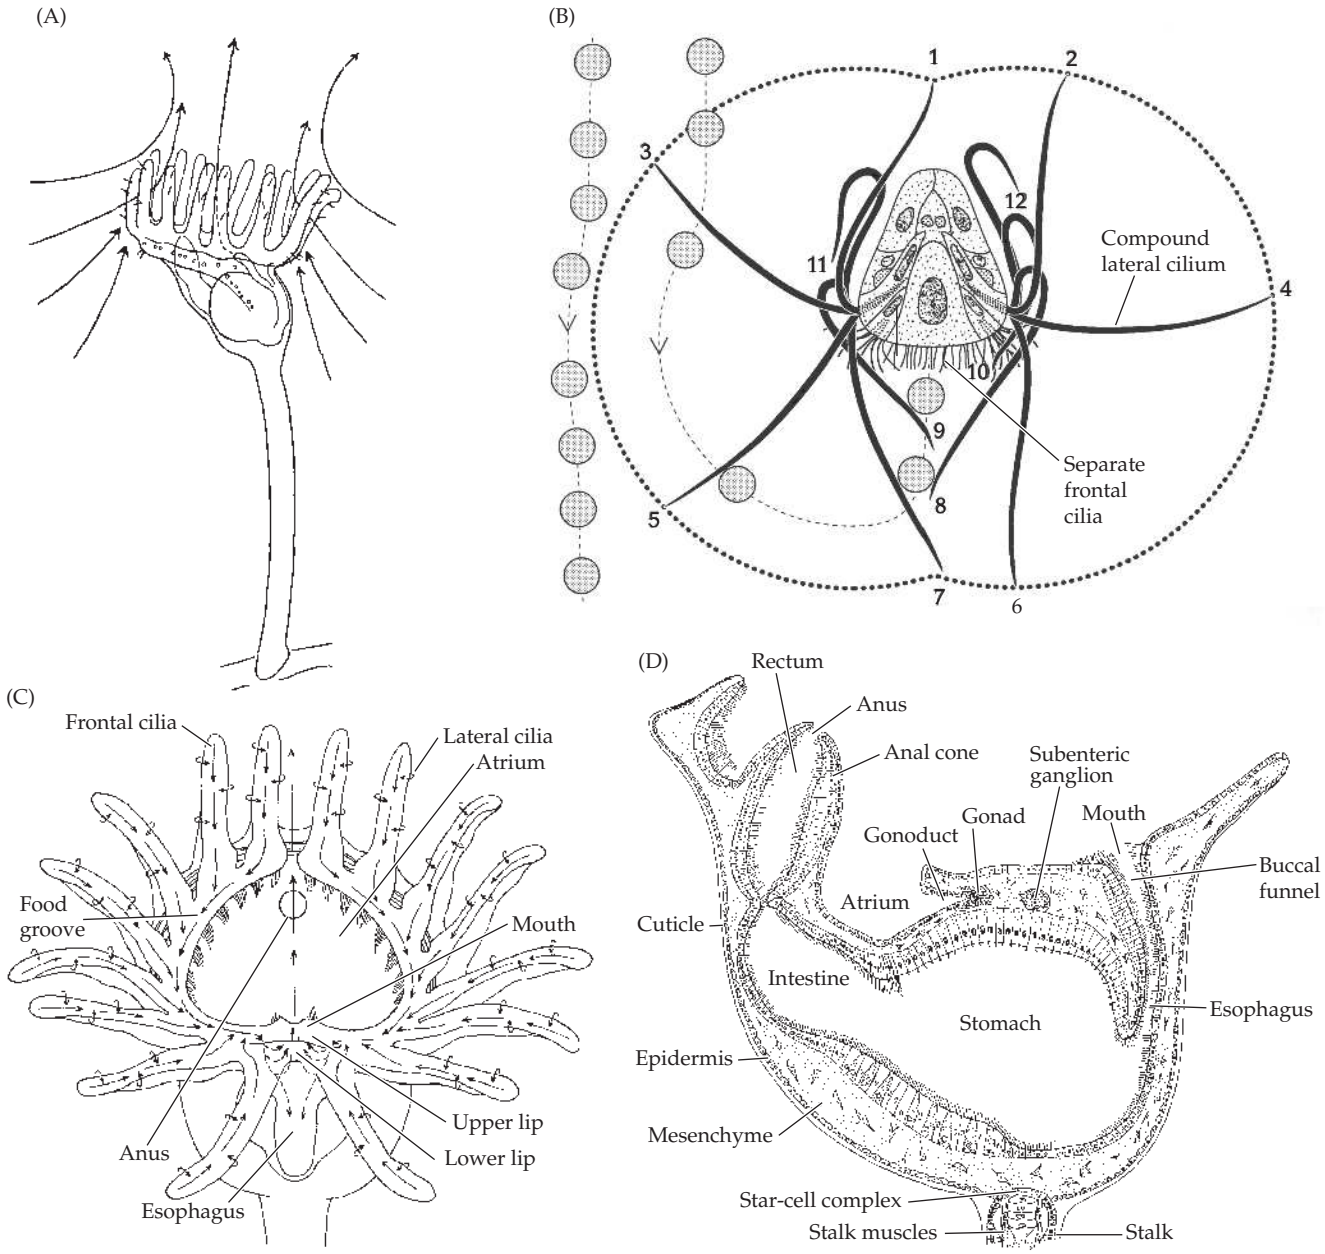

FIGURE 12.2 Entoproct feeding and digestion. (A) Water currents of the tentacle crown of *Loxosomella leptoclini* set up by the lateral cilia. (B) Downstream-collecting by the catch-up principle. A cross section through a tentacle with the movements of the large compound lateral cilia illustrated through successive steps (numbered 1–12) of a cilium on each side. The compound cilium catches up with the gray particle and pushes it to the frontal band of small separate cilia. (C) Ciliary feeding currents of the tentacle crown of a *Loxosomella*. Particles caught by the lateral cilia are transported along the frontal side of the tentacle to the food groove and further to the mouth. (D) Diagram of a median section of the calyx of a *Barentsia*.

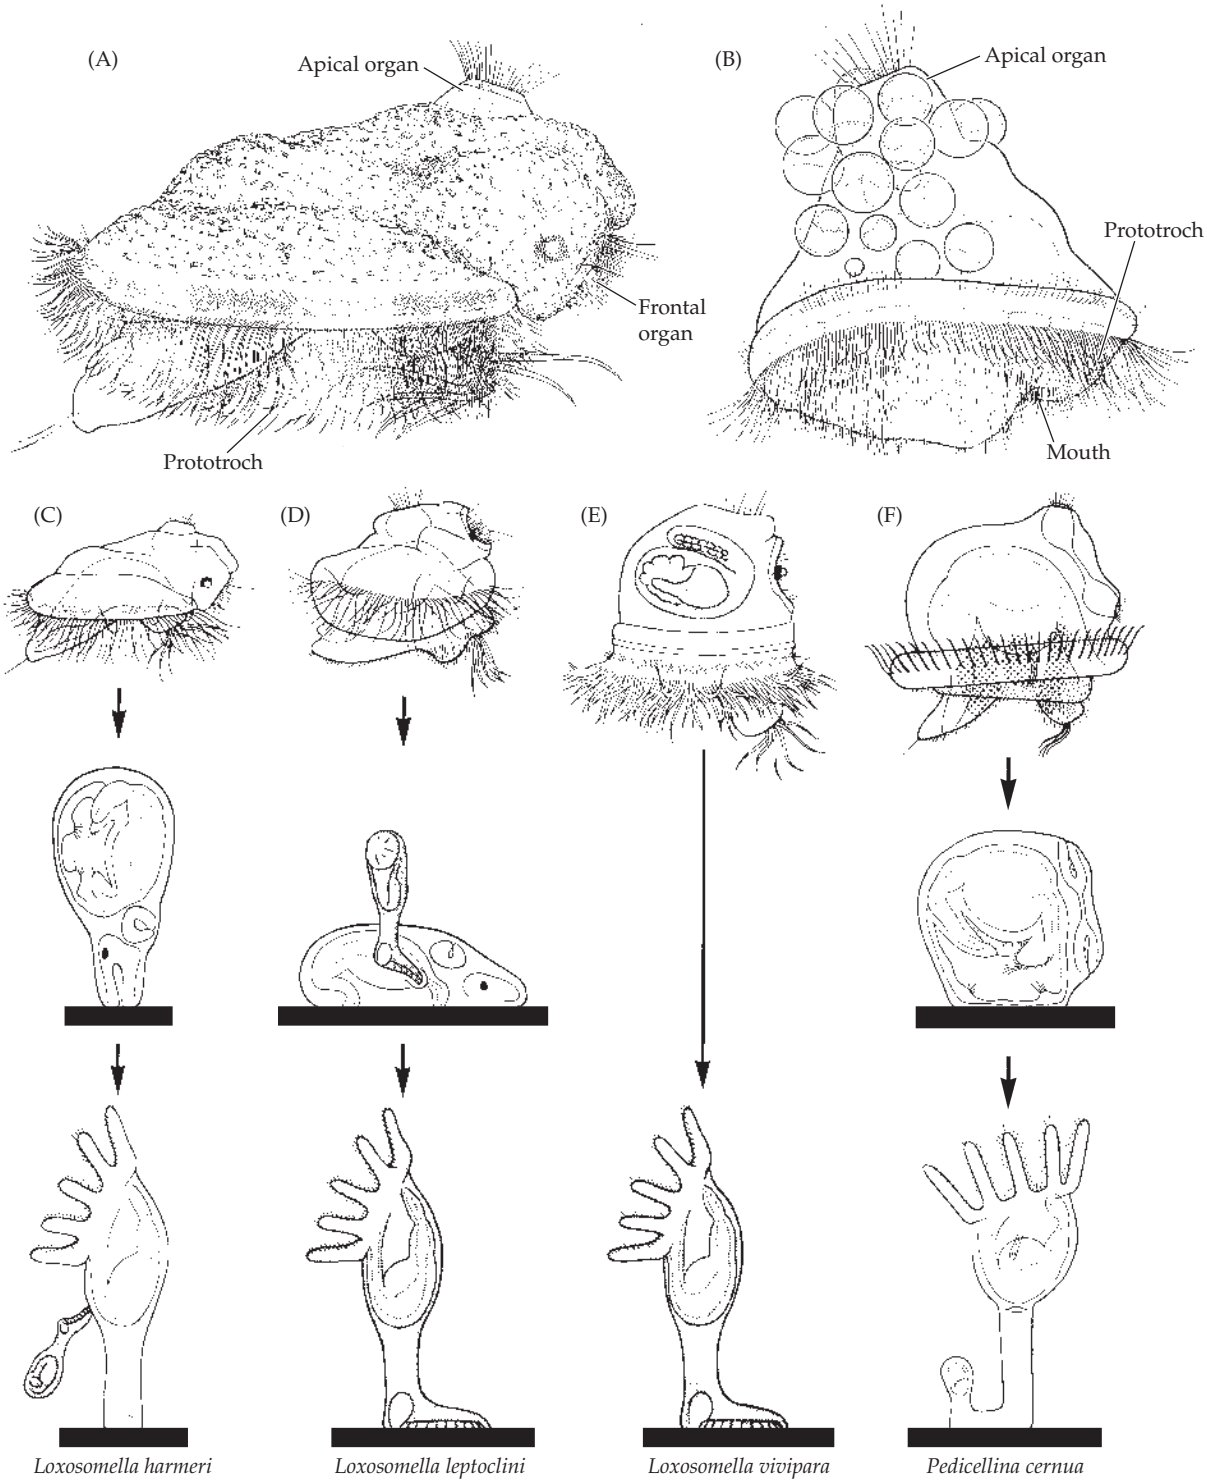
unrelated freshwater species, *Loxosomatoides sirindhornae*. In most species, protonephridia appear to be present also in the larvae.

Internal transport is largely through the expansive gut; diffusion distances through the mesenchyme are small between its lumen and the body wall. Colonial entoprocts have a so-called **star-cell organ** located near the stalk-calyx junction (Figure 12.2D). This structure is thought to function as a heart by pulsating and pumping fluid from the calyx to the stalk. Gas exchange probably occurs over much of the body surface, particularly at the cuticle-free tentacles and atrium.

Nervous System

As is often the case in sessile invertebrates, the nervous system is greatly reduced. A single dumbbell-shaped ganglionic mass, called the subenteric ganglion, lies between the stomach and atrial surface (Figures 12.1B and 12.2D). The subenteric ganglion gives rise to several



pairs of nerves to the tentacles, calyx wall, and stalk. Unicellular tactile receptors are concentrated on the tentacles and scattered over much of the body surface. Ciliated papillae form lateral sense organs in some loxosomatids.

Reproduction and Development

Colony growth occurs by budding from the tips of the stolons (Figure 12.1B–E) or in some barentsiids from joints of the stalk. Solitary forms asexually produce buds on the calyx in the region of the esophagus, and these eventually separate from the parent (Figure 12.3C).

Most, perhaps all, loxosomatids are hermaphroditic and many are protandric. Those that are thought to have separate sexes may also be protandric, but with a long time between the male and female phases. Colonial forms may have hermaphroditic or gonochoristic zooids, and colonies may contain one or both sexes. One or two pairs of gonads lie just beneath the surface of the atrium. Short gonoducts lead from the gonads to

◀ **FIGURE 12.3 Entoproct larvae and metamorphoses.** (A) Lecithotrophic larva of *Loxosomella harmeri*. (B) Planktotrophic larva of *Loxosoma pectinaricola*. (C–F) Settling and metamorphosis. (C) The larva settles with the frontal organ and becomes a juvenile (*Loxosomella harmeri*). (D) The larva settles and develops one or two buds that detach as juveniles; the larval body disintegrates (*Loxosomella leptoclini*). (E) The large internal bud disrupts the larval body and settles as a juvenile (*Loxosomella vivipara*). (F) The larva settles with the area just above the prototroch, and the gut rotates 180° with the mouth in front; the atrium reopens in the juvenile (*Pedicellina cernua*).

a common pore opening to the atrium (which serves as a brood chamber) (Figure 12.2D).

Sperm apparently are released into the water and then enter the female reproductive tract, with fertilization occurring in the ovaries or oviducts. As the zygote moves along the oviduct, cement glands secrete a tough surrounding membrane with a stalk by which the embryos are attached to the wall of the atrium/brood chamber. In a few species, the embryos are nourished by cells of the maternal atrium.

Cleavage in entoprocts is asynchronous, holoblastic, and clearly spiral. Nonsynchronous divisions produce five "quartets" of micromeres at about the 56-cell stage. Cell fates are similar to those in typical protostome development, including the derivation of mesoderm from the 4d mesentoblast. A coeloblastula forms and gastrulates by invagination. A larva develops that, in some species, resembles a typical planktotrophic trochophore (a basic larval type among protostomes), with a spiralian-like apical organ and proto- and metatroch bands used in swimming and downstream-collecting of food particles (Figure 12.3B). A few loxosomatids produce small eggs, and the larvae apparently spend a considerable period feeding in the plankton. Most of the loxosomatids and all the colonial species produce larger eggs; the fully differentiated larvae break the egg envelope and begin feeding. After release from the mother, these larvae have a short free period, and some of them do not feed (Figure 12.3A). Settling and metamorphosis show much variation. Some species of *Loxosomella* settle with a frontal organ, and the larval gut is retained in the adult (Figure 12.3C). Other loxosomatids develop external (Figure 12.3D) or internal (Figure 12.3E) buds from the episphere (the region above the prototroch) of the larva, and the larval body disintegrates. The larvae of the colonial species settle by cells just above the retracted prototroch and undergo a remarkable unequal growth of the body mass to rotate the gut so that the ventral, atrial surface points away from the substratum (Figure 12.3F).

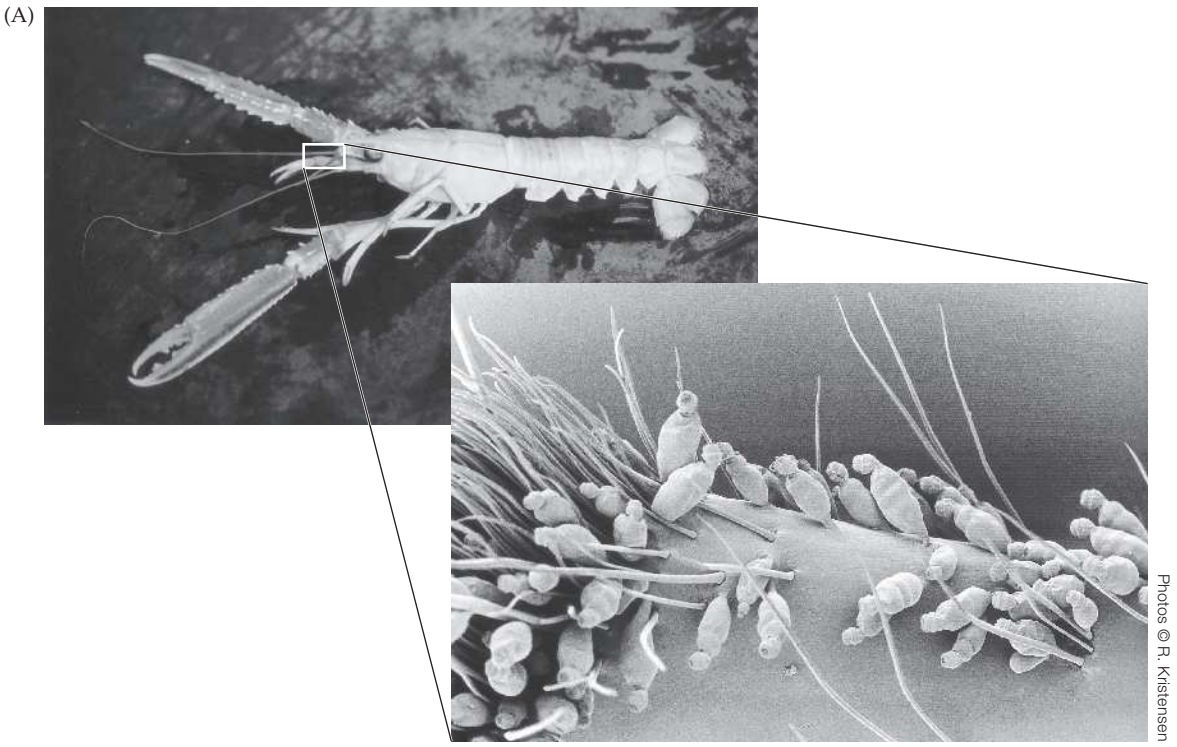
Phylum Cycliophora: The Cycliophorans

Symbion pandora is a microscopic marine animal first discovered in the 1960s living commensally on the mouthparts of the Norway lobster, *Nephrops norvegicus* (Figure 12.4; Box 12B). Not described until 1995, this apparently acoelomate animal was recognized as a separate phylum, Cycliophora. Since then, a second species, *Symbion americanus*, has been described from the American lobster, *Homarus americanus*, and investigations of the mouthparts of the European lobster (*Homarus gammarus*) suggest that a third species might also exist. The existence of one or more additional cryptic species on the American lobster has also been suggested by molecular studies. Cycliophorans appear to be highly host specific, though recent observations provided evidence for a possible symbiotic relationship between them and harpacticoid copepods. Although the role of copepods in the cycliophoran life cycle is unknown, two specimens of copepods carrying cycliophorans were collected from the mouthparts of a European lobster. The odd ecology of these minute metazoans is surpassed only by their bizarre anatomy and life history.

The life cycle of a cycliophoran is complex and involves various sexual and asexual phases alternating through a succession of stages. In striking contrast to sexual stages, asexual stages undergo a process of intense transcriptional and posttranscriptional regulation. Yet, whether this differential gene expression profile is connected with the shift to sexual reproduction remains inconclusive. The most conspicuous stage in the life cycle is an approximately 350 μm sessile individual

BOX 12B Characteristics of the Phylum Cycliophora

1. Triploblastic, bilateral, unsegmented, functionally acoelomate
2. Sessile, solitary symbionts of lobsters (feeding stage) or short-lived free-living phases; two described and two to three undescribed species known, all from Atlantic and Mediterranean lobsters
3. With layered cuticle, adhesive disc for attachment to host, and U-shaped gut
4. Suspension feeding, utilizing dense cilia situated on ring of multiciliate epidermal cells encircling opening of buccal funnel
5. Without circulatory system or respiratory organs
6. With one pair of protonephridia in the chordoid larva; excretory organs absent in all other stages
7. With a complex life cycle involving sexual and asexual stages that alternate through a succession of events
8. Cleavage apparently holoblastic, though pattern is unique among Spiralia
9. Maturation of the male involving a marked reduction of internal body volume, mainly by massive nuclei loss
10. With unique Pandora, Prometheus, and chordoid larvae



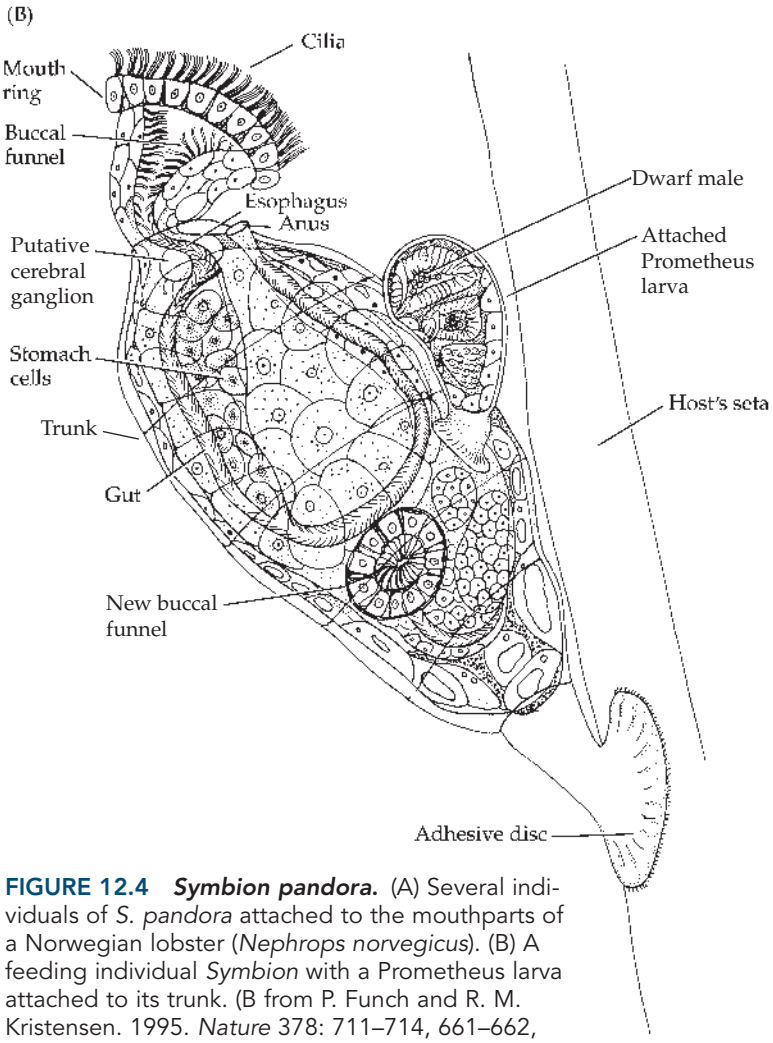


FIGURE 12.4 ***Symbion pandora.*** (A) Several individuals of *S. pandora* attached to the mouthparts of a Norwegian lobster (*Nephrops norvegicus*). (B) A feeding individual *Symbion* with a Prometheus larva attached to its trunk. (B from P. Funch and R. M. Kristensen. 1995. *Nature* 378: 711–714, 661–662, https://www.nature.com/articles/378711a0)

with a body divided into an anterior buccal funnel, an oval trunk, and a posterior adhesive disc by which the animal attaches to its host's setae (Figure 12.4). A layered cuticle covers the trunk and adhesive disc, the latter apparently composed entirely of cuticular material. Equipped with a U-shaped gut, this is the only cycliophoran stage able to feed—and the most likely stage to be found by a cycliophoran enthusiast. The region between the gut and body wall is packed with large mesenchymal cells, and no evidence of a body cavity has been observed. Suspension feeding is enhanced by creating water currents with dense cilia that are situated on a ring of epidermal cells encircling the open end of the buccal funnel. These multiciliate epidermal cells alternate with contractile myoepithelial cells, which form a pair of sphincters involved in the closure of the mouth opening. The U-shaped gut is ciliated along its entire length. The buccal funnel leads to a curved esophagus and then to a stomach consisting of large stomach cells that protrude into a narrow lumen. An intestine extends anteriorly to a short rectum and anus, located dorsally near the base of the buccal funnel. A complex sphincter is located proximally to the anus. The area between the gut and other organs is packed with a cellular mesenchyme. A pair of muscles span longitudinally along

for more ebook/ testbank/Solution manuals request, email 960126734@qq.com

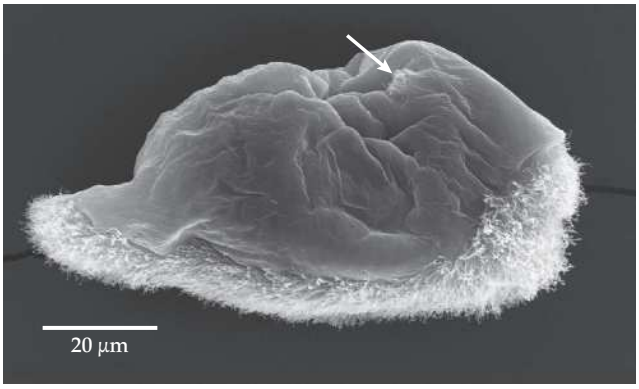
the buccal funnel, while several longitudinal muscle fibers (six in *S. americanus* and two to eight in *S. pandora*) begin at the most distal region of the trunk and span about two-thirds of its length.

Circulation and gas exchange are presumably accomplished by simple diffusion in these tiny animals. The nervous system is poorly understood, and two ganglia were originally described in the feeding individual: one ganglion located at the base of the buccal funnel, and the other partially surrounding the esophagus. However, further observations based on ultrastructural and immunohistochemical investigations have not confirmed the existence of these ganglia. Excretory organs have not been identified in the feeding individual, although a pair of protonephridia is present in one of the larval stages, the chordoid larva.

Feeding-stage individuals are able to reproduce asexually by a budding process that occurs inside the trunk and generates free-swimming stages, one at a time—these are the **Pandora larva**, the **Prometheus larva**, and the female. In order to rapidly increase the population density on a single host, the feeding individual generates Pandora larvae (170 μm long), which possess a buccal funnel inside their bodies. Once released, the Pandora larva settles close to the maternal individual on the lobster host and develops into a new feeding stage.

In the sexual part of the life cycle, a free-swimming Prometheus larva (120 μm long) settles on the trunk of a feeding individual and develops one to three dwarf males (40 μm long) inside its own body. Females (which like the males have also escaped from the maternal individual) carry a single oocyte and are impregnated by dwarf males in a process that is not yet well understood. A number of morphological structures might be involved in impregnation. For instance, a small (~3 μm in diameter), circular structure surrounded by cilia is located medially on the ventral side of the female body. This structure has been described as a putative gonopore, though a canal for the conductance of sperm is not evident. In addition, the external morphology of the male is characterized by a "penis" located ventroposteriorly, although its actual function as a true copulatory organ or as a mere anchoring and piercing device is uncertain. A recent investigation at the ultrastructural level revealed the presence of a sperm cell inside the penis of the dwarf male, which provides support for the former view. The female migrates from the body of the maternal cycliophoran individual to the lobster host, where it settles onto a sheltered area of the mouthparts and encysts, and the embryo develops into the so-called **chordoid larva**.

The chordoid larva (Figure 12.5) hatches from the cyst, swims away from it, and settles on a new host, where it eventually develops into a new feeding stage. This is probably the avenue by which dispersal to new host individuals is achieved. The anatomy of the chordoid larva was first described by Funch (1996), who suggested that it is a modified trochophore larva, homologous with those of many spiralians (e.g., annelids and molluscs). However, the overall neuroanatomy of this larval stage much more closely resembles the condition of adult rather than larval stages of spiralian taxa. The chordoid larva is also characterized by a ventral chordoid organ that spans the entire length of the body. The function of the chordoid organ is not known, although it might be supportive and locomotory; it is mainly muscular.



Courtesy of Ricardo Neves

FIGURE 12.5 ***Symbion pandora*, chordoid larva.** Note the dense ciliated field covering the ventral region of the body, from posterior (left) to anterior (right). The arrow points at the dorsal ciliated organ, which appears to have a sensory role.

Knowledge of cycliophoran development is quite limited. Details on early embryogenesis derive from observations on settled females bearing an internal embryo. The eight-cell-stage embryo is composed of a group of four macromeres and four micromeres. Cleavage appears to be holoblastic, though the arrangement of the blastomeres does not reveal any clear pattern similar to that seen in other spiralian taxa. As for asexual development, a recent study using serial block-face scanning electron microscopy provided new insights on the development of the dwarf male inside the attached Prometheus larva. During the maturation of a young male into a mature dwarf male, the body undergoes a reduction of about one-third in the internal body volume, mainly by extensive loss of nuclei in the majority of its somatic cells (but especially in cells of the muscles and epidermis). Organs seen in mature dwarf males—muscles, brain, testis, glands, etc.—are already formed in the young male. The young male stage possesses about 200 nucleated cells, whereas the mature male stage comprises only around 50 nucleated cells; muscle and epidermal cells of the mature male lack nuclei. Thus, contrary to typical development of metazoans, the cycliophoran dwarf male does not grow after organogenesis is concluded.

The external morphology of the Prometheus larva, the Pandora larva, and the female is similar in many respects. For example, an anteroventral ciliated field

and a posterior ciliated tuft, as well as four bundles of long cilia—which compose a sensory organ, or sensilla—are present in all these life cycle stages. In addition, all of these free-swimming stages possess a well-differentiated cuticle characterized by a polygonal sculptured surface. The external morphology of the chordoid larva differs from these stages in possessing anterior, ventral, and posterior ciliated fields, as well as a paired dorsal organ that appears to have a sensory role (Figure 12.5). The dwarf male is characterized by dense ventral and frontal ciliated fields, and sensilla situated laterally and frontally. The myoanatomy and nervous system of all cycliophoran free-swimming stages have been investigated by transmission electron and confocal laser scanning microscopy. In general, the musculature of the free stages is very complex and includes longitudinal muscles that span the body dorsally and ventrally, as well as dorsoventral muscles. All free-swimming stages possess a dorsal brain composed of a pair of lateral clusters of perikarya interconnected by a commissural neuropil. Moreover, the chordoid larva has four distinct ventral longitudinal neurites, while all the other free-swimming stages have only two. The typical spiralian apical organ is absent in all cycliophoran larval stages, thus rejecting a homology of any of these stages with a trochophore larva.

Chapter Summary

This chapter introduced you to the phyla Cycliophora and Entoprocta, two small taxa of minute size and uncertain affinity embedded in the large and highly diverse protostome clade called Platytrochozoa. Cycliophora and Entoprocta are fundamentally marine animals (two freshwater species of entoprocts are known), and both groups are so rare that common names don't exist for them. Entoprocts are small, probably acoelomate, solitary or colonial, polyplike creatures that have been known since the nineteenth century. Cycliophorans are microscopic, solitary, acoelomate symbionts on the mouthparts of lobsters, where they form large aggregations. They weren't discovered until the 1960s and are still quite poorly known, with their complex life cycle just beginning to be understood. Entoprocts show typical spiral development. Both phyla have planktonic larvae, those of Entoprocta probably being trochophores. Major research areas that are important to our understanding of these two phyla include their precise phylogenetic placement in the protostome tree of life, the nature of the cycliophoran symbiotic relationship with lobsters (and possibly also copepods), and the embryogeny and life cycle of cycliophorans.

CHAPTER 13

Introduction to the Lophotrochozoa, and the Phylum Mollusca

In Chapters 8 and 10 we introduced you to the Protostomia and Deuterostomia, and to the two protostome clades Spiralia and Ecdysozoa. While these higher-level clades are well supported by molecular data, the relationships within Spiralia still remain to be sorted out. As you can see in the Classification of the Animal Kingdom, we recognize two large clades of Spiralia, Gnathifera and Platytrochozoa (plus the enigmatic Dicyemida). Within the Platytrochozoa, a group of six phyla almost always cluster in molecular phylogenies. These are the Mollusca, Nemertea, Annelida, and the three lophophorate phyla (Phoronida, Bryozoa, Brachiopoda). These six phyla comprise the clade **Lophotrochozoa**, and their Cambrian remains, in the form of the so-called "small shelly fossils," seem to be shells, spicules, and setae of extant groups such as molluscs, brachiopods, annelids, and some of their stem group members (e.g., halkieriids, wiwaxiids, hyoliths, and tommotiids). The presence of such structures with a seemingly similar developmental origin, originating as epidermal formations whose secretory cells develop into a cup or a follicle with microvilli at its base, may be the morphological character that unites the members of Lophotrochozoa. In fact, it has been proposed that there has been co-option of Hox genes for making shells, spicules, and chaetae (see Schiemann et al. 2017), pushing the case for homology. Interestingly, this clade of animals primarily with spicules and/or sclerites also includes animals without such hard parts, as for example nemerteans and phoronids.

As a disclaimer, the name Lophotrochozoa has been given different meaning by different authors. While some use it as a synonym for the whole clade Spiralia, we prefer to use the

The section on Mollusca was revised by David R. Lindberg and Winston F. Ponder.

more restricted sense given here. The compound name of Lophotrochozoa refers to the clade Lophophorata (i.e., Brachiopoda, Bryozoa, and Phoronida), and the clade formerly known as Trochozoa (i.e., Annelida, Mollusca), plus other groups with a "cryptic trochophore" larva (Nemertea), and perhaps Entoprocta and Cycliophora. However, the position of the latter two phyla, probably closely related, is unstable in phylogenomic analyses. In this chapter we focus on one of the main lophotrochozoan phyla, the Mollusca.

Phylum Mollusca

Molluscs comprise the second largest phylum of animals (after arthropods) and include some of the best-known invertebrates; almost everyone is familiar with snails, clams, slugs, squid, and octopuses. Molluscan shells have been popular since ancient times, and some cultures still use them as tools, containers, musical devices, money, fetishes, religious symbols, ornaments, decorations, and art objects. Evidence of historical use and knowledge of molluscs is seen in ancient texts and hieroglyphics, on coins, in tribal customs, and in archaeological sites and aboriginal kitchen middens or shell mounds. Royal or Tyrian purple of ancient Greece and Rome, and even Biblical blue (Num. 15:38), were molluscan pigments extracted from certain marine snails.[1] Many aboriginal groups have for millennia relied on molluscs for a substantial portion of their diet and for use as tools. Today, coastal nations annually harvest millions of tons of molluscs commercially for food.

There are approximately 73,000 (±3,000) described, living mollusc species and about the same number of described fossil species. However, many species still await names and description, especially those from poorly studied regions and time periods. In addition to three familiar molluscan classes comprising the clams (Bivalvia), snails and slugs (Gastropoda), and squid and octopuses (Cephalopoda), there are five other extant classes: chitons (Polyplacophora), tusk shells (Scaphopoda), *Neopilina* and its kin (Monoplacophora), and the vermiform sclerite-bearing aplacophoran classes—Caudofoveata (or Chaetodermomorpha) and Solenogastres (or Neomeniomorpha). Although members of these eight classes differ enormously in superficial appearance, there is a suite of characters that diagnose their fundamental body plan (Box 13A).

BOX 13A Characteristics of the Phylum Mollusca

1. Bilaterally symmetrical (or secondarily asymmetrical), unsegmented, coelomate protostomes
2. Coelom limited to small spaces in nephridia, heart, and gonads
3. Principal body cavity a hemocoel (open circulatory system)
4. Viscera concentrated dorsally as a "visceral mass"
5. Body with a cuticle-covered epidermal sheet of skin, the mantle
6. Mantle with shell glands that secrete calcareous epidermal sclerites, shell plates, or shells
7. Mantle overhanging and forming a cavity (the mantle cavity) in which are housed the ctenidia, osphradia, nephridiopores, gonopores, and anus
8. Heart situated in a pericardial chamber and composed of a single ventricle and one or more separate atria
9. Typically with large, well-defined muscular foot, often with a flattened creeping sole
10. Buccal region provided with a radula and muscular odontophore
11. Complete (through) gut, with marked regional specialization, including large digestive glands
12. With large, complex metanephridial "kidneys"
13. Cleavage typically spiral and embryogeny protostomous, with cephalopods an exception
14. Typically with a trochophore larva, and a veliger larva in gastropods and bivalves; some groups with a test cell larva

Taxonomic History and Classification

Molluscs carry the burden of a very long and convoluted taxonomic history, in which hundreds of names for various taxa have come and gone. Aristotle recognized molluscs, dividing them into Malachia (the cephalopods) and Ostrachodermata (the shelled forms), the latter being divided into univalves and bivalves. Joannes Jonston (or Jonstonus) created the name Mollusca[2] in 1650 for the cephalopods and barnacles, but this name was not accepted until it was resurrected and redefined by Linnaeus nearly 100 years later. Linnaeus's Mollusca included cephalopods, slugs, and pteropods, as well as tunicates, anemones, medusae, echinoderms, and polychaetes—but he placed chitons, bivalves (including the unrelated brachiopods), univalves, nautilids, barnacles, and the serpulid

[1] Archaeological sites in Israel reveal the probable use of two muricid snails (*Bolinus brandaris* and *Hexaplex trunculus*) as sources of the royal purple dye.

[2] The vernacular for "Mollusca" is often spelled *mollusks* in the United States, whereas in many other parts of the world it is typically spelled *molluscs*. In biology, a vernacular or diminutive name is generally derived from the proper Latin name; thus the custom of altering the spelling of "Mollusca" by changing the *c* to *k* seems to be an aberration (although it may have its historic roots in the German language, which does not have the freestanding *c*; e.g., *Molluskenkunde*). We prefer the more widely used spelling *molluscs*, which seems to be the proper vernacularization and is in line with other accepted terms, such as "molluscan," "molluscoid," "molluscivore," etc.

for more ebook/ testbank/ solution manuals request to email 9601267344@qq.com

polychaetes (which secrete calcareous tubes) in another group, Testacea. In 1795 Georges Cuvier published a revised classification of the Mollusca that was the first to approximate modern views. Henri de Blainville (1825) altered the name Mollusca to Malacozoa, which won little favor but survives in the terms "malacology," "malacologist," etc.

Much of the nineteenth century passed before the phylum was purged of all extraneous groups. In the 1830s, J. Thompson and C. Brumeister identified the larval stages of barnacles and revealed them to be crustaceans, and in 1866 Alexander Kowalevsky removed the tunicates from Mollusca. Separation of the brachiopods from the molluscs was long and controversial and not resolved until near the end of the nineteenth century.

The first sclerite-covered, wormlike aplacophorans, members of what today we recognize as the class Caudofoveata, were discovered in 1841 by the Swedish naturalist Sven Lovén. He classified them with holothuroid echinoderms because of their vermiform bodies and the presence of calcareous sclerites in the body walls of both groups. In 1886, another Swede, Tycho Tullberg, described the first representative of the other aplacophoran group—the Solenogastres. Ludwig von Graff (1875) recognized both groups as molluscs, and in 1876 they were united in the Aplacophora by Hermann von Ihering. The Aculifera hypothesis of Amélie Scheltema unites molluscs that possess calcareous sclerites by placing Polyplacophora as the sister taxon of the aplacophorans (Caudofoveata + Solengastres). Aculifera was sometimes also called Amphineura, although this latter term has also been used by some workers to refer only to chitons. **Sclerites** are spicules, scales, and so on that cover or are embedded in the epidermis of molluscs and are often calcified.

The history of classification of species in the class Gastropoda has been volatile, undergoing constant change since Cuvier's time. Most modern malacologists have been influenced by the schemes of Henri Milne-Edwards (1848) and J. W. Spengel (1881). The former, basing his classification on the respiratory organs, recognized the groups Pulmonata, Opisthobranchia, and Prosobranchia. Spengel based his scheme on the nervous system and divided the gastropods into the Streptoneura and Euthyneura. In subsequent classifications, Streptoneura was equivalent to Prosobranchia; Euthyneura included Opisthobranchia and Pulmonata. The bivalves have been called Bivalvia, Pelecypoda, and Lamellibranchiata. More recently, anatomical, ultrastructural, and molecular studies have brought about considerable changes to molluscan classification. Also, many taxa have multiple names, and the more commonly encountered ones are noted below.

Molluscan classification at the genus and species levels can also be troublesome. Many species of gastropods and bivalves are also burdened with numerous names (synonyms) that have been proposed for the same species. This tangle is partly the result of a long history of amateur shell collecting, beginning with the natural history cabinets of seventeenth-century Europe, which required documentation and promoted multiple taxonomies and names based only on shell characters. Today, species are recognized based on a combination of shell, anatomical, and, most recently, molecular characters. However, because of the tremendous diversity of gastropods and bivalves many species still remain known only from their shells.

Only taxa with extant members are included in the following classification, and some examples of families are listed in Synopses of Major Molluscan Groups. The classification is mostly ranked, but in a few cases unranked group names are used. Examples of the major molluscan taxa appear in Figure 13.1.[3]

ABBREVIATED CLASSIFICATION OF LIVING MEMBERS OF THE PHYLUM MOLLUSCA[4]

CLASS CAUDOFOVEATA (= CHAETODERMOMORPHA)
Caudofoveatan aplacophorans (spicule worms)

CLASS SOLENOGASTRES (= NEOMENIOMORPHA)
Solenogaster aplacophorans (spicule worms)

CLASS MONOPLACOPHORA Monoplacophorans; deep sea, limpet-like

CLASS POLYPLACOPHORA Chitons, with eight shell valves

CLASS GASTROPODA Snails, slugs, and limpets

SUBCLASS EOGASTROPODA

INFRACLASS PATELLOGASTROPODA True limpets

[3]Multitudes of extinct molluscs have been described. Perhaps the most well known are some of the groups of cephalopods that had hard external shells, similar to those of living *Nautilus*. One of these groups was the ammonites. They differed from nautilids in having shell septa that were highly fluted on the periphery, forming complex mazelike septal sutures. Ammonites also had the siphuncle lying against the outer wall of the shell, as opposed to the condition seen in many nautilids where the siphuncle runs through the center of the shell.

[4]Note that the gastropod classification endorsed by Ponder and Lindberg (2020) dividing gastropods into Eogastropoda and Orthogastropoda and adopted in this chapter has been refuted by most molecular analyses (e.g., Aktipis et al. 2008), including phylogenomic analyses of gastropod relationships (Zapata et al. 2014; Cunha and Giribet 2019), which instead favor a sister group relationship of Patellogastropoda and Vetigastropoda, a clade named Psilogastropoda (Cunha and Giribet 2019). The remaining gastropods (Neritimorpha, Caenogastropoda, and Heterobranchia) are known as Adenogonogastropoda (Simone 2011) or Angiogastropoda (Cunha and Giribet 2019). Only some recent mitochondrial genome analyses support the Eogastropoda/Orthogastropoda division (Uribe et al. 2019).

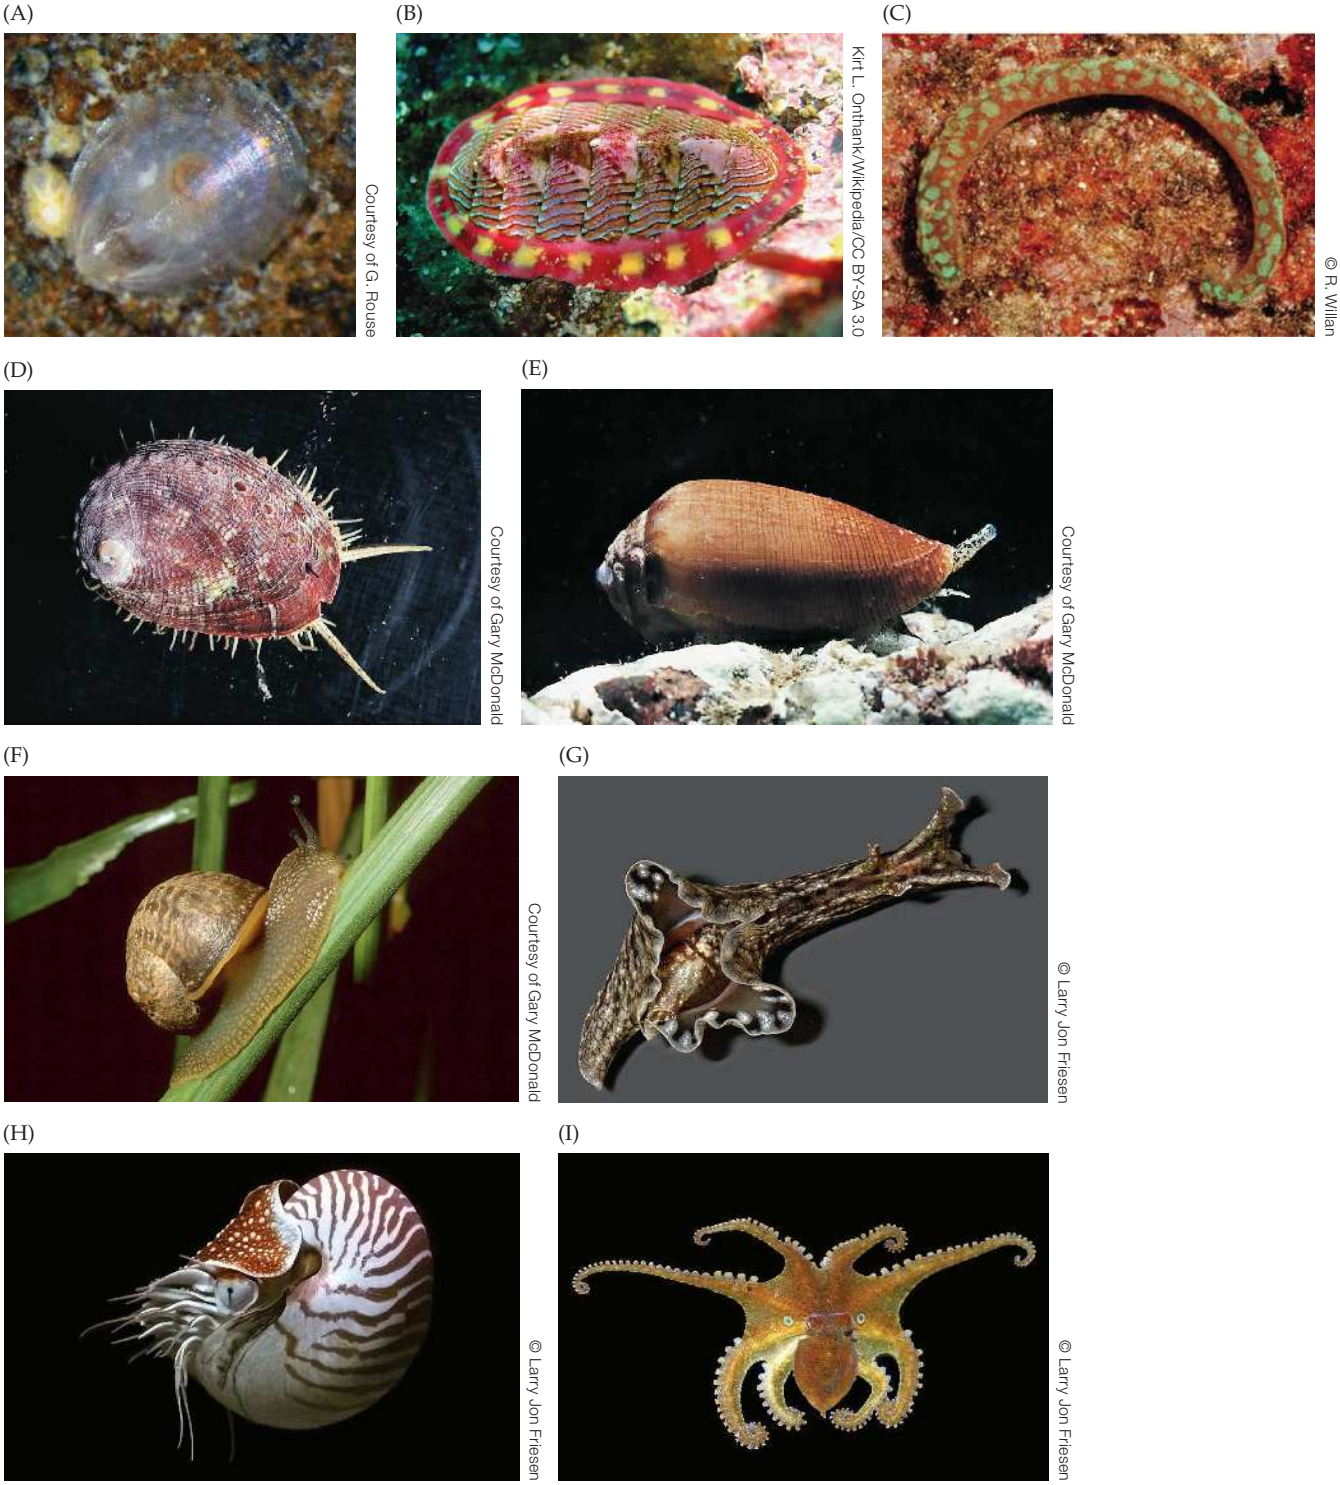

FIGURE 13.1 Morphological diversity among the molluscs. (A) *Laevipilina hyalina* (Monoplacophora). (B) *Tonicella lineata*, a lined chiton (Polyplacophora). (C) *Epimenia australis* (Solenogastres). (D) *Haliotis rufescens*, the red abalone (Gastropoda, Vetigastropoda); note the exhalant holes in the shell. (E) *Conus*, a predatory neogastropod; note anterior siphon extending beyond shell (Gastropoda, Hypsogastropoda). (F) A common garden snail, *Cornu aspersum* (Gastropoda, Panpulmonata). (G) *Aplysia*, the sea hare (Gastropoda, Euopisthobranchia). (H) The chambered *Nautilus* (Cephalopoda, Nautilida). (I) *Octopus bimaculoides* (Cephalopoda, Coleoida). (J) *Sepioteuthis lessoniana*, the bigfin reef squid (Cephalopoda, Coleoida). (K) *Histioteuthis*, a pelagic squid (Cephalopoda, Coleoida). (L) *Fustiaria*, a tusk shell (Scaphopoda). (M) Scallops (Bivalvia, Pteriomorphia), with a hermit crab in the foreground. (N) The giant clam *Tridacna maxima* (note zooxanthellate mantle), from the Marshall Islands, Northwest Pacific (Bivalvia, Heterodonta, Cardiida). (O) The European cockle *Acanthocardia tuberculata* (Bivalvia, Heterodonta, Cardiida). Note the partly extended foot. (P) *Lima*, a tropical clam that swims by clapping the valves together (Bivalvia, Pteriomorphia). (Q) The highly modified bivalve *Brechites* (Heterodonta, Anomalodesmata) known as watering-pot shells. It begins its life as a typical small bivalve but then secretes a large calcareous tube around itself through which water is pumped for suspension feeding.

SUPERORDER DECABRACHIA Cuttlefish, squid

SYNOPSES OF MAJOR MOLLUSCAN GROUPS

CLASS CAUDOFOVEATA (= CHAETODERMOMORPHA) (Figure 13.2A–C). Caudofoveatans, or spicule worms. Marine, benthic, burrowing; body vermiform, cylindrical, lacking any trace of a shell; body wall with a chitinous cuticle and imbricating scalelike aragonitic calcareous sclerites; mouth shield anterior to or surrounding the mouth; small posterior mantle cavity with a pair of bipectinate ctenidia; radula present; gonochoristic. Without foot, eyes, tentacles, statocysts, crystalline style, osphradia, or nephridia. About 130 species; burrow in muddy sediments and consume microorganisms such as foraminiferans. (e.g., *Chaetoderma, Chevroderma, Falcidens, Limifossor, Prochaetoderma, Psilodens*)

CLASS SOLENOGASTRES (= NEOMENIOMORPHA) (Figure 13.2D–K). Solenogasters, or spicule worms. Marine, benthic; body vermiform and nearly cylindrical; vestibulum (= atrium) with sensory papillae anterior to the mouth; small posterior mantle cavity lacking ctenidia but often with respiratory folds; body wall with a chitinous cuticle and imbued with calcareous sclerites (as spines or scales); with or without radula; hermaphroditic; pedal glands opening into a pre-pedal ciliary pit; foot weakly muscular, narrow, and retractable into a ventral furrow or "pedal groove." Without eyes, tentacles, statocysts, crystalline style, osphradia, or nephridia. About 260 described species, but many undescribed species are thought to exist; epibenthic carnivores, often found on (and consuming) cnidarians and a few other types of invertebrates. Solenogastres and Caudofoveata are sister groups in most phylogenetic schemes and are sometimes regarded as subclasses within the class Aplacophora. (e.g., *Alexandromenia*, *Dondersia*, *Epimenia*, *Kruppomenia*, *Neomenia*, *Proneomenia*, *Pruvotina*, *Rhopalomenia*, *Spengelomenia*, *Wirenia*)

(G) *Epimenia verrucosa*. The body is covered with warts. (H) *Neomenia carinata*, ventral view.

(*Continued on next page*)

CLASS MONOPLACOPHORA Monoplacophorans. With a single, caplike shell; foot forms weakly muscular ventral disc, with 8 pairs of retractor muscles; shallow mantle cavity around foot encloses 3–6 pairs of ctenidia; 2 pairs of gonads; 3–7 pairs of nephridia; 2 pairs of heart atria; a pair of statocysts; with radula and distinct but small head region; without eyes; short oral tentacles present around mouth; with posterior anus; without a crystalline style; gonochoristic or, rarely, hermaphroditic (Figures 13.1A and 13.3). Until the first living species (*Neopilina galatheae*) was discovered by the Danish Galathea Expedition in 1952, monoplacophorans were known only from Paleozoic (Cambrian to Devonian) fossils. Since then their unusual anatomy has been a source of much evolutionary speculation. Monoplacophorans are limpet-like in appearance, living species are less than

3 cm in length, and most live at considerable depths in the ocean. About 35 described species, in 8 genera (*Adenopilina*, *Laevipilina*, *Monoplacophorus*, *Neopilina*, *Rokopella*, *Veleropilina*, *Vema*, *Micropilina*).

CLASS POLYPLACOPHORA Chitons (Figures 13.1B and 13.4). Flattened, elongated molluscs with a broad ventral foot and 8 dorsal shell plates (composed of aragonite); mantle forms thick girdle that borders and may partly or entirely cover shell plates; epidermis of girdle usually with calcareous spines, scales, or bristles; mantle cavity encircles foot and bears from 6 to more than 80 pairs of bipectinate ctenidia; 1 pair of nephridia; head without eyes or tentacles; crystalline style, statocysts and osphradia absent; nervous system lacking discrete ganglia, except in buccal region; well-developed radula present. Shell canals (aesthetes) sometimes have eyes (which are image-forming in some species) (Figure 13.43C,D). Marine, intertidal to deep

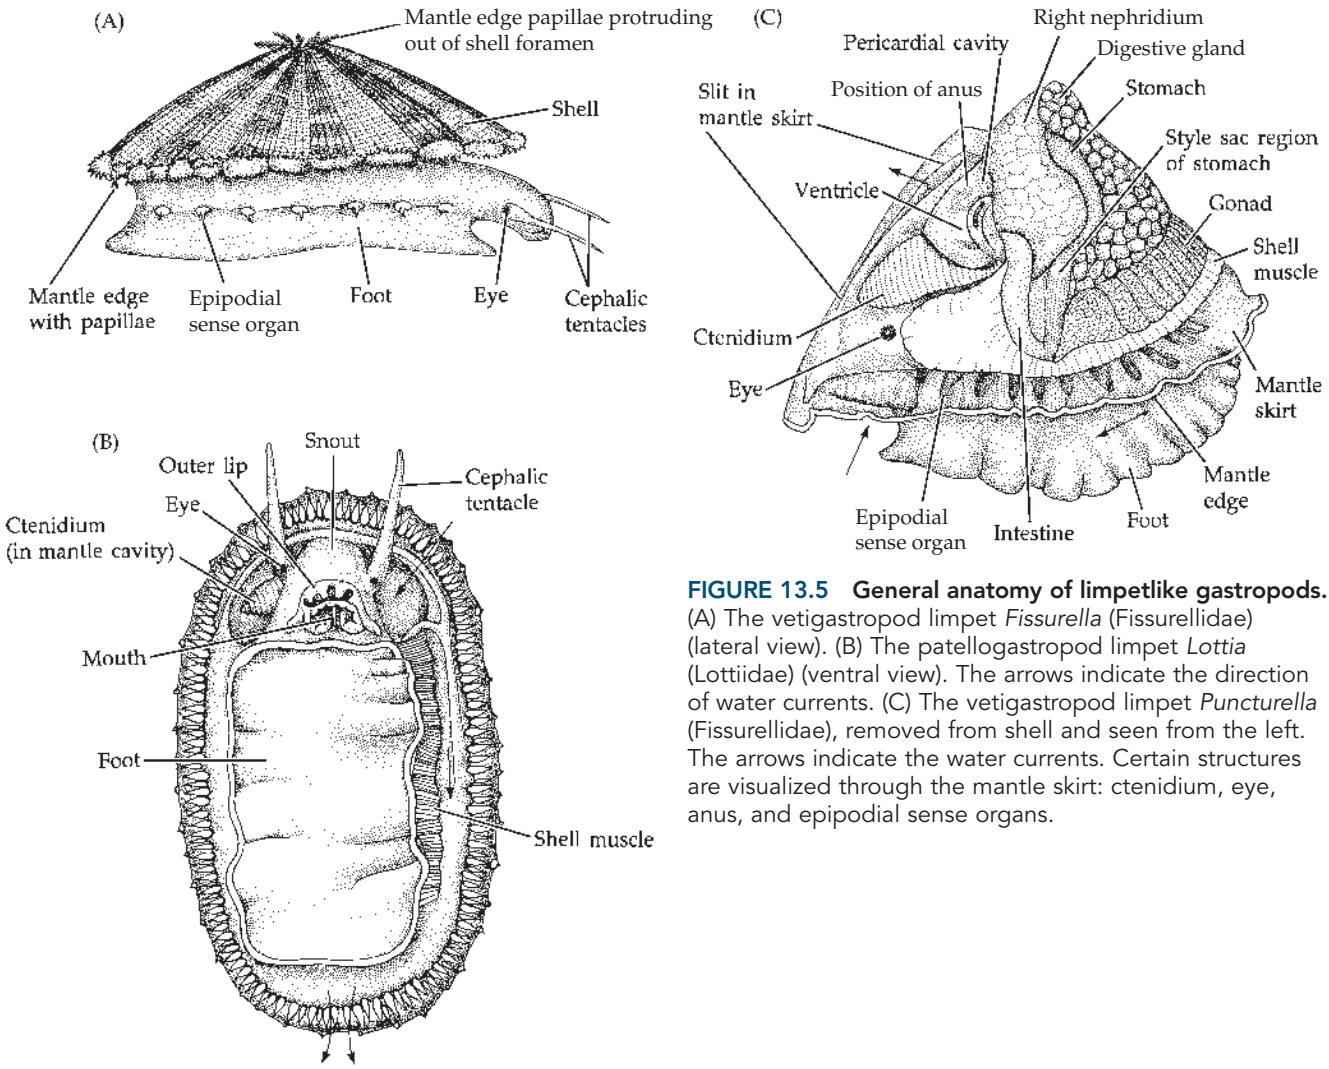

FIGURE 13.5 General anatomy of limpetlike gastropods. (A) The vetigastropod limpet *Fissurella* (Fissurellidae) (lateral view). (B) The patellogastropod limpet *Lottia* (Lottiidae) (ventral view). The arrows indicate the direction of water currents. (C) The vetigastropod limpet *Puncturella* (Fissurellidae), removed from shell and seen from the left. The arrows indicate the water currents. Certain structures are visualized through the mantle skirt: ctenidium, eye, anus, and epipodial sense organs.

CLASS GASTROPODA Snails, slugs and limpets (Figures 13.1D–G, 13.5, 13.6, and 13.7). Asymmetrical molluscs with single, usually spirally coiled shell into which body can be withdrawn; shell lost or reduced in many groups; during development, visceral mass and mantle rotate 90°–180° on foot (a process known as torsion), so mantle cavity lies anteriorly or on right side (rather than posteriorly as in other molluscs), and gut and nervous system are twisted; some taxa have partly or totally reversed the rotation (detorsion); with muscular creeping foot (modified in swimming and burrowing taxa); foot with operculum in larva and often in adult; head with eyes (often reduced or lost), and 1–2 pairs of tentacles, and a snout; most with radula and some with crystalline style, the latter being absent in most primitive and in many advanced groups; 1–2 nephridia; mantle (= pallium) usually forms anterior cavity housing ctenidia, osphradia, and hypobranchial glands; ctenidia sometimes lost and replaced with secondary gas exchange structures.

Gastropods comprise an estimated 32,000 described living species of marine, terrestrial, and freshwater snails and slugs. The class was traditionally divided into three groups treated as subclasses: prosobranchs (largely shelled marine snails), opisthobranchs (marine slugs), and pulmonates (terrestrial snails and slugs). However, recent anatomical and molecular studies have shown that classification to be incorrect.

SUBCLASS EOGASTROPODA Shell with foliated structure, lacking nacre; protoconch tubular; if limpet morphology, anterior dilation is exhibited. Foot lacks propodium; pedal muscle fibers not crossing. Radula docoglossate and stereoglossate, teeth with basal plates; jaw single, dorsal; odontophore with dorsolateral cartilages; style sac very long, intestine long, coiled. Hypobranchial glands absent. Blood lacks hemocyanin; ventricle attached to pericardium. Statocysts lateral to pedal ganglia; separate labial ganglia present; subradular organ well developed; osphradium with simple nerve endings; eyes lack lens. This grouping consists of mostly extinct Paleozoic taxa, with patellogastropods the only living clade.

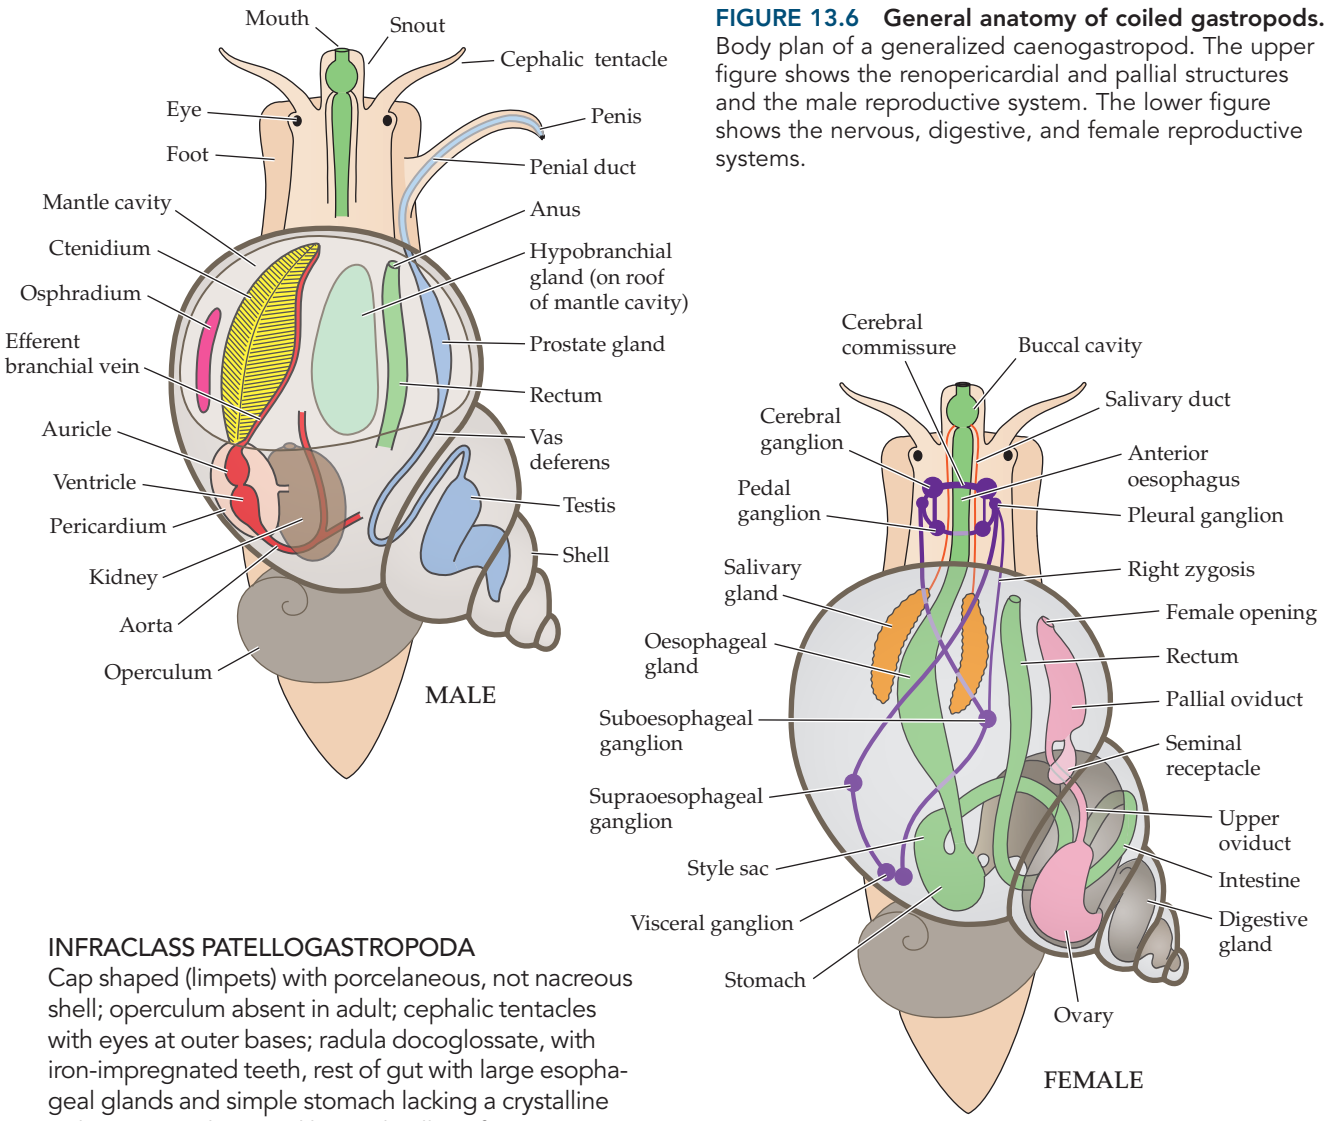

FIGURE 13.6 General anatomy of coiled gastropods. Body plan of a generalized caenogastropod. The upper figure shows the renopericardial and pallial structures and the male reproductive system. The lower figure shows the nervous, digestive, and female reproductive systems.

INFRACLASS PATELLOGASTROPODA
Cap shaped (limpets) with porcelaneous, not nacreous shell; operculum absent in adult; cephalic tentacles with eyes at outer bases; radula docoglossate, with iron-impregnated teeth, rest of gut with large esophageal glands and simple stomach lacking a crystalline style; intestine long and looped; gill configuration variable, single bipectinate ctenidium sometimes present (Figure 13.5B), and/or with mantle groove secondary gills, or gills lacking; shell muscle divided into discrete bundles; mantle cavity without siphon or hypobranchial glands; 2 rudimentary osphradia; single atria; 2 nephridia; usually gonochoristic; nervous system weakly concentrated, pleural ganglia near pedal ganglia, pedal and lateral cords present. Primarily marine with a few estuarine species; herbivorous. The patellogastropods include 6 families: Patellidae (e.g., *Patella*, *Scutellastra*), Nacellidae (e.g., *Cellana*), Lottiidae (e.g., *Lottia*), Acmaeidae (e.g., *Acmaea*), Lepetidae (e.g., *Lepeta*), and Neolepetopsidae (e.g., *Neolepetopsis*). These are often regarded as the "true" limpets.

SUBCLASS ORTHOGASTROPODA Shell without foliated structure, nacre present in some vetigastropods; protoconch coiled; if limpet morphology, posterior dilation exhibited; foot with propodium; pedal muscle fibers crossing. Radula flexoglossate, teeth lacking basal plates; odontophore lacking dorsolateral cartilages; jaw paired, lateral; style sac short to absent; intestine short with few coils or none. Hypobranchial glands present. Blood has hemocyanin; ventricle free from pericardium. Statocysts dorsal to pedal ganglia; labial ganglia fused with cerebral ganglia; subradular organ reduced or absent; osphradium with sensory cells; eyes with lens.

FIGURE 13.7 More gastropod anatomy: some caenogastropods and heterobranchs. (A–C) Caenogastropods. (A) The pelagic shelled heteropod *Carinaria* (Caenogastropoda). (B) Anatomy of *Carinaria*. (C) The shell-less heteropod *Pterotrachea* (Caenogastropoda). (D–J) Heterobranchs. (D) The pelagic shelled pteropod *Clio* (Heterobranchia, Euopisthobranchia). The arrows indicate the direction of water flow; water enters all around the narrow neck and is forcibly expelled by contraction of the sheath together with fecal, urinary, and genital products. (E) A swimming pteropod, *Corolla* (Heterobranchia, Euopisthobranchia). (F–I) Various nudibranchs (Heterobranchia, Nudipleura). (F) A doridid nudibranch, *Diaulula*. (G) An aeolid nudibranch, *Phidiana*.

FIGURE 13.7 (*continued*) More gastropod anatomy: some caenogastropods and heterobranchs. (H) A doridid nudibranch, *Goniobranchus geminus* (from the Red Sea). (I) The eastern Pacific "Spanish shawl" aeolid nudibranch, *Flabellina*. (J) The lettuce sea slug, *Elysia crispata* (Heterobranchia, Panpulmonata), from the Caribbean.

This group contains all the living gastropods except the patellogastropods.

INFRACLASS VETIGASTROPODA Shells both porcelaneous and nacreous; cephalic tentacles usually with eyes on short processes on outer bases; operculum usually circular, with a central nucleus and often many spirals, horny or calcareous; radula usually rhipidoglossate (with numerous transverse rows of teeth), rest of gut with esophagus having large glands, complex stomach with style sac but no crystalline style, looped intestine; 1–2 bipectinate ctenidia; shell muscles paired or single; mantle cavity with 1–2 hypobranchial glands, 1–2 atria, and 1–2 nephridia; usually gonochoristic; male generally without penis; nervous system weakly concentrated, ganglia poorly formed, pedal cords present; 1–2 osphradia, small, inconspicuous. All marine and benthic. Many species are microdetritivores or feed on films of bacteria or other organisms, or are microherbivores; some are macroherbivores, some grazing carnivores, and a few suspension feeders. Most gastropods found at hydrothermal vents, at cold seeps, and on deep-sea hard substrates are vetigastropods. Vetigastropods comprise about 42 living families, and their internal classification remains unsettled.

Vetigastropods include the slit-shelled snails Pleurotomariidae (e.g., *Entemnotrochus*, *Perotrochus*), Scissurellidae (e.g., *Scissurella*), and Anatomidae (e.g., *Anatoma*); the abalones Haliotidae (e.g., *Haliotis*); the keyhole and slit limpets Fissurellidae (e.g., *Diodora*, *Fissurella*, *Lucapinella*, *Puncturella*); deep-sea limpets comprising the Lepetellidae and related families (e.g., *Lepetella*, *Pseudococculina*); trochids Trochidae (e.g., *Trochus, Monodonta*); and related families such as Calliostomatidae (e.g., *Calliostoma*), Margaritidae (e.g., *Margarites*), Tegulidae (e.g., *Tegula*), and turbans Turbinidae (e.g., *Astraea*, *Turbo*); many of the hot-vent snails and limpets Neomphalidae (e.g., *Neomphalus*), Peltospiridae (e.g., *Hirtopelta*, *Peltaspira*), and Lepetodrilidae (e.g., *Lepetodrilus*); and the small, deep-sea wood and bone limpets Cocculinidae and Bathysciadiidae (e.g., *Cocculina*).

INFRACLASS NERITIMORPHA Shell coiled, limpet-like, or lost (Titiscaniidae). Shell porcelaneous, with interior whorls reabsorbed in many coiled groups; operculum typically present, of few spirals and with noncentral nucleus, horny or calcified, usually with internal peg; shell muscle divided into discrete bundles; only left ctenidium present; hypobranchial glands often lost on left side; stomach highly modified; right nephridium incorporated into complex reproductive system with multiple openings into mantle cavity; radula rhipidoglossate; most species gonochoristic, with copulatory structures; nervous system with ganglia concentrated, pleural ganglia near pedal ganglia, pedal cords present. Globally distributed in marine, estuarine, freshwater, and terrestrial habitats. There are 9 families of neritimorphans, of which Helicinidae (e.g., *Alcadia, Helicina*), Hydrocenidae (*Georissa*, *Hydrocena*), Proserpinellidae (e.g., *Proserpinella*), and Proserpinidae (*Proserpina*) are exclusively terrestrial. The five other families are Neritopsidae (*Neritopsis*), Titiscaniidae (*Titiscania*), Neritidae (e.g., *Nerita*, *Theodoxus*), Neritiliidae (cave nerites, e.g., *Neritilia, Pisulina*), and Phenacolepadidae (*Phenacolepas*).

for more ebook/ testbank/ solution manuals request to email:9601267344@qq.com

INFRACLASS CAENOGASTROPODA Shell mainly porcelaneous; operculum usually present and corneous, rarely calcified, with few spirals and usually with a noncentral nucleus, mostly not nacreous, rarely with internal peg(s); head with pair of cephalic tentacles, with eyes at outer bases; mantle cavity asymmetrical, with incurrent opening on anterior left, sometimes elaborated into an inhalant siphon; right ctenidium lost; left ctenidium monopectinate; right hypobranchial gland lost; right nephridium lost except for remnant incorporated into reproductive system; heart with only left atrium. Radula taenioglossate (7 rows of teeth), ptenoglossate (many rows of similar teeth), rachiglossate (1–3 rows of teeth), or toxoglossate (teeth modified as harpoons) or occasionally lost. Higher forms with concentrated ganglia, pleural ganglia usually near cerebral ganglia, pedal cords usually absent; osphradium conspicuous, often large, sometimes surface subdivided into lamellae. Most caenogastropods are gonochoristic and marine, but there are several freshwater groups and a few are terrestrial. The caenogastropods comprise the former "mesogastropods" and neogastropods, and they are often divided into two groups, as follows:

"ARCHITAENIOGLOSSA" Although this is not a monophyletic group, we retain it informally. Architaenioglossans differ from other caenogastropods in details of their nervous system and in the ultrastructure of their sperm and osphradia. They are divided among 13 extant families, including the freshwater Ampullariidae (apple snails, e.g., *Ampullaria, Pila*, *Pomacea*) and Viviparidae (river snails, e.g., *Viviparus*) and the terrestrial Cyclophoridae (e.g., *Cyclophorus*) and several related families such as Diplommatinidae (e.g., *Diplommatina*, *Opisthostoma*). Also included here are the marine families Campanilidae, Plesiotrochidae, and Ampullinidae.

COHORT SORBEOCONCHA This grouping contains the rest of the caenogastropods. These are divided into two main groups, Cerithiimorpha and Hypsogastropoda.

MEGAORDER CERITHIIMORPHA Usually without a penis; eggs usually laid in jelly, often in strings, or are brooded. The anterior aperture may or may not have a notch, housing a short siphon. Marine, brackish, and freshwater species are included. About 20 extant families are recognized, including the marine Cerithiidae (horn shells, e.g., *Cerithidea, Cerithium*, *Liocerithium*), Siliquariidae (slit worm shells, e.g., *Siliquaria*), and Turritellidae (tower or turret shells, e.g., *Turritella*) and the freshwater Melanopsidae (e.g., *Melanopsis*), Thiaridae (e.g., *Thiara*), and Pleuroceridae (e.g., *Pleurocera*).

MEGAORDER HYPSOGASTROPODA Comprises the remaining caenogastropods. The anterior mantle may be simple or can be enrolled, forming an anterior siphon that emerges from an anterior notch in the aperture or, in some, is contained within an extension of the shell, the siphonal canal. Male with cephalic penis; eggs usually laid in capsules or sometimes brooded. Nervous system concentrated; operculum, if present, chitinous, rarely calcareous. The classification of this group is unsettled. It includes the marine grazing snails Littorinidae (periwinkles, e.g., *Littorina*); several marine and freshwater families of small-sized taxa, including the Rissoidae (e.g., *Rissoa*, *Alvania*); and larger marine snails such as the Strombidae (conchs or strombids, e.g., *Aliger*, *Lambis, Strombus*) and the carrier shells, Xenophoridae (e.g., *Xenophora*). Also includes the uncoiled suspension-feeding worm snails (Vermetidae, e.g., *Dendropoma*, *Serpulorbis*) and the limpetlike Hipponicidae (e.g., *Hipponix*) which are deposit feeders, while Capulidae (e.g., *Capulus*) attach to other molluscs and mostly feed on their feces. The slipper shells Calyptraeidae (e.g., *Calyptraea*, *Crepidula*, *Crucibulum*) are suspension feeders. The Carinariidae (one of several families of pelagic molluscs collectively called heteropods, e.g., *Carinaria*) also have a cap-shaped shell.[6] Cypraeidae (cowries, e.g., *Cypraea*) are herbivores or grazing carnivores, while several other snail-like families are strictly carnivorous, including Naticidae (moon snails, e.g., *Natica*, *Polinices*) that feed mostly on bivalves, the ascidian-feeding Eratoidae (coffee bean shells, e.g., *Erato*, *Trivia*), and the soft-coral-feeding Ovulidae (egg shells, e.g., *Jenneria*, *Ovula*, *Simnia*). Tonnidae (tun shells, e.g., *Malea*) and related families such as Cassididae (helmet shells, e.g., *Cassis*) mainly feed on echinoderms, whereas Ficidae (fig shells, e.g., *Ficus*) are primarily polychaete feeders. Epitoniidae (wentletraps, e.g., *Epitonium*) feed on cnidarians and include the floating violet snails (e.g., *Janthina,* formerly in the family Janthinidae), which feed on siphonophores that drift on the surface of the ocean. Eulimidae are ectoparasites on echinoderms, and the sponge-feeding Triphoridae (e.g., *Triphora*) and Cerithiopsidae (e.g., *Cerithiopsis*) are highly diverse. There are some speciose families of small-sized freshwater snails such as the Hydrobiidae (e.g., *Hydrobia*) and several related families including the Pomatiopsidae (e.g., *Pomatiopsis*, *Tricula*), and there are also a few terrestrial taxa in families such as Pomatiasidae (e.g., *Pomatias*) and the otherwise mainly supralittoral Assimineidae and Truncatellidae.

[6]The term "heteropod" is an old taxonomic name now used informally for a group of planktonic, predatory caenogastropods that have a reduced shell or no shell at all.

The most derived hypsogastropod clade is the Neogastropoda. Its members have a rachiglossate or toxoglossate radula, with 1–5 teeth in each row; an anterior siphon is present; and the operculum, if present, is chitinous; the osphradium is large and pectinate and lies near the base of the anterior siphon. This highly diverse group comprises mostly carnivorous taxa. The neogastropods comprise about 45 living families of almost entirely marine snails, including whelks such as Buccinidae (e.g., *Buccinum*, *Cantharus*, *Macron*, *Neptunea*); Fasciolariidae (tulip shells and spindle shells, e.g., *Fasciolaria*, *Fusinus*, *Leucozonia*, *Troschelia*); Melongenidae (e.g., *Melongena*); Nassariidae (dog whelks and basket shells, e.g., *Nassarius* and the Asian freshwater genus *Clea*); dove shells, Columbellidae (e.g., *Anachis*, *Columbella*, *Mitrella*, *Pyrene*, *Strombina*); harp shells, Harpidae (e.g., *Harpa*); margin shells, Marginellidae (e.g., *Granula*, *Marginella*); miter shells, Mitridae (e.g., *Mitra*, *Subcancilla*) and Costellariidae (e.g., *Pusia*, *Vexillum*); rock shells and thaids, Muricidae (e.g., *Acanthina*, *Hexaplex*, *Morula*, *Murex*, *Neorapana*, *Nucella*, *Phyllonotus*, *Pterynotus*, *Purpura*, *Thais, Urosalpinx*), including the coral-associated subfamily Coralliophilinae (e.g., *Coralliophila*, *Latiaxis*); Olividae (olive shells, e.g., *Agaronia*, *Oliva*); Olivellidae (e.g., *Olivella*); the volutes, Volutidae (e.g., *Cymbium*, *Lyria*, *Voluta*) and nutmeg shells, Cancellariidae (e.g., *Admete*, *Cancellaria*); cone shells, Conidae (e.g., *Conus*) and the related Turridae (e.g., *Turris*); and several other allied families, including the auger shells, Terebridae (e.g., *Terebra*).

INFRACLASS HETEROBRANCHIA The heterobranchs were previously organized as two subclasses—Opisthobranchia (sea slugs and their kin) and Pulmonata (air-breathing snails). Although this division was long accepted, recent morphological and molecular studies now divide the heterobranchs into two main groups—an informal paraphyletic group often referred to as the "Lower Heterobranchia" (= Allogastropoda, Heterostropha) and the Euthyneura, which includes both pulmonates and the opisthobranchs.

The heterobranchs are characterized by lacking a true ctenidium and, usually, by a small to absent osphradium, a simple gut with the esophagus lacking glands, the stomach lacking a crystalline style in all but one group, and the intestine usually being short. The radula is highly variable, ranging from rhipidoglossate to consisting of a single row of teeth or being lost altogether. The shell may be well developed, reduced, or absent; the operculum, if present, is horny; the larval shell is heterostrophic (i.e., coils in a different plane than the adult shell). The head bears one or two pairs of tentacles, with the eyes variously placed; all are hermaphroditic. The nervous system is streptoneurous or euthyneurous with various degrees of concentration of the ganglia; pleural ganglia near pedal or cerebral ganglia, pedal cords absent. Mostly benthic; with marine, freshwater, and terrestrial species.

"LOWER HETEROBRANCHS" This informal group includes some snails long thought to be "Mesogastropoda," such as staircase or sundial shells Architectonicidae (e.g., *Architectonica, Philippia*) and some groups of small-sized marine snails, including Rissoellidae (e.g., *Rissoella*), Omalogyridae (e.g., *Omalogyra*), and the freshwater Valvatidae (e.g., *Valvata*). There are also several marine families such as Cornirostridae, Hyalogyrinidae, and Orbitestellidae. These snails are superficially similar to caenogastropods but often possess secondary gills and long cephalic tentacles with cephalic eyes set in the middle of their bases or on their inner sides. Another group included here are tiny interstitial slugs of the family Rhodopidae.

COHORT EUTHYNEURA Include most of the former opisthobranchs and pulmonates. The euthyneuran body has the shell either external or internal, or lost altogether; a heterostrophic larval shell; and a horny operculum, often absent in adult. Body variously detorted; head usually with one or two pairs of tentacles, eyes on inner sides or on separate stalks; ctenidia and mantle cavity usually reduced or lost; hermaphroditic; euthyneurous with various degrees of nervous system concentration. Mostly benthic; with marine, freshwater, and terrestrial species. Among other things, marine slugs are notable for their use of chemical defense; in most cases the compounds have dietary origin, and several lineages have the ability to biosynthesize metabolites de novo. The Euthyneura is divided into three major groups, which we treat here as superorders.

SUPERORDER NUDIPLEURA Includes both the internal-shelled Pleurobranchidae (e.g., *Berthella*, *Pleurobranchus*) and the Nudibranchia (shell-less or "true" nudibranchs), which includes many families. The doridoid nudibranchs include the Onchidoridiidae (e.g., *Acanthodoris, Corambe*), Polyceridae (e.g., *Gymnodoris, Polycera, Tambja*), Aegiretidae (e.g., *Aegires*), Chromodorididae (e.g., *Chromodoris*), Phyllidiidae (e.g., *Phyllidia*), Dendrodorididae (e.g., *Dendrodoris*), Discodorididae (e.g., *Discodoris*, *Diaulula, Rostanga*), Doridiidae (e.g., *Doris*), Platydoridiidae (e.g., *Platydoris*), Hexibranchidae (e.g., *Hexabranchus*), and Goniodorididae (e.g., *Okenia*). The cladobranch nudibranchs include the Arminidae (*Armina*), Proctonotidae (e.g.,

for more ebook/ testbank/ solution manuals request to email 9601267344@qq.com

Janolus), Embletoniidae (e.g., *Embletonia*), Scyllaeidae (e.g., *Scyllaea*), Tritoniidae (e.g., *Tritonia*), and Dendronotidae (e.g., *Dendronotus*). Also included are the cladobranch group collectively known as aeolididoids—including the Aeolidiidae (e.g., *Aeolidia*), Flabellinidae (e.g., *Coryphella*), Fionidae (e.g., *Fiona*), Facelinidae (e.g., *Hermissenda, Phidiana*), Tergipedidae (e.g., *Trinchesia*), Tethydidae (e.g., *Melibe*), and Glaucidae (e.g., *Glaucus*).

SUPERORDER EUOPISTHOBRANCHIA
Includes six main groups: (1) the basal acteonoideans, including Acteonidae (barrel or bubble snails, e.g., *Acteon, Pupa, Rictaxis*); (2) several families grouped as Cephalaspidea, for example, the slugs Aglajidae (e.g., *Aglaja, Chelidonura, Navanax*), Bullidae (bubble shells, e.g., *Bulla*), Haminoeidae (e.g., *Haminoea*), Retusidae (e.g., *Retusa*), and Scaphandridae (e.g., *Scaphander*); (3) the Runcinoidea, containing two families of tiny slugs, Ilbiidae (e.g., *Ilbia*) and Runcinidae (e.g., *Runcina*); (4) the Aplysiida or sea hares, including Aplysiidae (e.g., *Aplysia*, *Dolabella*, *Stylocheilus*); (5) the pelagic pteropods, comprising (a) the Thecosomata or shelled pteropods, which include the families Cavoliniidae (e.g., *Clio*, *Cavolinia*) and Limacinidae (e.g., *Limacina*), and (b) the distant group Gymnosomata or naked pteropods, which include Clionidae (e.g., *Clione*); and (6) the Umbraculida, composed of the umbrella slugs, Umbraculidae (e.g., *Umbraculum*) and Tylodinidae (e.g., *Tylodina*).

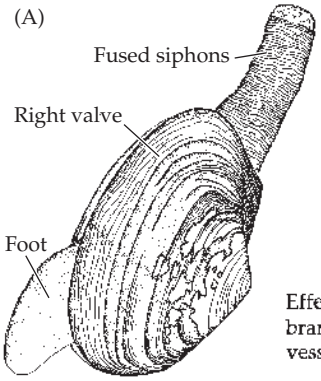
SUPERORDER PANPULMONATA This highly diverse group is characterized by reduction or loss of shell or variable shell shape of minute or moderate size; generally spirally coiled, planispiral, or limpet shaped; usually without an operculum as adults; eyes at bases of sensory stalks; secondary gills present in some members (e.g., *Pyramidella, Siphonaria*); body detorted; nervous system highly concentrated (euthyneurous); mantle-cavity-derived lung in the derived groups, with a contractile aperture in the Eupulmonata; marine (intertidal), brackish, freshwater, and amphibious.

Other panpulmonate groups include the sap-sucking sea slugs Sacoglossa (e.g., *Berthelinia*, *Elysia*, *Oxynoe*, *Tridachia,* and the "bivalved gastropods" Juliidae), which are shelled or shell-less; the small shell-less and sometimes spiculate acochlidian slugs that are often interstitial and usually marine (although there are some freshwater species); and the ectoparasitic Pyramidelloidea (e.g., *Odostomia, Pyramidella*, *Turbonilla*, *Amathina*), all of which were previously included in the Opisthobranchia. The remaining panpulmonates include all the members of the group previously known as Pulmonata, namely the mainly intertidal Siphonariidae (false limpets, e.g., *Siphonaria*, *Williamia*); two operculate families, the freshwater Glacidorbidae (e.g., *Glacidorbis*) and the estuarine Amphibolidae (*Amphibola, Salinator*); and the Hygrophila, including the mainly freshwater South American Chilinidae (e.g., *Chilina*) and freshwater Physidae (e.g., *Physa*), Planorbidae (e.g., *Ancylus*, *Bulinus*, *Planorbis*), and Lymnaeidae (e.g., *Lanx*, *Lymnaea*). These latter families are mostly snails, but some, such as *Lanx* and *Ancylus*, are limpets. The remaining "pulmonates" are contained within Eupulmonata. The best-known and largest group of eupulmonates is the Stylommatophora, comprising the land snails and slugs. In some of the shelled forms, the shell is partly or completely enveloped by the dorsal mantle. Their eyes are on the tips of long sensory stalks, and there is an anterior pair of tentacles. Eupulmonates are all terrestrial and are an enormous group with over 26,000 described species in 104 families. Some of those included are the land snail families Helicidae (e.g., *Cornu* [= *Helix*], *Cepaea*), Achatinidae (e.g., *Achatina*), Bulimulidae (e.g., *Bulimulus*), Haplotrematidae (e.g., *Haplotrema*), Orthalicidae (e.g., *Liguus*), Cerionidae (e.g., *Cerion*), Oreohelicidae (e.g., *Oreohelix*), Pupillidae (e.g., *Pupilla*), Testacellidae (*Testacella*), Cerastidae (e.g., *Rhachis*), Succineidae (e.g., *Succinea*), and Vertiginidae (e.g., *Vertigo*), as well as terrestrial slug families such as Arionidae (e.g., *Arion*) and Limacidae (e.g., *Limax*).

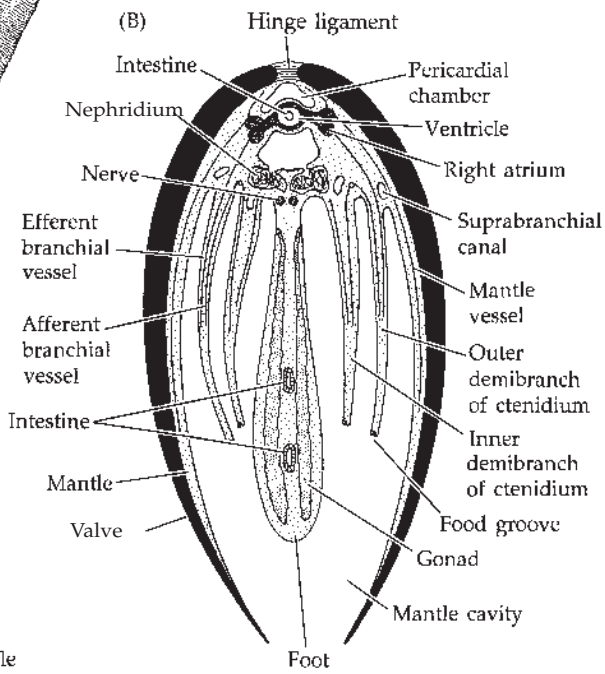
The remaining Eupulmonata include the orders Systellommatophora and Ellobiida. The former are sluglike, without internal or external shell; dorsal mantle integument forms a keeled or rounded notum; head usually with 2 pairs of tentacles, upper ones forming contractile stalks bearing eyes. Included are the mainly marine family Onchidiidae (e.g., *Onchidella*, *Onchidium*) and the terrestrial Veronicellidae (e.g., *Veronicella*). The Ellobiida include two superfamilies: the mainly supralittoral hollow-shelled ear snails, Ellobioidea (e.g., *Carychium, Ellobium, Melampus, Ovatella*), and the limpets and small intertidal snails or slugs of the Trimusculoidea (e.g., *Otina*, *Trimusculus*).

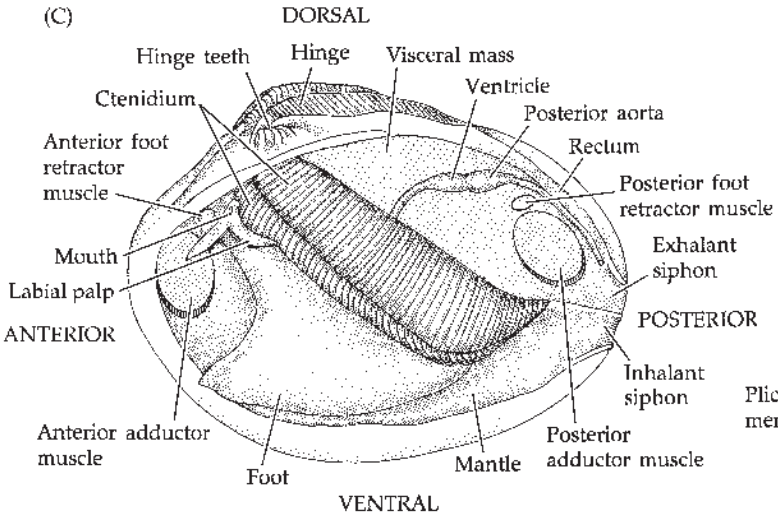
CLASS BIVALVIA (= PELECYPODA, LAMELLIBRANCHIATA)
Clams, oysters, mussels, scallops, etc. (Figures 13.1M–Q and 13.8). Laterally compressed; shell typically of two valves hinged together dorsally by elastic ligament and usually by a toothed hinge; shells closed by adductor muscles derived from mantle muscles; head rudimentary, without eyes, tentacles, or radula, but eyes may occur elsewhere on body, and tentacles may arise from the mantle edges; pair of large labial palps present

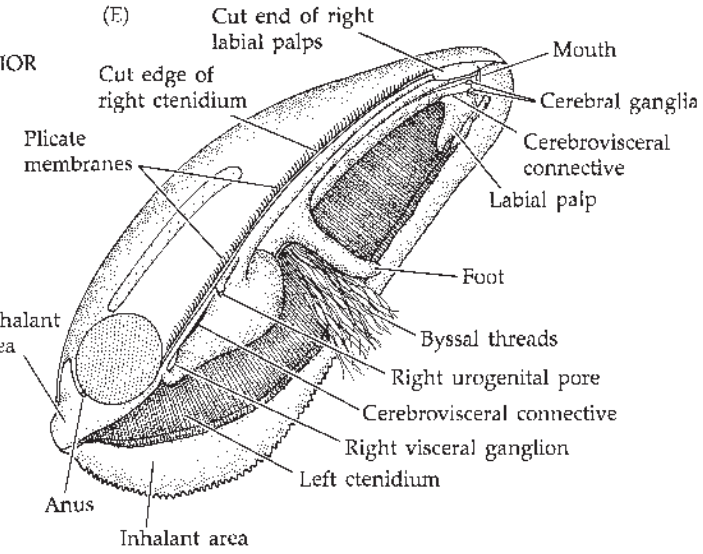
FIGURE 13.8 General anatomy of bivalves. (A) *Tresus*, a deep-burrowing eulamellibranch (Mactridae), with a digging foot and long, fused siphons. (B) A typical eulamellibranch (cross section). (C) The eulamellibranch *Mercenaria* (Veneridae), with the left shell valve and mantle removed. (D) Internal anatomy of *Mercenaria*. The visceral mass is opened up, the foot is dissected, and most of the gills are cut away. (E) The common mussel, *Mytilus* (Mytilidae), seen from the right side after removal of the right shell valve and mantle. (F) *Mytilus*, with the visceral mass opened up, the foot dissected, and most of the gills cut away.

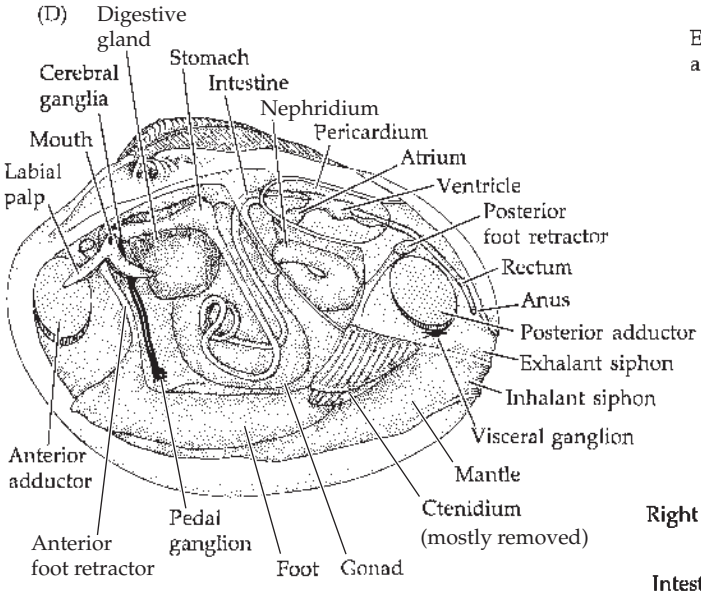


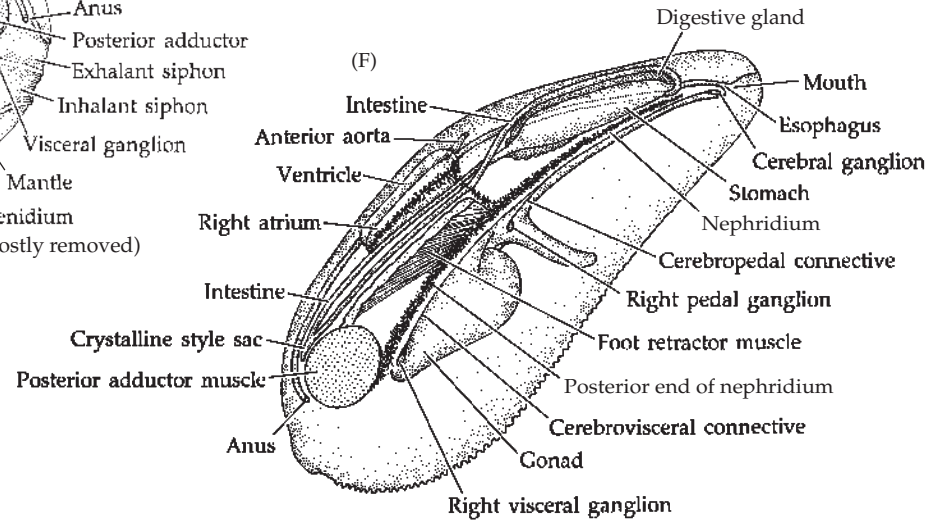
From Brusca and Brusca 1978











for more ebook/ testbank/ solution manuals request to email 9601267344@qq.com

composed of inner and outer parts that lie against one another; pair of statocysts present, associated with pedal ganglia, foot typically laterally compressed, often without a sole; 1 pair of large bipectinate ctenidia; large mantle cavity surrounds animal; mantle may be variously fused, sometimes forming extensions (siphons); 1 pair of nephridia; nervous system simple, typically composed of cerebropleural, pedal, and visceral ganglia.

Bivalves are marine or freshwater molluscs, primarily microphagous or suspension feeders. The class includes nearly 10,000 living species represented at all depths and in all marine environments. Bivalve classification had been unsettled until quite recently. Higher taxa have been delimited on the basis of shell characters (e.g., hinge anatomy, position of muscle scars), or, in other classifications, internal organ anatomy (e.g., ctenidia, stomach) has been used. However, beginning with the work of Giribet and Wheeler (2002), bivalve taxonomy has become more stable as both molecules and morphology have been combined with the fossil record to understand the relationships of the class.

SUBCLASS PROTOBRANCHIA Includes the former Palaeotaxodonta in part. Ctenidia are 2 pairs of simple, unfolded, bipectinate, platelike leaflets suspended in the mantle cavity. The ctenidia are mainly respiratory structures, while the labial palps are the primary food-collecting organs. The foot is longitudinally grooved and with a plantar sole, without byssal gland, and the nervous system is primitive, often with incomplete union of cerebral and pleural ganglia. These are the most primitive living bivalves, comprising three orders. The first two orders share the following characters: mantle open, with inhalant water entering anteriorly; shells with nacre; and gill filaments along ctenidial axis arranged opposite one another.

ORDER NUCULIDA Shell aragonitic, interior nacreous or porcelaneous; periostracum smooth; shell valves equal and taxodont (i.e., the valves have a row of similar interlocking short teeth along the hinge margins); adductor muscles equal in size; with large labial palps extended as proboscides used for food collection; ctenidia small, for respiration; marine (particularly in the deep sea), mainly infaunal detritivores. (e.g., Nuculidae, *Nucula*)

ORDER SOLEMYIDA (= CRYPTODONTA) Shell valves thin, elongate, and equal in size; uncalcified along outer edges, without hinge teeth; anterior adductor muscle larger than posterior one; ctenidia large, used mainly for housing symbiotic bacteria. Gut reduced or absent. (e.g., Solemyidae, *Solemya*). A fourth order, Manzanellida, can also be recognized, containing only a few living species (e.g., *Nucinella*). This monomyarian group shares the opposite gill filaments seen in the Nuculida and Solemyida, but it is often classified with Solemyida.

ORDER NUCULANIDA Mantle fused posteriorly, with siphons, inhalant water entering posteriorly; shells without nacre and gill filaments alternate along ctenidial axis. Several mainly deep-sea families, including Nuculanidae (e.g., *Nuculana*), Malletiidae (e.g., *Malletia*), and Sareptidae (e.g., *Yoldia*).

SUBCLASS AUTOBRANCHIA (= AUTOLAMELLIBRANCHIATA) Paired ctenidia, with very long filaments folded back on themselves so that each row of filaments forms two lamellae; adjacent filaments usually attached to one another by ciliary tufts (filibranch condition) or by tissue bridges (eulamellibranch condition). The greatly enlarged ctenidia are used in combination with the two pairs of labial palps in ciliary feeding; ctenidial surfaces capture waterborne particles and transfer them to the labial palps where the captured debris is sorted and potential food particles routed to the mouth. Gill filaments alternate on opposite sides of the gill axis. Shells with or without nacre.

INFRACLASS PTERIOMORPHIA (= FILIBRANCHIA) Ctenidia with outer fold not connected dorsally to visceral mass, with free filaments or with adjacent filaments attached by ciliary tufts (filibranch condition); shell aragonitic or calcitic, sometimes nacreous; mantle margin unfused, with weakly differentiated inhalant and exhalant apertures or siphons; mantle margins often form tentacles; foot well developed or extremely reduced; usually attached by byssal threads or cemented to substratum (or secondarily free). These primitive bivalves include several divergent ancient lineages separated as orders.

ORDER MYTILIDA The true (mostly marine) mussels, Mytilidae (e.g., *Adula, Brachidontes, Lithophaga, Modiolus, Mytilus*).

ORDER ARCIDA The ark shells, Arcidae (e.g., *Anadara, Arca, Barbatia*) and dog cockles, Glycymerididae (e.g., *Glycymeris*).

ORDER OSTREIDA The true oysters, Ostreidae (e.g., *Crassostrea, Ostrea*).

ORDER PTERIIDA Pearl oysters and their relatives, Pteriidae (e.g., *Pinctada, Pteria*); hammer oysters, Malleidae (e.g., *Malleus*); and pen shells, Pinnidae (e.g., *Atrina, Pinna*).

ORDER LIMIDA File shells, Limidae (e.g., *Lima*).

ORDER PECTINIDA Scallops, Pectinidae (e.g., *Chlamys, Lyropecten, Pecten*); thorny oysters, Spondylidae (e.g., *Spondylus*); jingle shells, Anomiidae (e.g., *Anomia, Pododesmus*).

INFRACLASS HETEROCONCHIA This clade encompasses the Palaeoheterodonta and Heterodonta, previously treated as separate higher groups but shown to be sister groups in recent molecular phylogenies.

COHORT PALAEOHETERODONTA Shell aragonitic, pearly internally; periostracum usually well developed; valves usually equal, with few hinge teeth; elongate lateral teeth (when present) are not separated from the large cardinal teeth; usually dimyarian; mantle opens broadly ventrally, mostly unfused posteriorly but with exhalant and inhalant apertures. About 1,200 species of marine and freshwater clams. With two very distinct groups, classified as orders.

ORDER TRIGONIIDA The relictual marine brooch shells (Trigoniidae), with only a few living species of *Neotrigonia* in Australia.

ORDER UNIONIDA Entirely freshwater, including the freshwater clams (or mussels), e.g., Unionidae (e.g., *Anodonta, Unio*), Margaritiferidae (e.g., *Margaritifera*), and Hyriidae (e.g., *Hyridella*). Many species threatened by human disturbance of streams and rivers.

COHORT HETERODONTA Two main groups, ranked as subcohorts, are recognized—the Archiheterodonta (with a single living order) and the Euheterodonta (with 4 living orders).

SUBCOHORT ARCHIHETERODONTA

ORDER CARDITIDA This group of primitive heterodonts is represented by the families Crassatellidae (e.g., *Crassatella*), Carditidae (e.g., *Cardita*), and Astartidae (e.g., *Astarte*).

SUBCOHORT EUHETERODONTA

ANOMALODESMATA Shells equivalved or inaequivalved, aragonitic, of 2–3 layers, innermost consisting of sheet nacre; periostracum often incorporates granulations; with 0–1 hinge teeth; generally isomyarian, rarely amyarian; posterior siphons usually well developed; mantle usually fused ventrally, with anteroventral pedal gape, and posteriorly with ventral inhalant and dorsal exhalant apertures or siphons; ctenidia eulamellibranchiate or septibranchiate (modified as a muscular pumping horizontal septum). This ancient and very diverse group of marine bivalves includes about 20 living families, including the rare deep-water Pholadomyidae (e.g., *Pholadomya*) and the aberrant watering-pot shells Clavagellidae (e.g., *Brechites*), as well as Pandoridae, Poromyidae, Cuspidariidae, Laternulidae, Thraciidae, Cleidothaeridae, Myochamidae, and Periplomatidae.

IMPARIDENTIA

ORDER LUCINIDA Includes the families Luncinidae (e.g., *Codakia*, *Lucina*), a group with symbiotic bacteria in their gills and an anterior water current, and Thysiridae.

ORDER VENERIDA Usually thick-valved, equivalve, and isomyarian, with posterior siphons. Includes surf clams, Mactridae (e.g., *Mactra*); solens, Solenidae (e.g., *Ensis*, *Solen*); tellins, Tellinidae (e.g., *Florimetis*, *Macoma*, *Tellina*); semelids, Semelidae (e.g., *Leptomya*, *Semele*); wedge shells, Donacidae (e.g., *Donax*); and Venus clams, Veneridae (e.g., *Chione*, *Dosinia*, *Pitar*, *Protothaca*, *Tivela*).

ORDER CARDIIDA Includes cockles and their kin, Cardiidae (e.g., *Cardium*, *Clinocardium*, *Laevicardium*, *Trachycardium,* and the giant clams, e.g., *Tridacna*).

ORDER SPHAERIIDA Contains the freshwater pea clams, Sphaeriidae (e.g., *Sphaerium, Pisidium*); the estuarine-to-freshwater Cyrenidae (e.g., *Corbicula, Batissa*); and the brackish-to-freshwater zebra mussels, Dreissenidae (e.g., *Dreissena*). The latter two families contain important invasive species.

ORDER MYIDA Burrowing forms with well-developed siphons. Includes soft-shell clams, Myidae (e.g., *Mya*); rock borers or piddocks, Pholadidae (e.g., *Barnea*, *Martesia*, *Pholas*); shipworms, Teredinidae (e.g., *Bankia*, *Teredo*); and basket clams, Corbulidae (e.g., *Corbula*). The monophyly of this order is uncertain.

CLASS SCAPHOPODA Tusk shells (Figures 13.1L and 13.9). Shell of one piece, tubular, usually tapering, open at both ends; head rudimentary, projecting from larger aperture; mantle cavity long, extending along entire posterior surface; without ctenidia or eyes; with radula; long, snoutlike "proboscis" and paired clusters of long, thin contractile tentacles with clubbed ends (captacula) that serve to capture and manipulate minute prey; heart absent; foot somewhat cylindrical, with epipodium-like fringe. Over 500 species, all marine, benthic, in 14 families and 2 orders.

ORDER DENTALIIDA Shell regularly tapering. Paired digestive gland with a muscular foot terminating in epipodial lobes and a cone-shaped process. Several families, including Dentaliidae (e.g., *Dentalium*, *Fustiaria*) and Laevidentaliidae (e.g., *Laevidentalium*).

ORDER GADILIDA Shell regularly tapering or bulbous with maximum shell diameter approximately nearer center of shell. Single digestive gland and foot with a terminal disk surrounded by epipodial papilla. Families include Pulsellidae (e.g., *Pulsellum*, *Annulipulsellum*) and Gadilidae (e.g., *Cadulus*, *Gadila*).

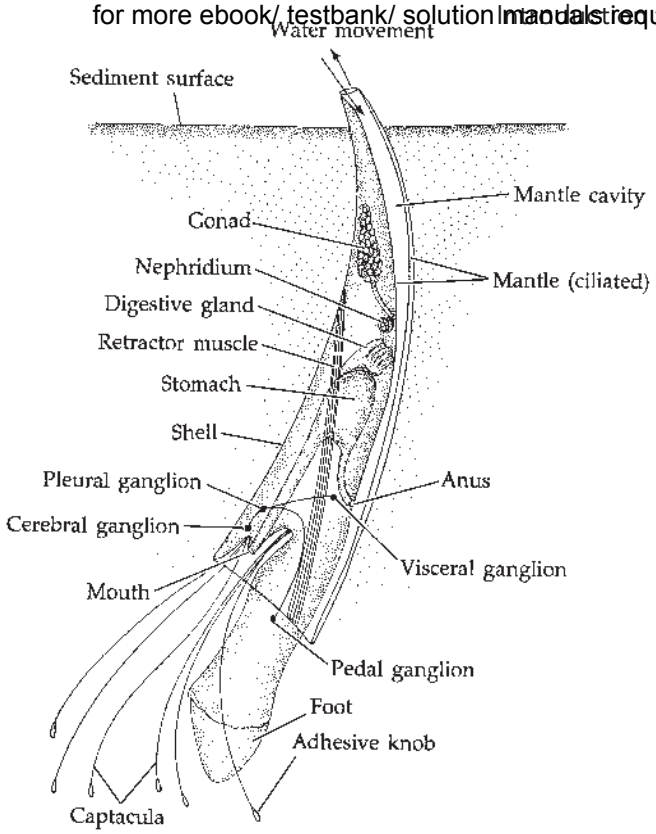

FIGURE 13.9 **General anatomy of a scaphopod.**

CLASS CEPHALOPODA Chambered nautilus, squid, cuttlefish, and octopuses (Figures 13.1H–K, 13.10, 13.11, 13.12, 13.17, and 13.22). With linearly chambered shell, usually reduced or lost in living taxa; if external shell present (*Nautilus*), animal inhabits last (youngest) chamber, with a filament of living tissue (the siphuncle) extending through older chambers; circulatory system largely closed; head with large, complex eyes and circle of prehensile arms or tentacles around mouth; with radula and beak; 1–2 pairs ctenidia, and 1–2 pairs complex nephridia; mantle forms large ventral mantle cavity containing 1–2 pairs of ctenidia; with muscular funnel (the siphon) through which water is forced, providing jet propulsion; some tentacles of male modified for copulation; benthic or pelagic, marine; about 750 living species.

SUBCLASS PALCEPHALOPODA Includes many fossil taxa, all with external shells, as well as the living chambered (pearly) nautilus.

ORDER NAUTILIDA (= TETRABRANCHIATA) The chambered (pearly) nautilus. Shell external, many-chambered, coiled in one plane, exterior porcelaneous, interior nacreous (pearly); head with many (80–90) suckerless tentacles (4 modified as spadix in male for copulation and protected by a fleshy hood); 13 tooth rows in radula; beak of chitin and calcium carbonate; funnel of 2 separate folds; 2 pairs of ctenidia ("tetrabranchiate"); 2 pairs of nephridia; eyes like a pinhole camera, without cornea or lens; nervous system with anterior elements concentrated into a brain, optic lobes large; statocyst simple; without chromatophores or ink sac. Fossil record rich but represented today by a single order (Nautilida) and two genera, *Allonautilus* and *Nautilus*, with 5 or 6 Indo-Pacific species.

SUBCLASS NEOCEPHALOPODA Includes one large fossil group (the ammonites) in addition to the coleoids. The shell is reduced and internal in most (and in all living taxa).

COHORT COLEOIDA (= DIBRANCHIATA) Octopuses, squid, and their kin. Shell reduced and internal or absent; head and foot united into a common anterior structure bearing 8 or 10 prehensile appendages (arms and tentacles) bearing suckers and, often, cirri, one arm usually modified in male for copulation; 7 tooth rows in radula; with chitinous beak; funnel a single closed tube; 1 pair of ctenidia ("dibranchiate"); 1 pair of nephridia; eyes complex, with lens and often with cornea; nervous system well developed and concentrated into a brain; with a complex statocyst; with chromatophores and ink sac.

SUPERORDER OCTOBRACHIA Members of this group, which includes the octopuses and vampire squid, do not have the head distinctly separated from the rest of the body; have 8 arms, with 2 additional retractile filaments in the vampire squid; lateral fins on the body are present or absent.

ORDER OCTOPODA Octopuses. Body short, round, usually without fins; internal shell vestigial or absent; 8 similar arms joined by web of skin (interbrachial web); suckers with narrow stalks; most are benthic. About 200 species, in two groups: the Incirrata, including the benthic octopuses and some pelagic taxa that lack fins and cirri, examples being Octopodidae (e.g., *Octopus*) and Argonautidae (*Argonauta*), the paper nautilus; and Cirrata, which are mainly pelagic deep-sea cephalopods with fins and cirri, such as Cirroteuthidae (e.g., *Cirroteuthis*), Opisthoteuthidae (e.g., *Opisthoteuthis*), and Stauroteuthidae (e.g., *Stauroteuthis*).

ORDER VAMPYROMORPHA The vampire squid. Body plump, with 1 pair of fins; shell reduced to thin, leaf-shaped, uncalcified, transparent vestige; 4 pairs of equal-sized arms, each with 1 row of unstalked distal suckers and 2 rows of cirri; arms joined by extensive web of skin (interbrachial membrane); fifth pair of arms represented by 2 tendril-like, retractable filaments; hectocotylus lacking; radula well developed; ink sac degenerate; mostly in deep water. One living species, *Vampyroteuthis infernalis*, that lives in the oxygen minimum zone of the deep sea.

SUPERORDER DECABRACHIA (= DECAPODA) Members of this group, which includes the squid and cuttlefish, have the head distinctly separated from the rest of the body; with 8 arms and 2 retractile (into pits) tentacles with suckers only on expanded tips; suckers with wide bases, sometimes with spines or hooks; lateral fins on body. The internal shell is large (as in the cuttlefish or in *Spirula*), reduced to an uncalcified gladius, or lost.

ORDER SPIRULIDA The only living species is the ram's horn, *Spirula spirula* (Spirulidae), a small deep-sea squid with a coiled, internal, chambered shell.

ORDER SEPIIDA Cuttlefish. Body short, dorsoventrally flattened, with lateral fins; shell internal, calcareous, straight or slightly curved, chambered, or shell horny or absent; 8 short arms and 2 long tentacles; suckers lack hooks. Includes the shell-less Sepiolidae (e.g., *Rossia*, *Sepiola*); the Sepiidae (e.g., *Sepia*) with an internal calcareous shell, the cuttlebone; and Idiosepiidae (e.g., *Idiosepis*), being tiny squid that live in seagrass to which they attach with a special sucker. Their shell is reduced to a horny gladius.

ORDER MYOPSIDA Squid with the eye covered with a cornea and having a well-developed gladius. Body elongate, tubular, with lateral fins. Two families, Loliginidae (e.g., *Loligo*, *Doryteuthis*) and Australiteuthidae (*Australiteuthis*).

ORDER OEGOPSIDA Includes the majority of squid (and the former Teuthoida in part); the eye lacks a cornea and the shell is a gladius. Body elongate, tubular, with lateral fins; suckers often with hooks. Some of the many families in this group include Architeuthidae (*Architeuthis*), Bathyteuthidae (e.g., *Bathyteuthis*, sometimes treated as a separate order), Chiroteuthidae (e.g., *Chiroteuthis*), Ommastrephidae (e.g., *Ommastrephes*, *Dosidiscus*, *Illex*), Gonatidae (e.g., *Gonatus*), Histioteuthidae (e.g., *Histioteuthis*), Lycoteuthidae (e.g., *Lycoteuthis*), and Octopoteuthidae (e.g., *Octopoteuthis*).

The Molluscan Body Plan

Mollusca is probably the most morphologically diverse phylum in the animal kingdom. Molluscs range in size from microscopic solenogasters, bivalves, snails, and slugs, to whelks attaining 70 cm in length, giant clams (Cardiidae) over 1 m in length, and giant squid (*Architeuthis*) reaching at least 13 m in overall length (body plus tentacles). The giant Pacific octopus (*Octopus dofleini*) commonly attains an arm span of 3–5 m and a weight of over 40 kg. It is the largest living octopus, and one particularly large specimen was estimated to have an arm span of nearly 10 m and a weight of over 250 kg! Despite their differences, giant squid, cowries, garden slugs, eight-plated chitons, and wormlike aplacophorans are all related and share a common body plan (Box 13A). In fact, the myriad ways in which evolution has shaped the basic molluscan body plan provide some of the best lessons in homology and adaptive radiation in the animal kingdom.

Molluscs are bilaterally symmetrical, coelomate protostomes, but the coelom generally exists only as small vestiges around the heart (the **pericardial chamber**), the gonads, and parts of the nephridia (kidneys). The principal body cavity is a hemocoel composed of several large sinuses of the open circulatory system, except in some cephalopods that have a largely closed system. In general, the body comprises three distinguishable regions: a head, foot, and centrally concentrated visceral mass, but the configuration differs in different classes (Figure 13.13). The head may bear various sensory structures, most notably eyes and tentacles; statocysts may be located in the foot region, and chemosensory structures can also be present.

The visceral mass is covered by a thick epidermis called the **mantle** (also known as the pallium), which is sometimes covered in cuticle and plays a critical role in the organization of the body. It secretes the hard calcareous skeleton, either as minute sclerites, or plates, that are embedded in the body wall or as an internal or external shell. Ventrally the body usually bears a large, muscular **foot**, which typically has a creeping **sole**.

Surrounding or posterior to the visceral mass is a cavity—a space between the visceral mass and folds of the mantle itself. This **mantle cavity** (also known as the pallial cavity) often houses the gills (the original molluscan gills are known as **ctenidia**), along with the openings of the gut, excretory, and reproductive systems, and, in addition, special patches of chemosensory epithelium in many groups, notably the osphradia. In aquatic forms, water is circulated through this cavity, passing over the ctenidia, excretory pores, anus, and other structures.

Molluscs have a complete, or through gut that is regionally specialized. The buccal region of the foregut typically bears a uniquely molluscan structure, the **radula**, which is a toothed, rasping, tonguelike strap used in feeding. It is located on a muscular **odontophore** that moves the radula through its feeding motions. The circulatory system usually includes a heart in a pericardial cavity and a few large vessels that empty into or drain hemocoelic spaces. The excretory system consists of one or more pairs of metanephridial kidneys (here simply referred to as nephridia), with openings (nephrostomes) to the pericardium via renopericardial canals and to the mantle cavity via a nephridiopore. The nervous system typically includes a pair of dorsal cerebral ganglia, a circumenteric nerve ring (encircling the buccal area or esophagus), and two pairs of longitudinal nerve cords that arise from paired pleural ganglia and connect with the visceral ganglia posteriorly in the body. Other anterior paired ganglia (buccal and labial) may be present. Pedal ganglia lie in the foot and may give off pedal nerve cords.

Gametes are produced by the gonad in the visceral mass, and fertilization may be external or internal. Development is typically protostomous, with spiral cleavage and a trochophore larval stage. There is also a

In cephalopods the foot is modified to form the funnel (= siphon) and at least parts of the arms.

secondary larval form unique to gastropod and bivalve molluscs called the **veliger**.

Although this general summary describes the basic body plan of most molluscs, notable modifications occur and are discussed throughout this chapter. The eight classes have been characterized (see Abbreviated Classification of Living Members of the Phylum Mollusca) and are briefly summarized here.

Some of the most bizarre molluscs are the "aplacophorans"—Solenogastres and Caudofoveata (Figures 13.1C and 13.2). Members of these groups are wormlike and typically small and either burrow in sediment (Caudofoveata) or may spend their entire lives on the branches of various cnidarians such as gorgonians, or bryozoans, upon which they feed (Solenogastres). Caudofoveata lack a foot, but a reduced one

is present in the Solenogastres, and neither group has a solid shell. Aplacophorans also have no distinct head, eyes, or tentacles. They were traditionally considered primitive molluscs that evolved before the appearance of solid shells, but some data suggest they may be derived forms that have lost the shell and have acquired a paedomorphic body morphology.

Polyplacophorans, or chitons, are oval molluscs that bear eight (seven in some Paleoloricata) separate articulating shell plates on their dorsal surface (Figures 13.1B and 13.4). They range in length from about 7 mm to over 35 cm. These marine animals are inhabitants of deep-sea to intertidal regions around the world, at all latitudes.

Monoplacophorans are limpetlike molluscs with a single cap-shaped shell ranging from about 1 mm to about 4 cm in length (Figures 13.1A and 13.3). Most live in the deep sea, some at great depths (>6,000 m). Their most notable feature is the repetitive arrangement of gills, gonads, and nephridia, a condition that has led some biologists to speculate that they must represent a link to some ancient segmented ancestor of the Mollusca (an idea no longer deemed correct).

Gastropods are by far the largest group of molluscs and include some of the best-studied species (Figures 13.1D–G, 13.5, 13.6, and 13.7). This class includes the common snails and slugs in all marine and many freshwater habitats; they are the only molluscan class to have successfully invaded terrestrial environments, and they have done this multiple times. They are the only molluscs that undergo torsion during early development, a process involving a 90°–180° rotation of the visceral mass relative to the foot (for details see Torsion, or "How the Gastropod Got its Twist").

Bivalves include the clams, oysters, mussels, and their kin (Figures 13.1M–Q and 13.8). They possess two separate shells, called **valves**, hinged dorsally. The smallest bivalves are in the marine family Carditidae, some of which are about 1 mm in length; the largest are giant tropical clams (*Tridacna*), one species of which (*T. gigas*) may weigh over 400 kg! Bivalves inhabit all marine environments and many freshwater habitats.

Scaphopods, the tusk shells, live in marine surface sediments at various depths. Their distinctive single, tubular uncoiled shell opens at both ends and ranges from a few millimeters to about 15 cm in length (Figures 13.1L and 13.9).

The cephalopods are among the most highly modified molluscs and include the chambered (pearly) nautilus, squid, cuttlefish, octopuses, and a host of extinct forms, including the ammonites (Figures 13.1I–K, 13.10, 13.11, 13.12, 13.17, and 13.22). This group includes the largest of all living invertebrates, the giant squid, with body and tentacle lengths around 13 m. Among living cephalopods, only the species of nautilus have an external shell. The cephalopods differ markedly from other molluscs in several ways. For example, they have a spacious body cavity that includes the pericardium, gonadal cavity, nephriopericardial connections, and gonoducts, all of which form an interconnected system representing a highly modified but true coelom. In addition, unlike all other molluscs, many coleoid cephalopods have a functionally closed circulatory system. The nervous system of cephalopods is the most sophisticated of all invertebrates, with unparalleled learning and memory abilities. Most of these modifications are associated with the adoption of an active predatory lifestyle by these remarkable creatures.

The Body Wall

The body wall of molluscs typically comprises three main layers: the cuticle (when present), epidermis, and muscles (see Figure 13.15A). The cuticle is composed largely of various amino acids and sclerotized proteins (called conchin), but it apparently does not contain chitin (except in the aplacophorans). The epidermis is usually a single layer of cuboidal to columnar cells, which are ciliated on much of the body. Many of the epidermal cells participate in secretion of the cuticle. Other kinds of secretory gland cells can also be present, some of which secrete mucus, and these can be very abundant on external surfaces such as the sole of the foot. Other specialized epidermal cells occur on the dorsal body wall, or mantle. Many of these cells constitute the molluscan **shell glands**, which produce the calcareous sclerites or shells characteristic of this phylum. Still other epidermal cells are sensory receptors. The epidermis and outermost muscle layer are often separated by a basement membrane and occasionally a dermislike layer.

The body wall usually includes three distinct layers of smooth muscle fibers: an outer circular layer, a middle diagonal layer, and an inner longitudinal layer. The diagonal muscles are often in two groups with fibers running at right angles to each other. The degree of development of each of these muscle layers differs among the classes (e.g., in solenogasters the diagonal layers are frequently absent).

The Mantle and Mantle Cavity

The significance of the mantle cavity and its importance in the evolutionary success of molluscs has already been alluded to. Here we offer a brief summary of the nature of the mantle cavity and its disposition in each of the major groups of molluscs.

The mantle, as the name implies, is a sheetlike organ that forms the dorsal body wall, and in most molluscs it grows during development to envelop the molluscan body. At its edge there are one or two folds that contain muscle layers and hemocoelic channels (see Figure 13.15C). The outward growth creates a space lying between the mantle fold(s) and the body proper. This space, the mantle cavity, may be in the form of a groove surrounding the foot or a primitively posterior

for more ebook/ testbank/ solution manuals request to email 9601267344@qq.com

chamber through which water is passed by ciliary or, in more derived taxa, by muscular action. Generally, the mantle cavity houses the respiratory surface (usually the ctenidia or other gill-like structures) and receives the fecal material discharged from the anus and excretory waste from the nephridia. Gametes are also primitively discharged into the mantle cavity. Incoming water provides a source of oxygen for respiration and a means of flushing waste and, in some instances, also carries food for suspension feeding.

The mantle cavity of chitons is a groove surrounding the foot (Figures 13.4A and 13.13A,B). Water enters the groove from the front and sides, passing medially over the ctenidia and then posteriorly between the ctenidia and the foot. After passing over the gonopores and nephridiopores, water exits the back end of the groove and carries away fecal material from the posteriorly located anus.

The aplacophorans have a small mantle cavity, with either a pair of ctenidia (Caudofoveata) or lamella-like folds or papillae on the mantle cavity wall (Solenogastres). The paired coelomoducts and the anus also open into the mantle cavity.

The mantle cavity of gastropods originates during development as a ventrally located chamber. As development proceeds, however, most gastropods undergo a rotation of the visceral mass and shell to bring the mantle cavity over the head (Figures 13.5, 13.6, and 13.13C) (see the Torsion, or "How the Gastropod Got its Twist" section). The different orientation does not affect the water flow, which still passes through this chamber via the ctenidia and then past the anus, gonopores, and nephridiopores. A great many secondary modifications on this plan have evolved in the Gastropoda, including rerouting of current patterns; loss or modification of associated structures such as the gills, hypobranchial glands, and sensory organs; and even "detorsion," as discussed in later sections of this chapter.

Bivalves possess a greatly enlarged mantle cavity that surrounds both sides of the foot and visceral mass (Figures 13.8 and 13.13D,E). The mantle lines the laterally placed shells, and the folds making up the mantle edges are often fused in various ways posteriorly to form inhalant and exhalant siphons, through which water enters and leaves the mantle cavity. The water passes over and through the ctenidia that, in autobranch bivalves, extract suspended food material as well as accomplishing gas exchange. The water flow then sweeps across the gonopores and nephridiopores and finally past the anus as it exits through the exhalant siphon.

Scaphopods have a tapered, tubular shell opening at both ends (Figures 13.9 and 13.13F). Water enters and leaves the elongate mantle cavity through the small opening in the top of the shell and flushes over the mantle surface, which, in the absence of ctenidia, is the site of gas exchange. The anus, nephridiopores, and gonopores also empty into the mantle cavity.

While no detailed studies of the functioning of the monoplacophoran mantle cavity have been made, observations of the first living specimens in 1977 revealed that the gills vibrated, apparently circulating water through the mantle groove. It was also noted that shell movement was accompanied by an acceleration of gill beating. Vibrating gills are also found in some protobranch bivalves. In other molluscs ciliary action, sometimes assisted by muscular contractions, moves water through the mantle cavity. The anus, nephridiopores, and gonopores also open into the mantle cavity.

With the exception of monoplacophorans and some protobranch bivalves, in all of the above cases water is moved through the mantle cavity by the action of long lateral cilia on the ctenidia. In cephalopods the ctenidial gills are not ciliated; in *Nautilus* a ventilatory current is passed through the mantle cavity by the undulatory movements of two muscular flaps associated with the funnel lobes. In the coleoid cephalopods, however, well-developed, highly innervated mantle muscles perform this function through the regular pulsation of the mantle wall. The exposed, fleshy body surface of squid and octopuses is, in fact, the mantle itself (Figures 13.11, 13.12, and 13.13G). Unconstrained by an external shell, the mantle of these molluscs expands and contracts to draw water into the mantle cavity and then forces it out through the narrow muscular **funnel** (= **siphon**). The forceful expelling of this jet of exhalant water can also provide a means of rapid locomotion for most cephalopods. In the mantle cavity the water passes through the ctenidia and then past the anus, reproductive pores, and excretory openings.

The remarkable adaptive qualities of the molluscan body plan are manifested in these variations in the position and function of the mantle cavity and its associated structures. In fact, the nature of many other structures is also influenced by mantle cavity arrangement, as shown schematically in Figure 13.14. That molluscs have been able to successfully exploit an extremely broad range of habitats and lifestyles can be explained in part by these variations, which are central to the story of molluscan evolution. We will have more to say about these matters throughout this chapter.

The Molluscan Shell

Except for the two aplacophoran classes, all mollusc classes have solid calcareous shells (composed of either aragonite or calcite) produced by shell glands in the mantle. In the Caudofoveata and Solenogastres, aragonite sclerites (spicules or scales) are formed extracellularly in the mantle epidermis and are embedded in the cuticle. In the other classes molluscan shells vary greatly in shape and size, but they all adhere to the basic construction plan of calcium carbonate produced extracellularly, laid down on a protein matrix

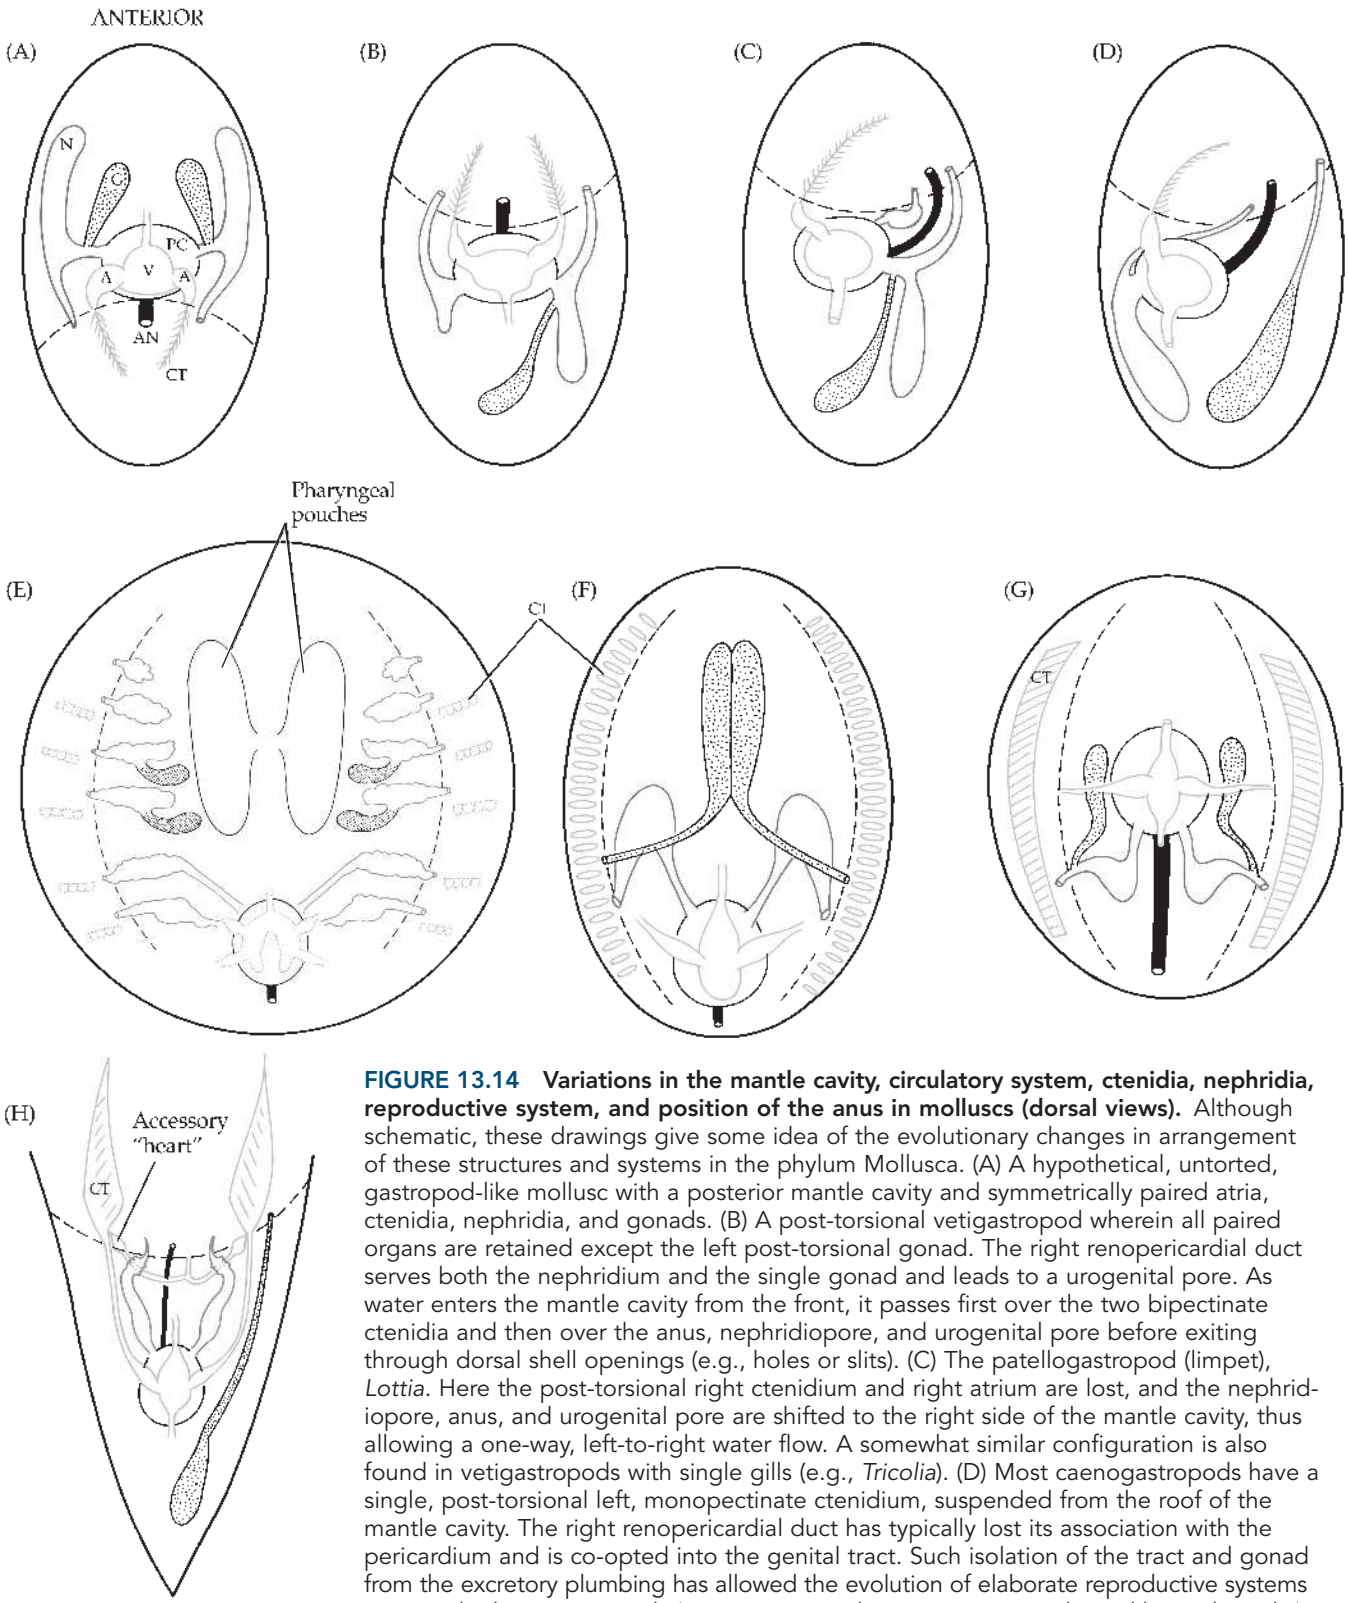

FIGURE 13.14 Variations in the mantle cavity, circulatory system, ctenidia, nephridia, reproductive system, and position of the anus in molluscs (dorsal views). Although schematic, these drawings give some idea of the evolutionary changes in arrangement of these structures and systems in the phylum Mollusca. (A) A hypothetical, untorted, gastropod-like mollusc with a posterior mantle cavity and symmetrically paired atria, ctenidia, nephridia, and gonads. (B) A post-torsional vetigastropod wherein all paired organs are retained except the left post-torsional gonad. The right renopericardial duct serves both the nephridium and the single gonad and leads to a urogenital pore. As water enters the mantle cavity from the front, it passes first over the two bipectinate ctenidia and then over the anus, nephridiopore, and urogenital pore before exiting through dorsal shell openings (e.g., holes or slits). (C) The patellogastropod (limpet), *Lottia*. Here the post-torsional right ctenidium and right atrium are lost, and the nephridiopore, anus, and urogenital pore are shifted to the right side of the mantle cavity, thus allowing a one-way, left-to-right water flow. A somewhat similar configuration is also found in vetigastropods with single gills (e.g., *Tricolia*). (D) Most caenogastropods have a single, post-torsional left, monopectinate ctenidium, suspended from the roof of the mantle cavity. The right renopericardial duct has typically lost its association with the pericardium and is co-opted into the genital tract. Such isolation of the tract and gonad from the excretory plumbing has allowed the evolution of elaborate reproductive systems among "higher" gastropods (e.g., neritomorphs, caenogastropods, and heterobranchs) and is probably important in the story of gastropod success. (E) The condition in monoplacophorans includes the serial repetition of several organs. (F) In polyplacophorans, the gonoducts and nephridioducts open separately into the exhalant regions of the lateral mantle grooves. (G) A generalized bivalve condition. The gonads and nephridia may share common pores, as shown here, or else open separately into the lateral mantle chambers. (H) The condition in a generalized cephalopod with a single, isolated reproductive system and an effectively closed circulatory system.

in layers, and often covered by a thin organic surface coating called a **periostracum** (Figure 13.15). The periostracum is composed of a type of conchin (largely quinone-tanned proteins) similar to that found in the epidermal cuticle. The calcium layers have four crystal types: prismatic, spherulitic, laminar, and crossed structures. All incorporate conchin onto which the calcareous crystals precipitate. The majority of living molluscs have an outer prismatic layer and an inner porcelaneous, crossed layer. In monoplacophorans, cephalopods, and some gastropods and bivalves, an iridescent, nacre (laminar) layer replaces the layer of crossed crystals. Shells are often made up of multiple layers of different crystal types.

Molluscs are noted for their wonderfully intricate and often flamboyant shell color patterns and sculpturing (Figure 13.16), but very little is known about the evolutionary origins and functions of these features. Some molluscan pigments are metabolic by-products, and thus shell colors might largely represent strategically deposited food residues, while others appear to have no relationship to diet. Molluscan shell pigments include such compounds as pyrroles and porphyrins. Melanins are common in the integument (cuticle and epidermis), the eyes, and internal organs, but they are rare in shells.

Some shell sculpture patterns are correlated with specific behaviors or habitats. For example, shells with low spires are more stable in areas of heavy wave shock or on vertical rock surfaces. Similarly, the low, cap-shaped shells of limpets (Figures 13.5A and 13.16H,I) are presumably adapted for withstanding exposure to strong waves or currents and have evolved in multiple lineages of gastropods. Heavy ribbing, thick or inflated shells, and a narrow gape in bivalves are all possible adaptations to provide protection from predators. In some gastropods, fluted shell ribs help them land upright when they are dislodged from rocks. Several groups of soft-bottom benthic gastropods and bivalves have long spines on the shell that may help stabilize the animals in loose sediments as well as provide some protection from predators. Many molluscs, particularly clams, have shells covered with living epizootic organisms such as sponges, annelid tube worms, bryozoans, entoprocts, and hydroids. Some studies suggest that predators have difficulty recognizing such camouflaged molluscs as potential prey.

Molluscs may have one shell, two shells, eight shells, or no shell. In the last case, the outer body wall may contain calcareous sclerites of various sorts. In the aplacophorans, for example, the cuticular sclerites vary in shape and range in length from microscopic to about 4 mm. These sclerites are essentially crystals composed almost entirely of calcium carbonate as aragonite. Caudofoveates produce platelike cuticular sclerites that give their body surface a

scaly texture and appearance. The sclerites in both taxa appear to be secreted by a diffuse network of specialized groups of cells, and different shapes are found in different regions of the body.

The eight transverse plates, or valves (Figures 13.4 and 13.16A–F), of polyplacophorans are encircled by and embedded in a thickened region of the mantle called the **girdle**. The size of the girdle varies from narrow to broad and may cover much of the valves. In the giant Pacific "gumboot" chiton, *Cryptochiton stelleri*, the girdle completely covers the valves. The girdle is thick, heavily cuticularized, and usually covered with calcareous sclerites, spines, scales, or noncalcareous bristles secreted by specialized epidermal cells. These sclerites are probably homologous with those in the body wall of aplacophorans.

The anterior and posterior valves of chitons are referred to as the end valves, or cephalic (= anterior) and anal (= posterior) plates; the six other valves are called the intermediate valves. Some details of chiton valves are shown in Figure 13.16A–F. The shells of chitons have three layers, with an outer periostracum, a colored **tegmentum**, and an inner calcareous layer, or **articulamentum** (with an underlying hypostracum). The periostracum is a very thin, delicate organic membrane and is not easily seen. The tegmentum is composed of organic material (probably a form of conchin) and calcium carbonate suffused with various pigments. It is penetrated by vertical canals (**aesthetes**) that lead to minute pores in the surface of the valves. The pores are of two sizes: the larger ones (megalopores) house the **megaesthetes,** and the smaller ones (micropores) the **microaesthetes**. In some species, megaesthetes may be modified as **shell eyes** (see section on Sense Organs), with compound lenses made of large crystals of aragonite. The vertical aesthete canals arise from a layer of horizontal canals in the lower part of the tegmentum and the articulamentum (see Figure 13.43C), and some pass through the articulamentum to join with nerves in the mantle at the lower edge of the shell valve. The articulamentum is a thick, calcareous, porcelaneous layer that differs in certain ways from the shell layers of other molluscs.

Monoplacophorans have a single, limpetlike shell with the apex situated far forward (Figures 13.1A and 13.3). The shell has a distinctive outer prismatic layer and an inner layer formed of foliated aragonite in most species. As in chitons, the mantle encircles the body and foot as a circular fold, forming lateral mantle grooves.

The bivalves possess two shells, or **valves**, that are connected dorsally by an elastic, proteinaceous **ligament** and enclose the body and spacious mantle cavity (Figures 13.1M–P, 13.8, and 13.16J,K). Shells of bivalves typically have a thin periostracum, covering two to four calcareous layers that vary in composition and structure. The calcareous layers are often aragonite or an aragonite/calcite mixture, and they usually have a substantial organic framework. The periostracum and organic matrix may account for over 70% of the shell's dry weight in some thin-shelled taxa. Each valve has a dorsal protuberance called the umbo, which is the oldest part of the shell or larval shell (the **prodissoconch**). Concentric growth lines radiate outward from the umbo. When the valves are closed by contraction of the adductor muscles, the outer part of the ligament is stretched and the inner part is compressed. Thus, when the adductor muscles relax, the resilient ligament causes the valves to open. The hinge apparatus comprises various sockets and toothlike pegs or flanges (hinge teeth) that align the valves and prevent lateral movement. In most bivalves, the adductor muscles contain both striated and smooth fibers, facilitating both rapid and sustained closure of the valves. This division of labor is apparent in some bivalves, as for example in oysters, where the large single adductor muscle is clearly composed of two parts, a dark striated region that functions as a rapid-closure muscle, and a white smoother region (the catch muscle) that functions to hold the shell tightly closed for long periods of time.

The thin mantle lines the inner valve surfaces in bivalves and separates the visceral mass from the shell. The edge of a bivalve mantle bears three longitudinal ridges or folds—the inner, middle, and outer folds (Figure 13.15C). The innermost fold is the largest and contains radial and circular muscles, some of which attach the mantle to the shell. The line of mantle attachment appears on the inner surface of each valve as a scar called the **pallial line** (Figure 13.16J), and this scar is often a useful diagnostic character. The middle mantle fold is sensory in function, and the outer fold is responsible for secreting the shell. The cells of the outer lobe are specialized: the medial cells lay down the periostracum, and the lateral cells secrete the first calcareous layer. The entire mantle surface is then responsible for secreting the remaining innermost calcareous portion of the shell. A thin extrapallial space lies between the mantle and the shell, and it is into this space that materials for shell formation are secreted and mixed. Should a foreign object, such as a sand grain, lodge between the mantle and the shell, it may become the nucleus around which are deposited concentric layers of smooth nacreous or porcelaneous shell. The result is a pearl, either free in the extrapallial space or partly embedded in the growing shell.[7]

Scaphopod shells resemble miniature, hollow elephant tusks, hence the vernacular names "tusk shell" and "tooth shell" (Figures 13.1L and 13.9). The scaphopod shell is open at both ends, with the smaller opening at the dorsal end of the body. Most tusk shells are slightly curved, the concave side being equivalent to the anterior of other molluscs. The mantle is long, lining the entire posterior side of the shell. The dorsal aperture serves for both inhalant and exhalant water currents.

[7]Pearls are also found in some gastropods with nacreous inner shell layers, such as abalone.

Most extant cephalopods have a reduced shell or are shell-less. A completely developed external shell is found only in fossil forms and the living species of *Nautilus* and *Allonautilus*. In squid and cuttlefish the shell is reduced and internal, and in octopuses it is entirely lacking or present only as a small rudiment.

The shell of *Nautilus* is coiled in a planispiral fashion (whorls lie in a single plane) and has a thin periostracum (Figures 13.10, 13.17A, and 13.22B). *Nautilus* shells (and all cephalopod shells) are divided into internal chambers by transverse septa, and only the last chamber is occupied by the body of the living animal. As the animal grows, it periodically moves forward, and the posterior part of the mantle secretes a new septum behind it. Each septum is interconnected by a tube through which extends a cord of tissue called the **siphuncle**. The siphuncle helps to regulate buoyancy of the animal by varying the amounts of gas and fluid in the shell chambers. The shell is composed of an inner nacreous layer and an outer porcelaneous layer containing prisms of calcium carbonate and an organic matrix. The outer surface may be pigmented or pearly white. The junctions between septa and the shell wall are called **sutures** and are simple and straight, or slightly waved (as in *Nautilus*), or were highly convoluted (as in the extinct ammonites). In cuttlefish (order Sepiida), the shell is highly modified and internal, with chambers that are very narrow spaces separated by thin septa. Like *Nautilus*, a cuttlefish can regulate the relative amounts of fluid and gas in its shell chambers. The small, open-coiled, septate, gas-filled internal shells of the deep-water "squid" *Spirula* are often found washed up on beaches.

Fossil data suggest that the first cephalopod shells were probably small curved cones. From these ancestors both straight and coiled shells evolved, although secondary uncoiling occurred in several groups. Some straight-shelled cephalopods from the Ordovician Period exceeded 5 m in length, and some Cretaceous coiled species had shell diameters of 2 m or more.

Gastropod shells are extremely diverse in size and shape (Figure 13.1D,G). The smallest are microscopic (less than 1 mm), and the largest may reach 70 cm in length. The "typical" shape is the familiar conical spiral wound around a central axis or columella (Figure 13.16G). The turns of the spire form whorls, demarcated by lines called sutures. The largest whorl is the last (or body) whorl, which bears the aperture through which the foot and head protrude. The traditional view of a coiled gastropod shell with the spire uppermost is actually "upside down," since the lower edge of the aperture is anterior and the apex of the shell spire is posterior. The first few, very small, whorls at the apex are the larval shell, or **protoconch** (or its remnant), which usually differs in sculpturing and color from the rest of the shell. The last whorl and aperture may be notched and drawn out into an anterior **siphonal canal**, to house a siphon when present. A smaller posterior canal may also be present on the rear edge of the aperture that houses a siphonlike fold of the mantle where waste and water are expelled.

Every imaginable variation on the basic spiraled shell occurs among the gastropods (and some unimaginable): the shell may be long and slender (e.g., auger shells) or short and plump (e.g., trochids), or the shell may be flattened (e.g., sundials). In some the spire may be more or less incorporated into the last whorl and eventually disappear from view (as in cowries). In some with a much larger last whorl, the aperture may be reduced to an elongated slit (Figure 13.1E) (e.g., cowries, olives, and cones). In a few groups the shell may coil so loosely as to form a meandering wormlike tube (e.g., the so-called "tube snails," vermetids and siliquariids; see Figure 13.19E). In a number of gastropod groups, the shell may be reduced and overgrown by the mantle; it may disappear entirely, resulting in a slug, or, as in the

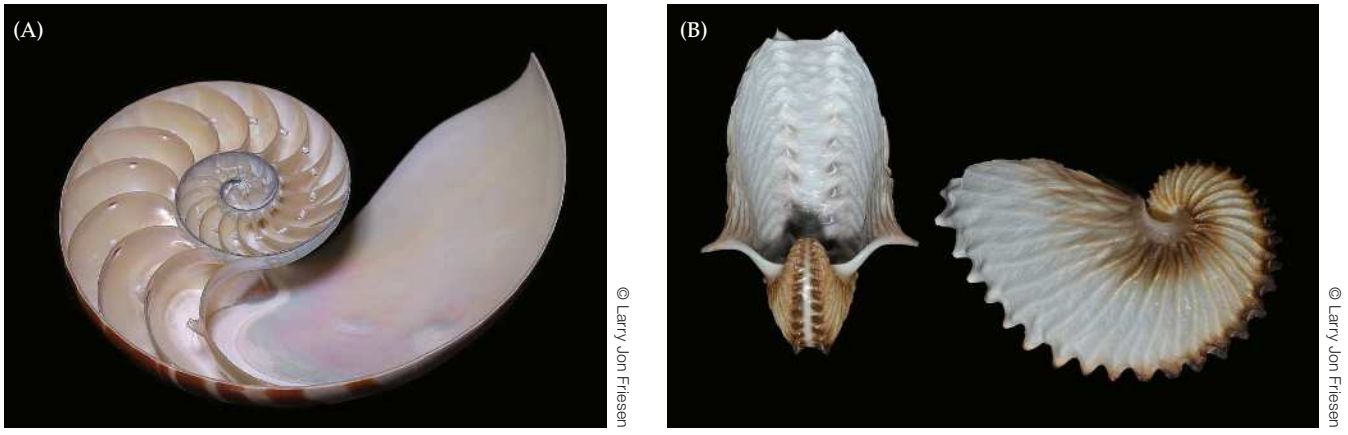

FIGURE 13.17 Two very different kinds of cephalopod shells. (A) The chambered shell of *Nautilus*, cut in longitudinal section. (B) The egg case "shell" of the paper nautilus, *Argonauta*, which is secreted by modified arms, not the mantle.

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

sacoglossan family Juliidae, it may even be bivalved. Most gastropods spiral clockwise; that is, they show right-handed, or dextral, coiling. Some are sinistral (left-handed), and some normally dextral species may occasionally produce sinistral individuals. In limpets the shell is cap shaped, with a low conical shape with no or little visible coiling (Figure 13.16H,I). The limpet shell form has been derived from coiled ancestors on numerous occasions during gastropod evolution.

Gastropod shells consist of an outer thin organic periostracum and two or three calcareous layers: an outer prismatic (or palisade) layer, and middle and inner lamellar or crossed layers. In many vetigastropods the inner layer is nacreous. In some patellogastropods up to six calcareous layers are distinguishable, but in the great majority of living gastropods, the shell structure is primarily one layer composed of crossed crystals (crossed lamellar shell structure). Gastropods in which the shell is habitually covered by mantle lobes lack a periostracum (e.g., olives and cowries), but in some other groups the periostracum is very thick, and sometimes it is produced into lamellae or hairs. The prismatic and lamellate layers consist largely of calcium carbonate, either as calcite or aragonite. These two forms of calcium are chemically identical, but they crystallize differently and can be identified by microscopic examination of sections of the shell. Small amounts of other inorganic constituents are incorporated into the calcium carbonate framework, including chemicals such as phosphate, calcium sulfate, magnesium carbonate, and salts of aluminum, iron, copper, strontium, barium, silicon, manganese, iodine, and fluorine.

An intriguing aspect of gastropod evolution is shell loss and the achievement of the "slug" form. Despite the fact that evolution of the coiled shell led to great success for the gastropods—75% of all living molluscs are snails—secondary loss of the shell occurred many times in this class but mostly in various groups of euthyneurans such as the sea slugs and land slugs. In forms such as the land and sea slugs, the shell may persist as a small vestige covered by the dorsal mantle (e.g., in the euthyneuran sea slugs Aplysiidae and Pleurobranchidae and the caenogastropod family Velutinidae), or it may persist as a small external rudiment, as in the carnivorous land slug *Testacella* (Panpulmonata), or it may be lost altogether (e.g., in the nudibranchs, the systellommatophorans and some terrestrial stylommatophoran slugs, and in the neritimorph *Titiscania*). In the nudibranchs the larval shell is first covered, then resorbed, by the mantle during ontogeny. Shell loss occurred numerous times in gastropods, particularly among the sea slugs (the former "opisthobranchs") and stylommatophoran pulmonates. Shells are energetically expensive to produce and require a reliable source of calcium in the environment, so it might be advantageous to eliminate them if compensatory mechanisms exist. For example, most, if not all, sea slugs secrete chemicals that make them distasteful to predators. In addition, the bright coloration of many nudibranchs may serve a defensive function. In some species, the color matches the animal's background, such as in the small red nudibranch, *Rostanga pulchra*, which matches almost perfectly the red sponge on which it feeds. Many nudibranchs are, however, conspicuous in nature. In these cases, the color may serve to warn predators of the noxious taste of the slug, or as suggested by Rudman (1991), predators may simply ignore such bright "novelties" in their environment. Because of their secondary metabolites, many heterobranchs are thus a focus for studies in chemical ecology and drug development.

Torsion, or "How the Gastropod Got its Twist"

One of the most remarkable and dramatic steps taken during the course of molluscan evolution was the advent of torsion, a unique synapomorphy of gastropods, a process quite unlike anything else in the animal kingdom. Traditionally, it is described as the rotation of the visceral mass and shell by as much as 180° with respect to the head and foot. This twisting is always counterclockwise (viewing the animal from above), and this concept has been referred to as the **rotational hypothesis** (Figures 13.18 and 13.53). However, numerous recent studies have called this description into question, and a more complex and accurate picture of torsion is emerging. This alternative hypothesis is called the **asymmetry hypothesis** and was proposed by Louise Page in 2006.

Gastropod torsion is best characterized as a developmental phenomenon and is proceeded by **ano-pedal flexure**—the movement of the telotroch in the trochophore from its posterior position to a ventral position behind the forming foot and blastopore (mouth) (see Figure 13.51). This placement gives rise to the subsequent formation of a U-shaped gut, and this movement is produced by differential cell proliferation during the formation of the dorsal shell gland. The mantle cavity first becomes apparent as an invagination on the right side of the larva behind the foot and through differential growth moves dorsally to lie over the forming head of the snail. This process is not accompanied by shell rotation in the asymmetry hypothesis. Thus, it is this ventral to dorsal movement of the developing viscera and mantle cavity that produces the crossed nerves and rotated gut so characteristic of gastropods that have undergone torsion.

However, like any anatomical feature or developmental process, torsion has been subject to subsequent evolution over the course of gastropod history. The above summary is based primarily on two early groups—the Patellogastropoda and Vetigastropoda. In other taxa, specifics and the sequence of events may differ, including the occurrence of detorsion. For example,

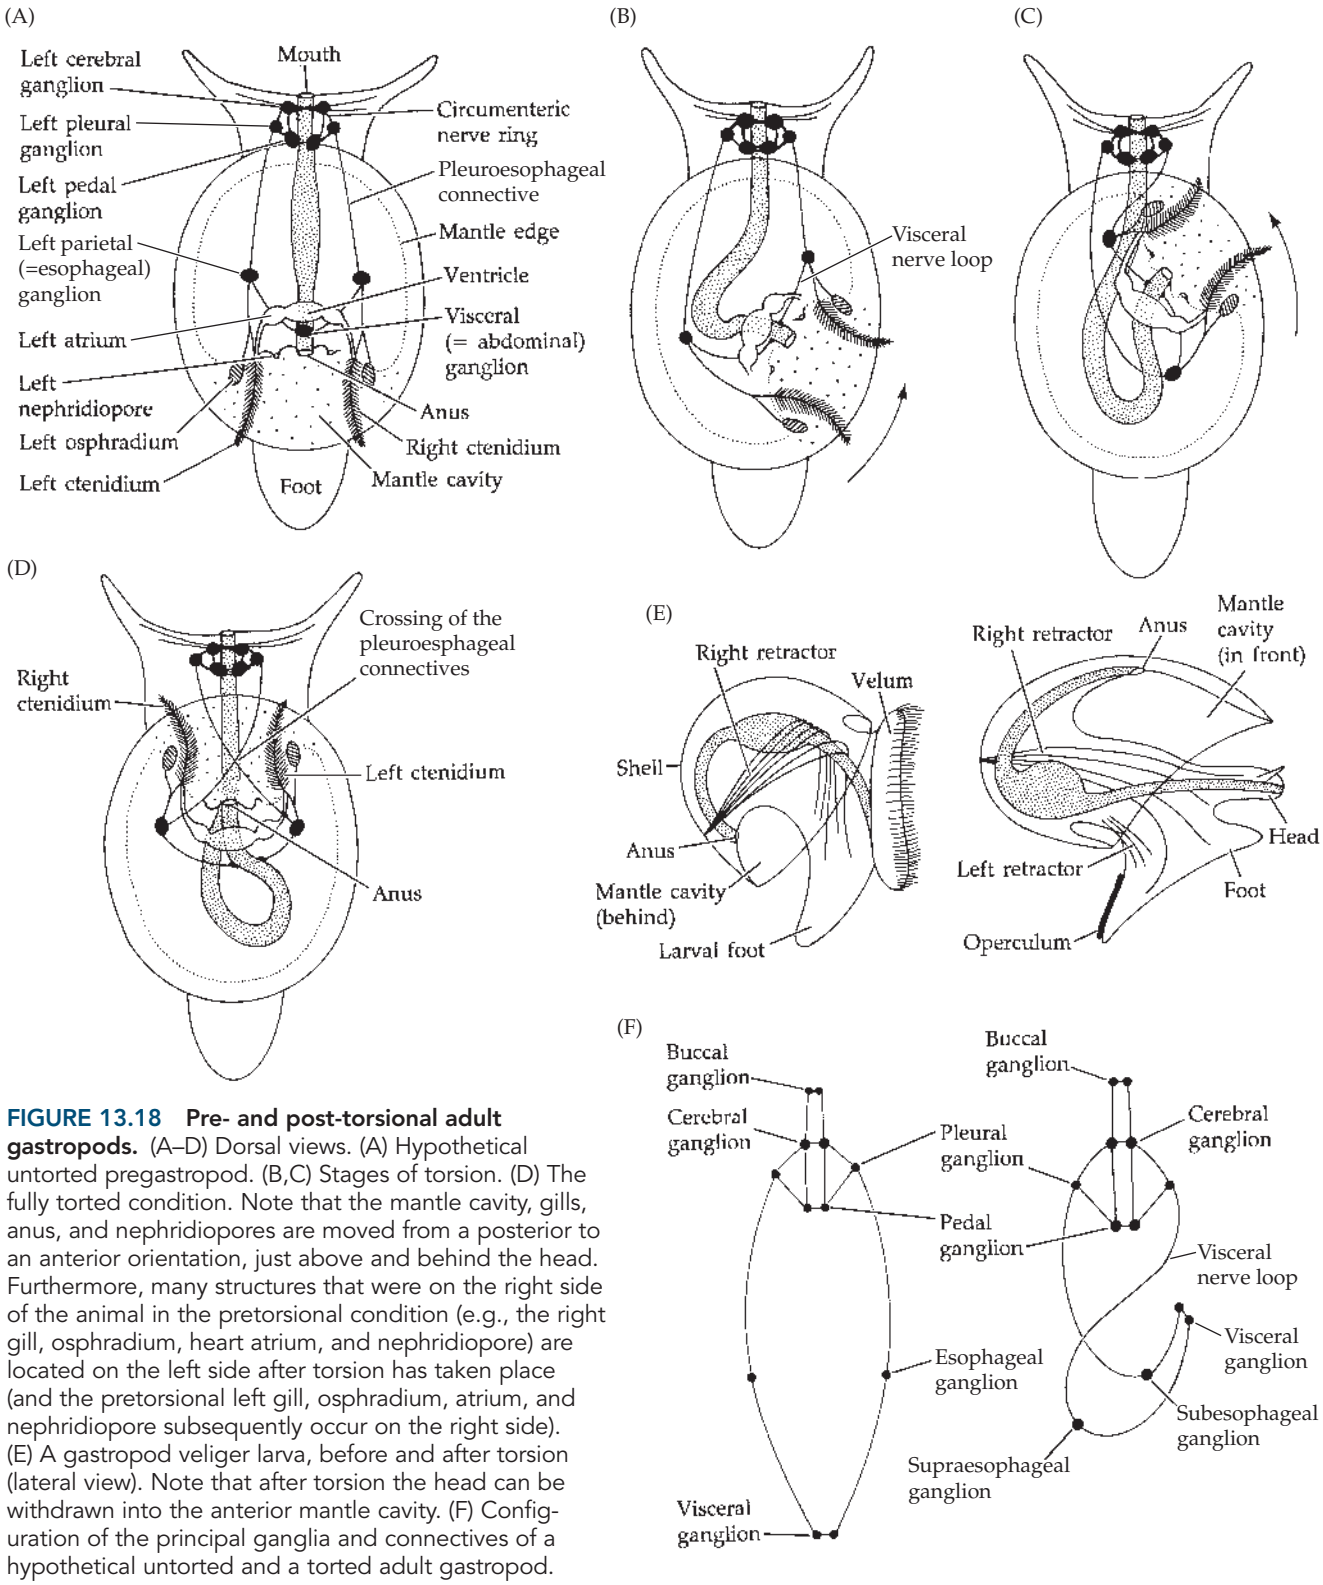

FIGURE 13.18 Pre- and post-torsional adult gastropods. (A–D) Dorsal views. (A) Hypothetical untorted pregastropod. (B,C) Stages of torsion. (D) The fully torted condition. Note that the mantle cavity, gills, anus, and nephridiopores are moved from a posterior to an anterior orientation, just above and behind the head. Furthermore, many structures that were on the right side of the animal in the pretorsional condition (e.g., the right gill, osphradium, heart atrium, and nephridiopore) are located on the left side after torsion has taken place (and the pretorsional left gill, osphradium, atrium, and nephridiopore subsequently occur on the right side). (E) A gastropod veliger larva, before and after torsion (lateral view). Note that after torsion the head can be withdrawn into the anterior mantle cavity. (F) Configuration of the principal ganglia and connectives of a hypothetical untorted and a torted adult gastropod.

the size and position of the early mantle cavity varies in different taxa, and its enlargement and the appearance of mantle cavity components (gills, sense organs, excretory openings) typically occur after the mantle is in its final position—not before, as in the rotational hypothesis. In other taxa, larval shell rotation and viscera rotation are not synchronous but disassociated. In the abalone *Haliotis kamtschatkana,* the shell obtains a full 180° rotation, while the mantle cavity rudiment has rotated only 90°. Additional differential growth expands the mantle cavity into a more central and dorsal position. Similar disassociation of shell and mantle cavity rotation has

for more ebook/ testbank/ solution manuals request to email 960126734@qq.com

been observed in some Caenogastropoda and Heterobranchia. In the heterobranch *Ovatella* the mantle cavity does not even invaginate until torsion is completed.

Gastropods that retain torsion into adulthood are said to be **torted**; those that have secondarily reverted back to a partially or fully untorted state in adulthood are **detorted**. The torted, figure-eight configuration of the nervous system is referred to as **streptoneury**. The detorted condition, in which the visceral nerves are secondarily untwisted, is referred to as **euthyneury**. Detorted gastropods, such as many heterobranchs, undergo a postveliger series of changes through which the original torsion is reversed to various degrees. The process shifts the mantle cavity and at least some of the associated organs about 90° back to the right (as in many "pulmonates" and some sea slugs), or in some cases all the way back to the rear of the animal (the detorsion seen in some nudibranchs). Like torsion, detorsion is not a single developmental event, but rather an adult character suite achieved through a variety of different developmental pathways and, often, further dissociation of the components of the mantle cavity.

After torsion the anus lies in front; this means that the first gastropods could no longer grow in length easily. Subsequent increase in body size thus occurred by the development of loops or bulges in the middle portion of the gut region, thereby producing the characteristic coiled visceral hump. The first signs of torsion and coiling occur at about the same time during gastropod development. The earliest coiled gastropod shells in the fossil record include both planispiral and conispiral forms, and it is possible that coiling predated the appearance of torsion in gastropods. Once both features were established, they coevolved in various ways to produce what we see today in living gastropods.

The evolution of asymmetrically coiled shells had the effect of restricting the right side of the mantle cavity, a restriction that led to reduction or loss of the structures it contained on the adult right side (the original pre-torsional left ctenidium, atrium, and osphradium). At the same time, these structures on the adult left side (the original pre-torsional right ctenidium, atrium, and osphradium) tended to enlarge. Possibly correlated with torsion and coiling was the loss of the left post-torsional gonad. The single remaining gonad opens on the right side via the post-torsional right nephridial duct and nephridiopore. Patellogastropods and most vetigastropods retain two functional nephridia, the plesiomorphic condition in gastropods, although the post-torsional left one is often reduced. In other gastropods the post-torsional right nephridium is lost, but its duct and pore remain associated with the reproductive tract in neritimorphs and caenogastropods. Such profound changes in spatial relations between major body regions as those brought about by torsion and spiral coiling in gastropods are rare among other animals.

Several theories on the adaptive significance of torsion have been proposed and are still being argued. The great zoologist Walter Garstang suggested that torsion was an adaptation of the veliger larva that served to protect the soft head and larval ciliated velum from predators (see the Development section). When disturbed, the immediate reaction of a veliger is to withdraw the head and foot into the larval shell, whereupon the larva begins to sink rapidly. This theory may seem reasonable for evasion of very small planktonic predators, but it seems illogical as a means of escape from larger predators in the sea, which no doubt consume veligers whole—and any adaptive value to adults is not explained. Two zoologists finally tested Garstang's theory by offering torted and untorted abalone veligers to various planktonic predators; they found that, in general, torted veligers were not consumed any less frequently than untorted ones (Pennington and Chia 1985).

Other workers have hypothesized that torsion was an adult adaptation that might have created more space for retraction of the head into the shell (perhaps also for protection from predators) or for directing the mantle cavity with its gills and water-sensing osphradia anteriorly. Still another theory asserts that torsion evolved in concert with the evolution of a coiled shell—as a mechanism to align the tall spiraling shells from a position in which they stuck out to one side (and were presumably poorly balanced and growth limiting) to a position more in alignment with the longitudinal (head–foot) axis of the body. The latter position would theoretically allow for greater growth and elongation of the shell while reducing the tendency of the animal to topple over sideways.

No matter what the evolutionary forces were that led to torsion in the earliest gastropods, the results were to move the adult anus, nephridiopores, and gonopores to a more anterior position, corresponding to the new position of the mantle cavity. It should be noted, however, that the actual position and arrangement of the mantle cavity and its associated structures show great variation; in many gastropods these structures, while pointing forward, may actually be positioned farther toward the posterior region of the animal's body. Torsion is not a perfectly symmetrical process.

Most of the stories of gastropod evolution focus on changes in the mantle cavity and its associated structures, and many of these changes seem to have been driven by some negative impacts of torsion. Many anatomical modifications of gastropods appear to be adaptations to avoid fouling, for without a change in the original flow of water through the mantle cavity in a primitive gastropod with two ctenidia, waste from the centrally positioned anus (and perhaps the nephridia) would be dumped on top of the head and potentially pollute the mouth and ctenidia. Hence, it has long been hypothesized that the first

step, subsequent to the evolution of torsion, was the development of slits or holes in the shell, thus altering water flow so that a one-way current passed first over the ctenidia, then over the anus and nephridiopore, and finally out the slit or shell holes. This arrangement is seen in some vetigastropods, such as the slit shells (Pleurotomarioidea) and abalone and keyhole limpets (Figures 13.1D, 13.16I, and 13.36). As reasonable as it sounds, there has been surprisingly little empirical evidence in support of this hypothesis. In addition, the adaptive significance of shell holes was examined by Voltzow and Collin (1995), who found that blocking the holes in keyhole limpets did not result in damage to the organs of the mantle cavity. Thus, the adaptive significance of torsion in gastropod evolution remains an open question.

Once evolutionary reduction or loss of the gill and osphradium on the right side had taken place, water flow through the mantle cavity was from left to right, passing through the left gill and osphradium first, then across the nephridiopore and anus, and on out the right side. This strategy also had the effect of allowing structures on the left side to enlarge and eventually to develop more control over water flow into and out of the mantle cavity, including the evolution of long siphons. While most gastropods have retained full or partial torsion, many heterobranchs, all of which lost the original ctenidium, have undergone various degrees of detorsion, and a host of other modifications, perhaps in response to the absence of constraints originally brought on by torsion.

Locomotion

The foot in aplacophorans is either rudimentary or lost (Figure 13.2). Caudofoveata are mostly infaunal burrowers and move by peristaltic movements of the body wall, using the anterior mouth shield as a burrowing device and anchor. The foot of solenogasters is only weakly muscular, and locomotion is primarily by slow ciliary gliding movements through or upon the substratum, as they are largely symbiotic on various cnidarians. Most other molluscs possess a distinct and obvious foot, with the exception of the cephalopods, where it is very highly modified. In chitons, monoplacophorans, and most gastropods, the foot often forms a flat, ventral, creeping sole (Figures 13.3B, 13.4B, 13.5B, and 13.19). The sole is ciliated and imbued with numerous gland cells that produce a mucous trail over which the animal glides. In gastropods, enlarged pedal glands supply substantial amounts of mucus (slime), this being especially important in terrestrial species that must glide on relatively dry surfaces. In most gastropods, there are anterior mucous glands, which open in a slit on or just behind the anterior edge of the foot. This anterior lobe is called the **propodium**, the rest of the foot the **metapodium**. In some caenogastropods, an enlarged metapodial mucous gland opens into the middle of the sole. Small molluscs may move largely by ciliary propulsion, but most move primarily by waves of muscular contractions along the foot.

The gastropod foot possesses pedal retractor muscles, which attach to the shell. These and smaller muscles in the foot act in concert to raise and lower the sole or to shorten it in either a longitudinal or a transverse direction. Contraction waves may move from back to front (direct waves), or from front to back (retrograde waves) (Figure 13.19A,B). Direct waves depend on contraction of longitudinal and dorsoventral muscles beginning at the posterior end of the foot; successive sections of the foot are thus "pushed" forward. Retrograde waves involve contraction of transverse muscles interacting with hemocoelic pressure to extend the anterior part of the foot forward, followed by contraction of longitudinal muscles. The result is that successive areas of the foot are "pulled" forward (Figure 13.19A,B). In some gastropods the muscles of the foot are separated by a midventral line, so the two sides of the sole operate somewhat independently of each other. The right and left sides of the foot alternate in their forward motion, almost in a stepping fashion, resulting in a sort of "bipedal" locomotion.

Modifications of this general benthic locomotory scheme occur in many groups. Some gastropods, such as moon snails (Figure 13.19D), plow through the sediment, and some even burrow beneath the sediment surface. Such gastropods often possess an enlarged, shieldlike propodium that acts like a plough, and some naticids and cephalaspideans possess a dorsal flaplike fold of the foot that covers the head as a protective shield. Other burrowers, such as augers, dig by thrusting the foot into the substratum, anchoring it by engorgement with hemolymph, and then pulling the body forward by contraction of longitudinal muscles. In the conch *Stombus*, the operculum forms a large "claw" that digs into the substratum and is used as a pivot point as the animal thrusts itself forward using its muscular, highly modified foot. In some heterobranchs, notably the sea hares (Aplysiidae), lateral flaps of the foot expand dorsally as parapodia, and these are fused dorsally in some species.

Some molluscs that inhabit high-energy littoral habitats, such as chitons and limpets, have a very broad foot that can adhere tightly to hard substrata. Chitons also use their broad girdle for additional adhesion to the substratum by clamping down tightly and raising the inner margin to create a slight vacuum. Some snails, such as the Vermetidae and Siliquariidae, are entirely sessile, the former attached to hard substrata, the latter (Figure 13.19E) living in sponges. These gastropods have typical larval and juvenile shells; but after they settle and start to grow, the shell whorls become increasingly separated from

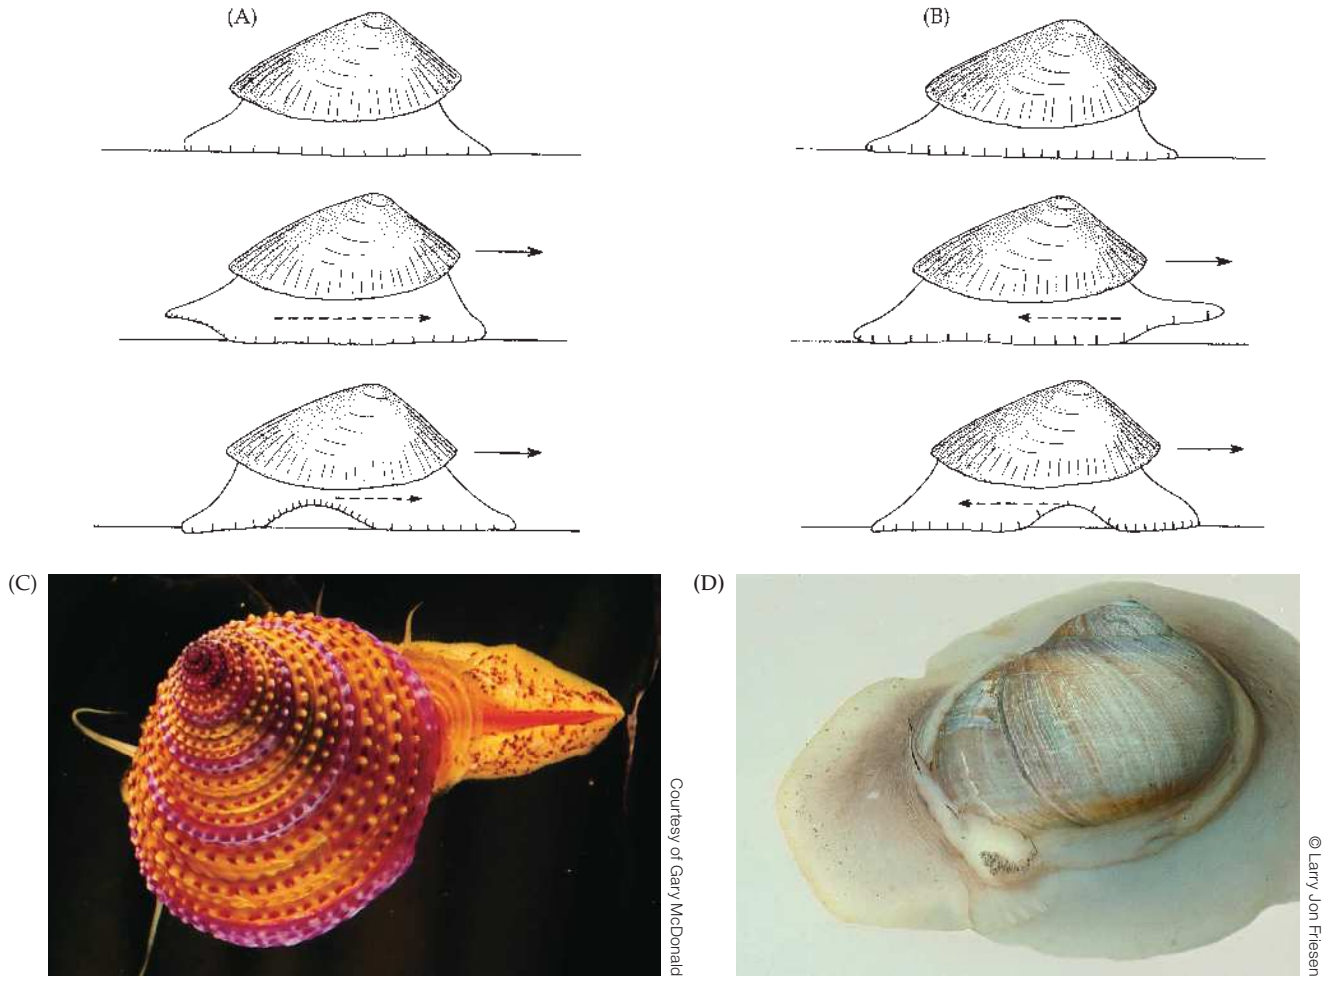

FIGURE 13.19 Locomotion in gastropods. (A,B) Locomotion in a benthic gastropod moving to the right by waves of contraction of the pedal and foot muscles (solid arrow indicates direction of animal movement; dashed arrow indicates direction of muscle wave). In (A) the waves of contraction are moving in the same direction as the animal, from back to front (direct waves). Muscles at the rear of the animal contract to lift the foot off the substratum; the foot shortens in the contracted region and then elongates as it is placed back down on the substratum after the wave passes. In this way, successive sections of the foot are "pushed" forward. In (B) the animal moves forward as the contraction waves pass in the opposite direction, from front to back (retrograde waves). In this case, the pedal muscles lift the anterior part of the foot off the substratum, and the foot elongates, is placed back on the substratum, then contracts to "pull" the animal forward, rather like "stepping." (C) *Calliostoma*, a vetigastropod (Calliostomatidae) adapted to crawling on hard substrata. Note the line separating the right and left sides of the trailing foot; the line denotes a separation of muscle masses that allows a somewhat "bipedal-like" motion as the animal moves (see text for further details). (D) The moon snail, *Polinices* (Naticidae), has a huge foot that can be inflated by incorporating water into a network of channels in its tissue, thus allowing the animal to plow through the surface layer of soft sediments. (E) *Tenagodus* (Siliquariidae), a sessile siliquariid worm snail.

one another, resulting in a corkscrew or twisted shape. Other gastropods, such as slipper shells, are sedentary. They tend to remain in one location and feed on organic particles in the surrounding water. The sole of the hipponicid limpets secretes a calcareous plate, and the adults are thus oysterlike and deposit feed by using their long snout.

Some limpets and a few chitons exhibit homing behaviors. These activities are usually associated with feeding excursions stimulated by changing tide levels or darkness, after which the animals return to their homesites, which are seen as a scar or even a depression on the rock surface. Homing behaviors are also seen in some land snails and slugs.

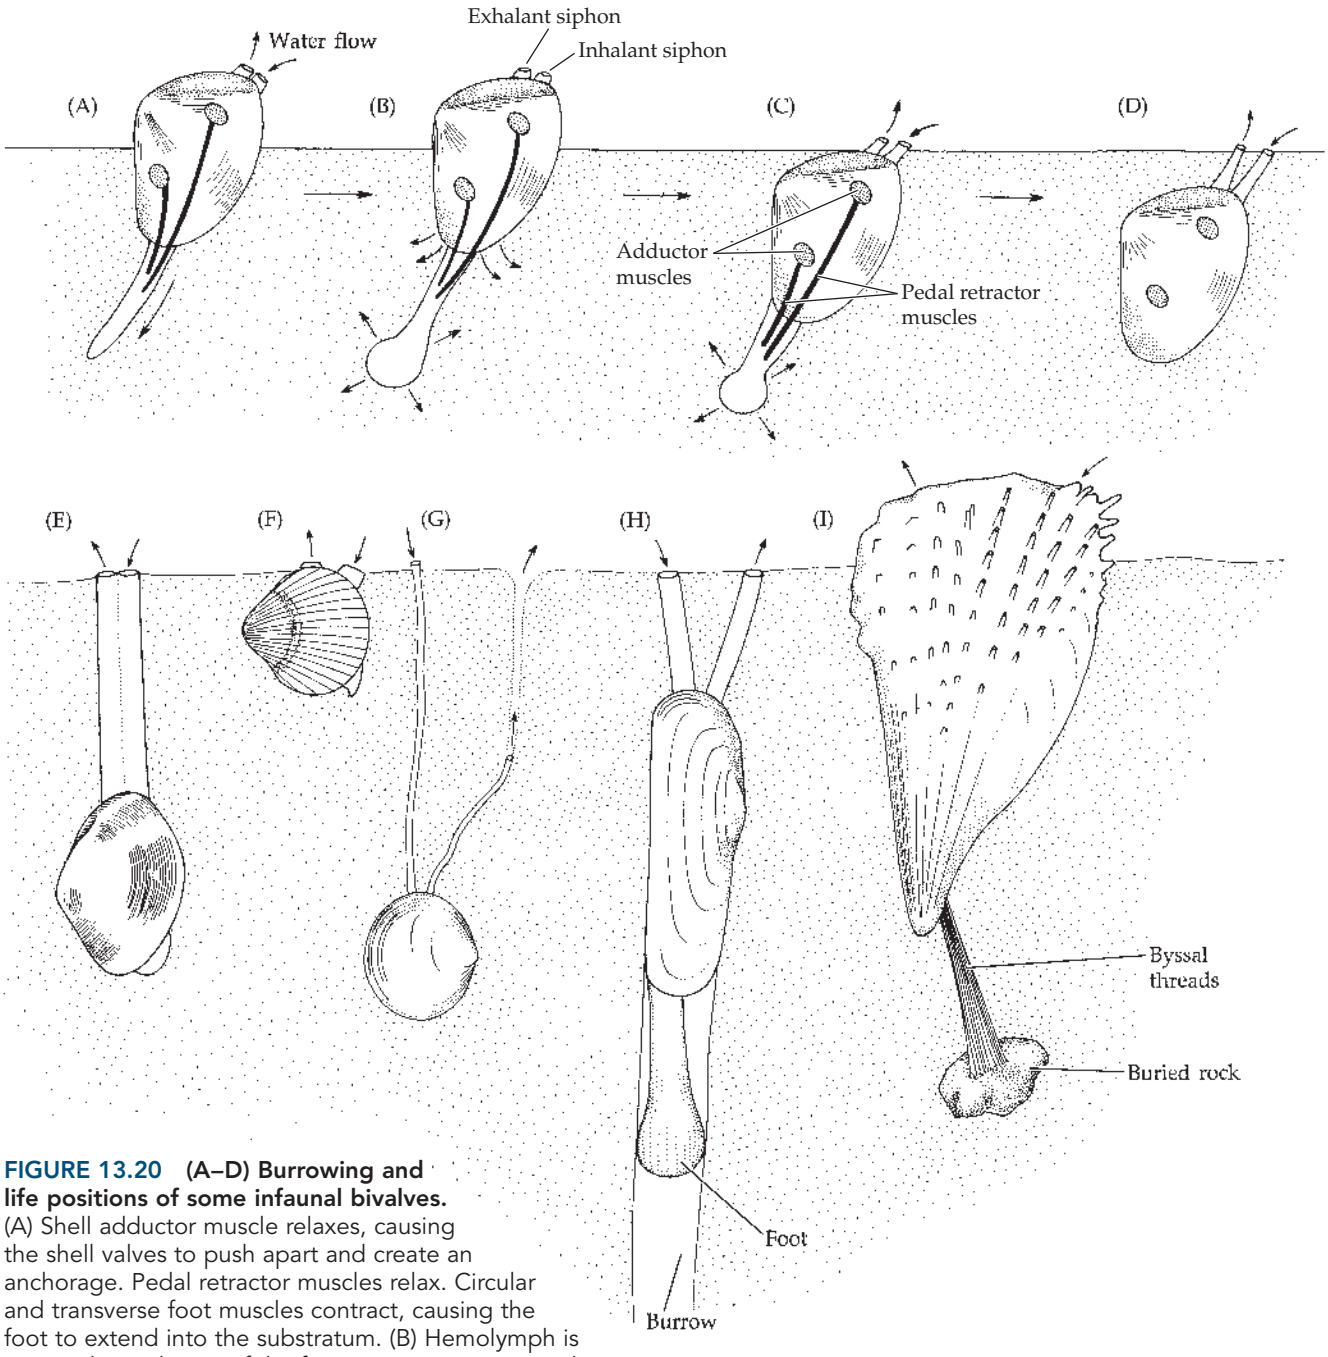

FIGURE 13.20 (A–D) Burrowing and life positions of some infaunal bivalves. (A) Shell adductor muscle relaxes, causing the shell valves to push apart and create an anchorage. Pedal retractor muscles relax. Circular and transverse foot muscles contract, causing the foot to extend into the substratum. (B) Hemolymph is pumped into the tip of the foot, causing it to expand and form an anchorage. Siphons close and withdraw as the shell adductor muscles contract, closing the shell and forcing water out between the valves and around the foot. (C) Anterior and posterior pedal retractor muscles contract, pulling the clam deeper into the substratum. (D) The shell adductor muscle relaxes to allow shell valves to push apart and create an anchorage in the new position. The foot is withdrawn. (E–I) Five bivalves in soft sediments; arrows indicate direction of water flow. (E) A deep burrower with long, fused siphons (*Tresus*). (F) A shallow burrower with very short siphons (*Clinocardium*). (G) A deep burrower with long, separate siphons (*Scrobicularia*). (H) The razor clam (*Tagelus*) lives in unstable sands and maintains a burrow into which it can rapidly escape. (I) The pen shell (*Atrina*) attaches its byssal threads to solid objects buried in soft sediments.

Most bivalves live in soft benthic habitats, where they burrow to various depths in the substratum (Figure 13.20E–I). In these infaunal species the foot is usually bladelike and laterally compressed (the word "Pelecypoda" means "hatchet foot"), as is the body in general, but the foot of protobranchs has a flattend surface or sole. The pedal retractor muscles in bivalves are somewhat different from those of gastropods, but they still run from the foot to the shell (Figure 13.8D). The foot is directed anteriorly and used primarily in burrowing and anchoring. It operates through a combination of muscle action and hydraulic pressure (Figure 13.20A–D). Extension of the foot is accomplished by engorgement with hemolymph, coupled with the action of the pedal protractor muscles. With the foot extended, the valves are

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

pulled together by the shell adductor muscles. More hemolymph is forced from the visceral mass hemocoel into the foot hemocoel, causing the foot to expand and anchor in the substratum. Once the foot is anchored, the anterior and posterior pairs of pedal retractor muscles contract and pull the shell downward. Withdrawal of the foot into the shell is accomplished by contraction of the pedal retractors coupled with relaxation of the shell adductor muscles. Many infaunal bivalves burrow upward in this same manner, but others back out by using hydraulic pressure to push against the anchored end of the foot. Most motile bivalves possess well-developed anterior and posterior adductor muscles (the **dimyarian** condition).

There are several groups of bivalves that have epifaunal lifestyles and are permanently attached to the substratum. They do this either by cementing one valve to a hard surface, as in the true oysters such as the rock oysters (Ostreidae) and rock scallops (Spondylidae), or by using special anchoring threads (**byssal threads**), as in marine mussels (Mytilidae) (Figure 13.21A,B), ark shells, winged or pearl oysters (Pteriidae), and numerous other pteriomorphian bivalves, including the Pinnidae and many Pectinidae. While the juveniles of many heterodont bivalves produce one or a few temporary

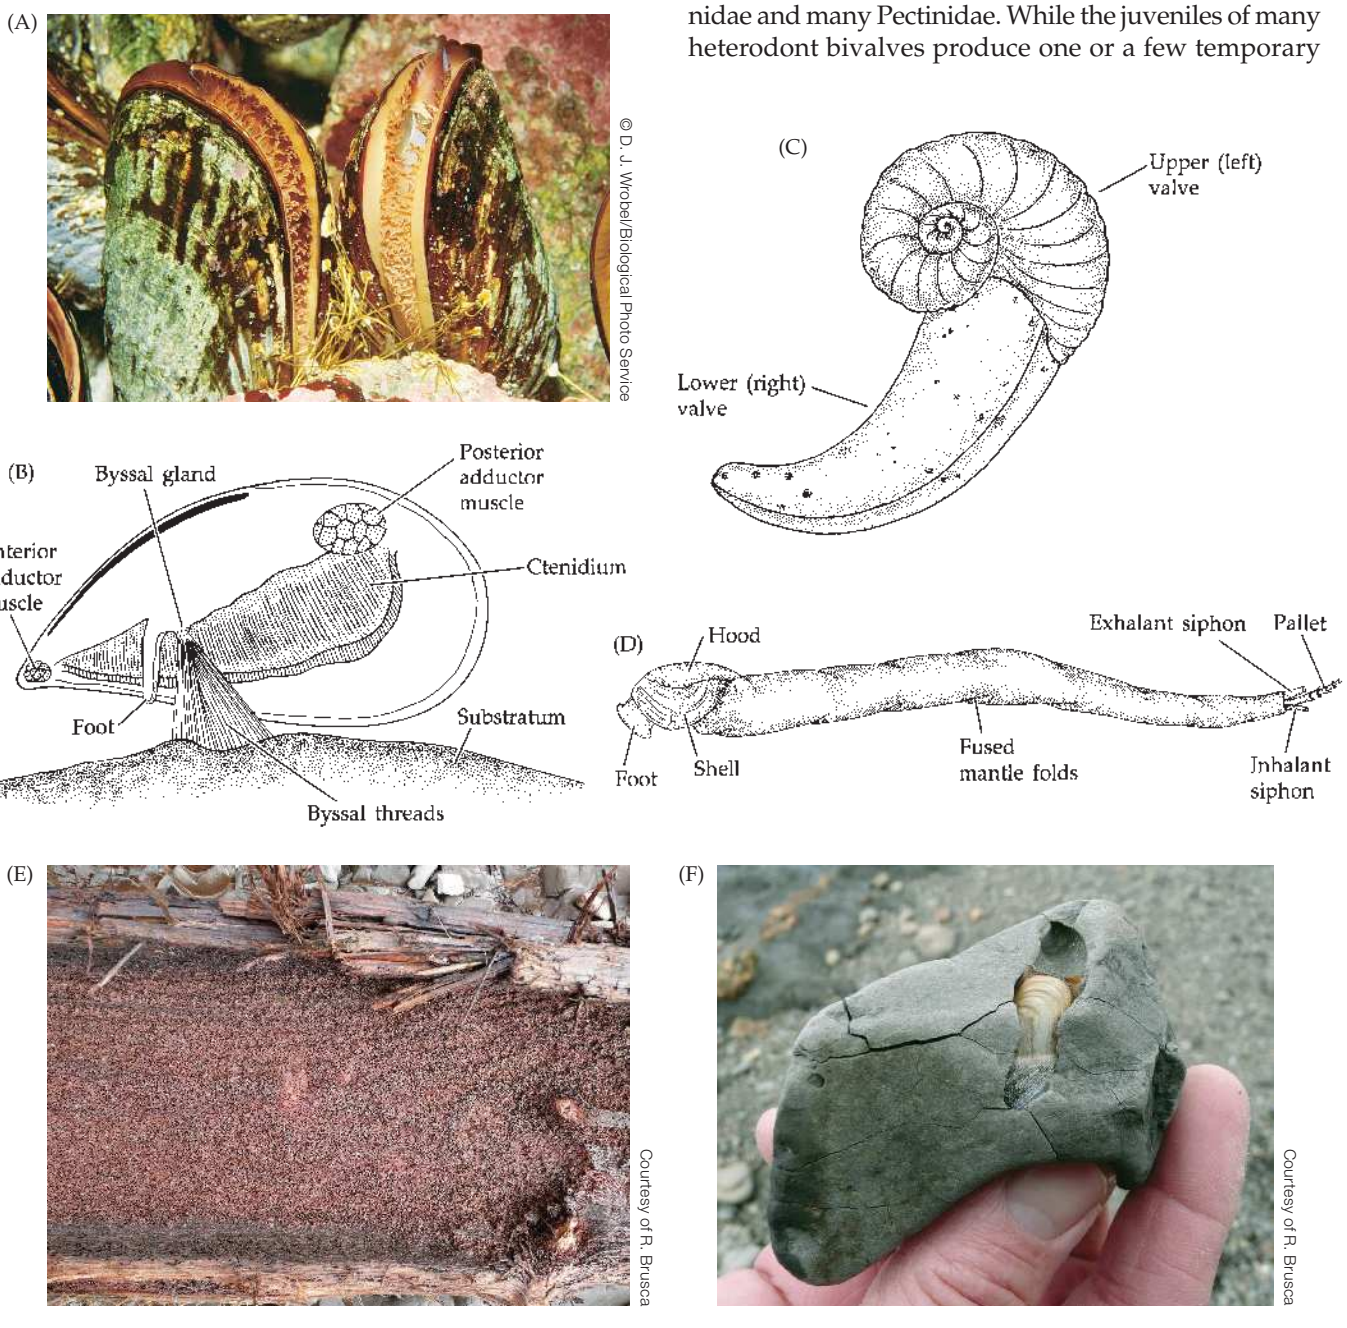

FIGURE 13.21 More bivalves. (A) A "bed" of mussels (*Mytilus californianus*) attached by byssal threads (close up of two mussels). (B) A mussel (lateral view, with left valve removed). (C) Shell of the Mesozoic rudist clam *Coralliochama*. (D) The wood-boring bivalve (shipworm) *Teredo*. The pallets (only one is shown) are a pair of shelly plates that close over the siphons when they are retracted. (E) A shipworm-bored piece of driftwood (notice the numerous small holes). (F) A pholad-bored rock. The pholad can be seen in its bore hole.

byssal threads, a few species, such as the zebra mussel (*Dreissena*), remain byssally attached as adults.

The true oysters (Ostreidae), including the edible oysters, initially anchor as a settling veliger larva (called a **spat** by oyster farmers) by secreting a drop of adhesive from the byssus gland. Adults, however, have one valve permanently cemented to the substratum, with the cement being produced by the mantle.

Byssal threads are secreted as a liquid by the **byssus gland** in the foot. The liquid flows along a groove in the foot to the substratum, where each thread becomes tightly affixed. The threads are placed by the foot; once attached, they quickly harden by a tanning process, whereupon the foot is withdrawn. A byssal thread retractor muscle may assist the animal in pulling against its anchorage. Mussels have a small, fingerlike foot whose principal function is generation and placement of the byssal threads. Giant clams (Cardiidae, Tridacninae) initially attach by byssal threads but usually lose these as they mature and become heavy enough not to be cast about by currents (Figure 13.1N). In jingle shells (Anomiidae), the byssal threads run from the upper valve through a hole in the lower valve to attach to the substratum, after which they become secondarily calcified. Byssal threads probably represent a primitive and persisting larval feature in those groups that retain them into adulthood, and many bivalves lacking byssal threads as adults utilize them for initial attachment during settlement.

In many families of attached bivalves, such as mussels and true oysters, the foot and anterior end are reduced. This often leads to a reduction of the anterior adductor muscle (**anisomyarian condition**) or its complete loss (**monomyarian condition**).

Great variation occurs in shell shape and size among attached bivalves. Some of the most remarkable were the Mesozoic rudists, in which the lower valve was hornlike and often curved, and the upper valve formed a much smaller hemispherical or curved lid (Figure 13.21C). Rudists were large, heavy creatures that often formed massive reeflike aggregations, either by somehow attaching to the substratum or by simply accumulating in large numbers on the seabed, in "logjams." These accumulations of fossil shells provide the spaces in which oil deposits formed in sediments in many parts of the Middle East, Gulf of Mexico, and Caribbean.

Some bivalves have evolved to live openly on the seafloor (e.g., some Pectinidae and Limidae) (Figure 13.1M). Some are capable of short bursts of "jet-propelled" swimming, which is accomplished by quickly clapping the valves together.

The habit of boring into hard substrata has evolved in several different bivalve lines. In all cases, excavation begins soon after larval settlement. As the animal bores deeper, it grows in size and soon becomes permanently trapped, with only the siphons protruding out of the original small opening. Boring is usually by a mechanical process; the animal uses serrations on the anterior region of the shells to abrade or scrape away the substratum. Some species also secrete an acidic mucus that partially dissolves or weakens hard calcareous substrata (limestone, coral, large dead shells). Some species bore into wood, such as *Martesia* (Pholadidae), *Xylophaga* (Xylophagaidae), and nearly all species in the family Teredinidae (*Bankia*, *Teredo*). Teredinids, with their long wormlike bodies, are known as shipworms because of the destruction that they can cause to the wooden hulls of ships (and wood pier pilings). In the teredinids the shells are reduced to small anterior bulblike valves that serve as the drilling apparatus (Figure 13.21D,E) and also have siphonal calcareous structures called pallets. Some pholadids bore into soft rock (e.g., *Pholas*; Figure 13.21F) or into other substrata (e.g., *Barnea*). Some species in the family Mytilidae are also borers, such as *Lithophaga* (which bores by mechanical and possibly chemical means into calcareous rocks, shells of various other molluscs including chitons, and corals), the genus *Adula* (which bores into soft rocks), and *Idas* (associated with whale falls).

Scaphopods are adapted to infaunal habitats, burrowing vertically by the same basic mechanism used by many bivalves (Figures 13.1L and 13.9). The elongate foot is projected downward into soft substrata, whereupon a rim in the distal part of the foot is expanded to serve as an anchoring device; contraction of the pedal retractor muscles pulls the animal downward.

Perhaps the most remarkable locomotory adaptation of molluscs is swimming, which has evolved in several different taxa in several different ways, including by valve flapping in scallops (Pectinidae) and some Limidae (e.g., flame scallops). In most other swimming molluscs the foot is modified as the swimming structure. In the unique caenogastropod group known as heteropods, the body is laterally compressed, the shell is greatly reduced, the foot forms a fin, and the animal swims upside down (Figure 13.7A–C). Swimming has evolved several times in the heterobranchs, including the pteropods (sea butterflies), where the parapodial extensions of the foot form two long lateral fins that are used like oars (Figure 13.7D,E). Some nudibranchs also swim by graceful undulations of flaplike parapodial folds along the body margin or by vigorous undulations of the body. Although not actually swimming, violet shells (*Janthina*) float about the ocean's surface on a raft of bubbles secreted by the foot, and some planktonic nudibranchs (e.g., *Glaucus*, *Glaucilla*) stay afloat by use of an air bubble held in the stomach!

The champion swimmers are, of course, the cephalopods (Figures 13.1J,K and 13.22). These animals have abandoned the generally sedentary habits of other molluscs and have become highly effective swimming predators. Virtually all aspects of their biology have evolved to exploit this lifestyle. Most cephalopods swim by rapidly expelling water from the mantle cavity. In

FIGURE 13.22 Swimming cephalopods. (A) *Sepia*, the cuttlefish. (B) *Nautilus*. (C) *Grimpoteuthis*, a pelagic "dumbo octopus."

the coleoid cephalopods the mantle has both radial and circular muscle layers. Contraction of the radial muscles and relaxation of the circular muscles draws water into the mantle cavity, while reversal of this muscular action forces water out of the mantle cavity. The mantle edge is clamped tightly around the head to channel the escaping water through a ventral tubular **funnel**, or **siphon** (Figure 13.11B,C). The funnel is highly mobile and can be manipulated to point in nearly any direction, thus allowing the animal to turn and steer. Squid attain the greatest swimming speeds of any aquatic invertebrates, and several species can even leave the water and propel themselves many feet into the air. Most octopuses are benthic and lack the fins and streamlined bodies characteristic of squid. Although octopuses still use water-powered jet propulsion, they more commonly rely on their long suckered arms for crawling about the seafloor. Some octopuses even move about upright on only two tentacles—bipedal locomotion! Cuttlefish are slower than squid, and they often use their fins for forward swimming as well as stabilization and to assist in steering and propulsion.

Nautilus move up and down in the water column on a diel cycle, often traveling hundreds of meters in each direction. They can actively regulate their buoyancy by secretion and reabsorption of shell chamber fluid and gases (chiefly nitrogen) by the cells of the siphuncle. The unoccupied chambers of these shells are filled partly with gas and partly with a liquid called the **cameral fluid**. The septa act as braces, giving the shells strength to withstand external pressure at depth. As discussed earlier, each septum in nautiloid shells is perforated by a small hole, through which runs the siphuncle, which originates in the viscera and is enclosed in a porous calcareous tube. Various ions dissolved in the cameral fluid can be pumped through the porous outer layers into the cells of the siphuncular epithelium. When the cellular concentration of ions is high enough, the diffusion gradient thus created draws fluid from the shell chambers into the cells of the siphuncle while the fluid is replaced with gas. The result is an increase in buoyancy. By regulating this process, *Nautilus* may be able to remain neutrally buoyant at whatever depth they are. It was once thought that this gas-fluid "pump" mechanism allowed buoyancy changes sufficient to explain all the large-scale vertical movements of *Nautilus*, but density changes may not be the sole source of power for moving great distances up and down in the water column. *Nautilus* can move using jet propulsion by forcefully contracting its head, not by mantle muscle contraction, and move slowly by passing water out of the funnel by the action of funnel flaps.

Feeding

Two basic and fundamentally different types of feeding occur among molluscs: the first encompasses the feeding modes of most molluscs and includes micro- to macrophagy involving browsing and scraping, herbivory, carnivorous grazing, and predation, while the second is suspension feeding (suspension microphagy). The basic mechanics of these two feeding modes are examined in Chapter 3. Here we briefly summarize the ways in which these feeding behaviors are employed by molluscs. In this section we also discuss a uniquely molluscan structure, the radula, which is used in microphagy, herbivory, and predation and has

become modified in a variety of unusual and interesting ways. A few molluscs also supplement their diet with photosynthesis and chemosynthesis thanks to an array of symbionts.

The buccal cavity may contain a pair of lateral jaws (or a single dorsal jaw), muscularized regions with chitinous plates that can be solid or composed of multiple small units. Molluscan jaws are highly variable. For example, in some heterobranchs the jaws can be quite complex, with distinct "teeth." In some carnivorous caenogastropods the jaws can be large. In cephalopods the jaws are modified to form the beak, which has upper and lower elements. Some molluscs, including chitons and bivalves, have no jaws at all.

The radula is tipically a ribbon of recurved chitinous teeth (Figures 13.23, 13.24, 13.25, and 13.26). The teeth may be simple, serrate, pectinate, or otherwise modified. The radula often functions as a scraper to remove food particles for ingestion, although in many groups it has become adapted for other actions. A radula is present in the majority of living molluscan classes, though it is absent in all bivalves, and is assumed to have originated in the earliest stages of molluscan evolution. In the aplacophoran groups the teeth, when present, may be borne not on a ribbon per se but on a relatively thin cuticle covering the foregut epithelium—presumably a homologue of the ribbonlike radula. In some aplacophorans, the teeth form simple plates embedded in either side of the lateral foregut wall, while in others they form a transverse row, or up to 50 rows, with as many as 24 teeth per row.

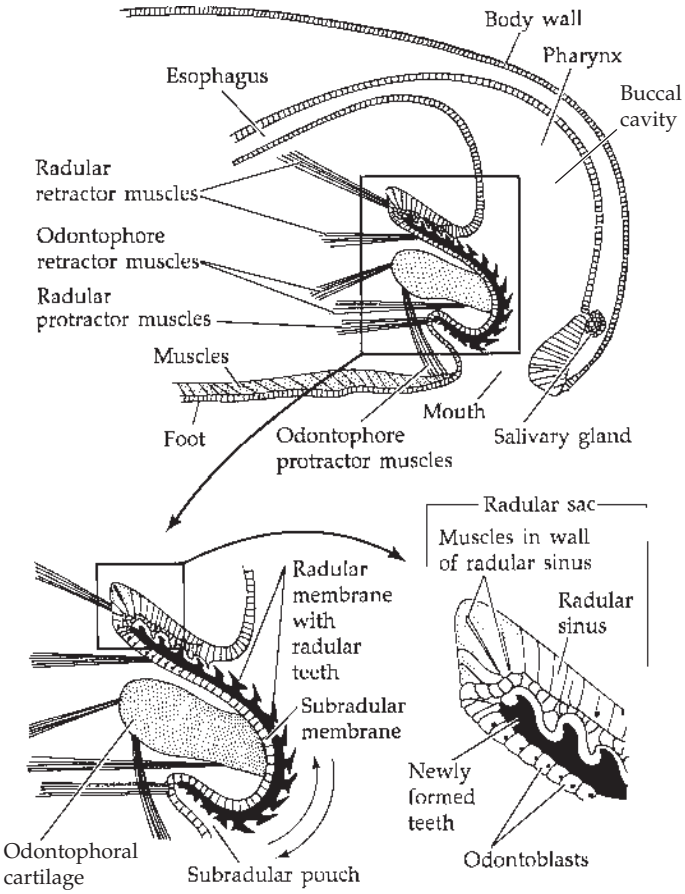

FIGURE 13.23 A generalized molluscan radula and associated buccal structures, at three "magnifications" (longitudinal section).

In gastropods and other molluscs (except bivalves) an **odontophore** projects from the floor of the buccal cavity (sometimes called the pharynx). It is a muscular structure bearing the complex tooth-bearing radular ribbon (Figure 13.23). The ribbon, called a **radular membrane**, is moved back and forth by sets of radular protractor and retractor muscles over cartilages encased in the odontophore (Figure 13.23). These cartilages are absent in many heterobranch gastropods. The radula originates in a **radular sac**, in which the radular membrane and new teeth are continually being produced by special cells called **odontoblasts**, to replace those lost by erosion during feeding. Measurements of radular growth indicate that up to five rows of new teeth may be added daily in some species. The odontophore itself is moved in and out of the buccal cavity during feeding by sets of odontophore protractor and retractor muscles, which also assist in applying the radula firmly against the substratum (Figure 13.24A).

The number of radular teeth ranges from a few to thousands and serves as an important taxonomic character in many groups. In some molluscs, the radular teeth are hardened with iron compounds, such as magnetite (in chitons) and goethite (in patellogastropods). Just as in many vertebrates, the radular teeth show adaptations to the type of food eaten. In vetigastropods (e.g., keyhole limpets, abalones, top shells), the **rhipidoglossate radulae** bear large numbers of fine marginal teeth in each row (Figures 13.25A and 13.26A). As the radula is pulled over the bending plane of the odontophore, these teeth act like stiff brushes, sweeping small particles to the midline, where they are caught on the recurved parts of the central teeth, which draw the particles into the buccal cavity. Most vetigastropods are intertidal foragers that live on diatoms and other algae and microbes on the substratum. In contrast, patellogastropods (e.g., lottiid and patellid limpets) possess a **docoglossate radula**, which is impregnated with iron and bears relatively few teeth in each transverse row. Lottiid radulae, for example, have only one, two, or no marginal teeth, and only three pairs of lateral teeth per row (Figure 13.26B). The lottiid radula is capable of powerful rasping and often leaves grooves on the substrate. Some homing species leave mucous trails that serve as adhesive traps for spores and diatoms and may enhance the densities of algae, thereby increasing their primary food resources.

The radula of many caenogastropods is the **taenioglossate type**, in which there are only two marginal

(D) The worn radular teeth of *Nucella*. (E) The radula of the polycerid nudibranch *Triopha*, seen here in dorsal view as it rests in the animal.

teeth in each row, along with three other teeth (laterals and central) (Figure 13.25B–D). In conjunction with the elaboration of jaws, taenioglossate radulae are capable of powerful rasping, which enables some littorinid snails to feed by directly scraping off the surface cell layers of algae.

The most derived caenogastropods (Neogastropoda) usually have **rachiglossate radulae**, which lack marginal teeth altogether (Figures 13.25E and 13.26C,D). They use the remaining (one to three) teeth for rasping, tearing, or pulling. These snails are usually carnivores or carrion feeders, although some members of one family, the Columbellidae, are herbivores. Caenogastropods of the families Muricidae and Naticidae eat other molluscs by boring through the prey's calcareous shell to obtain the underlying flesh. This ability to bore has evolved entirely independently in the two groups. It is mainly mechanical, the predator boring with its radula while holding the prey with the foot. The boring activity is complemented by the secretion of an acidic chemical from a **boring gland** (also called the "accessory boring organ"); the chemical is periodically applied to the drill hole to weaken the calcareous matrix. The boring gland of the neogastropod muricids is located on the foot while that of the naticids is located on the anterior end of the proboscis (Figure 13.24B). Boring gastropods such as the Atlantic oyster drill (*Urosalpinx cinerea*) and the veined whelk (*Rapana venosa*) cause losses of millions of dollars annually for oyster farms.

Some carnivorous gastropods (e.g., *Janthina*) do not gnaw or rasp their prey, but swallow it whole. In these gastropods a **ptenoglossate radula** forms a covering of strongly curved spines over the buccal mass. The prey is seized by the quickly extruded buccal mass and simply pulled whole into the gut. A somewhat similar feeding method is seen in the carnivorous slug *Testacella*, where the hooked radula catches earthworms that the slug consumes whole. The nudibranch *Melibe* (Tethydidae) uses its large hood to sweep the water for copepods, amphipods, and other small planktonic prey.

A few gastropods have lost the radula altogether and feed by sucking body fluids from their prey, a habit seen, for example, in some nudibranchs. Pyramidellids do this with the aid of a hypodermic stylet (a modified jaw) on the tip of an elongate proboscis.

for more ebook/ testbank/ solution manual request email 9601267344@qq.com

One of the most specialized feeding modes in gastropods is seen in the cone snails (*Conus*) and their relatives (Neogastropoda). Their **toxoglossate radula** is formed from a few harpoonlike, venom-injecting teeth that are modified marginal teeth. The teeth (Figure 13.25F) are discharged from the end of a long proboscis that can be extended very rapidly to capture prey, usually a fish, a worm, or another gastropod, which is then pulled into the gut (Figure 13.27). The venom is injected through the hollow, curved radular teeth by contraction of a venom gland. A few Indo–West Pacific cones produce a potent neuromuscular toxin that has caused human deaths.

Among the most unusual gastropod feeding strategies are those that involve parasitism on fishes. For example, the neogastropod *Cancellaria cooperi* attaches to the Pacific electric ray and makes small cuts in the skin, through which the proboscis is inserted to feed on the ray's blood and cellular fluids. Several other neogastropods parasitize "sleeping" reef fishes by inserting their proboscides into the hosts and sucking out fluids, while the nudibranch *Gymnodoris nigricolor* (Polyceridae) attaches to the fins of gobiids on which it feeds. Some other gastropods are known to parasitize various invertebrate hosts, notably the Pyramidellidae on a variety of invertebrates (including other molluscs), and the Eulimidae on echinoderms; the Eulimidae include some internal parasites that have lost their shells and become wormlike.

Certain euthyneurans also show various radular modifications. Groups of "opisthobranchs" that feed on cnidarians, bryozoans, and sponges, as well as those that scrape algae (e.g., aplysiids), usually have typical rasping radulae. In sacoglossans, however, the radula is modified as a single row of lancelike teeth that can pierce the cellulose wall of filamentous algae, allowing the gastropod to suck out the cell contents. A similar type of feeding strategy is also seen in the microscopic lower heterobranch *Omalogyra*.

Aeolid nudibranchs (Figure 13.7G) have a well-deserved reputation for their particular mode of feeding, in which portions of their cnidarian prey are held by the jaws while the radula rasps off pieces for ingestion. A similar mode of feeding has also been observed in the caenogastropod family Epitoniidae.

Many aeolid nudibranchs engage in a remarkable phenomenon called **kleptocnidism**. Some of the prey's nematocysts are ingested unfired, passed through the nudibranch's gut, and eventually transported to lobes of the digestive gland in dorsal fingerlike extensions called **cerata** (singular, ceras) (see Figure 13.32D,E). How the nematocysts undergo this transport without firing is still a mystery. Popular hypotheses are that mucous secretions by the nudibranch limit the discharge, or that a form of acclimation occurs (like that suspected to occur between anemone fishes and their host anemones), or perhaps that only immature nematocysts survive, to later undergo maturation in the dorsal cerata. It may also be that, once the cnidocytes are digested, the nematocysts' firing threshold is raised, thereby preventing discharge. In any case, once in the cerata, the nematocysts are stored in structures called cnidosacs and presumably help the nudibranch to fend off attackers. Discharge might even be under the control of the host nudibranch, perhaps by means of pressure exerted by circular muscle fibers around each cnidosac.

Some doridid nudibranchs also utilize their prey in remarkable ways. Many doridids secrete complex toxic compounds incorporated into mucus released from the mantle surface. These noxious chemicals act to deter potential predators. While some of these chemicals may be manufactured in some doridids, in most cases

FIGURE 13.27 Sequence of photographs of a cone snail (*Conus*) capturing and swallowing a small fish. The proboscis is extended and swept back and forth above the substratum in search of prey; when a fish is encountered, a poison-charged tooth of the toxoglossan radula is fired like a harpoon, and the prey is quickly paralyzed and ingested.

it appears that they are obtained from the sponges or bryozoans on which they feed. In some species, such as the "Spanish dancer" nudibranch (*Hexabranchus sanguineus*), the slug not only uses a chemical from its prey (in this case a sponge) for its own defense, but deposits some of the noxious chemical on its egg mass, helping to protect the embryos until they hatch.

In polyplacophorans there are generally 17 teeth in each transverse row of the radula (a central tooth flanked by eight on each side). Most chitons are herbivorous grazers. Notable exceptions are certain members of the order Chitonida (family Mopaliidae, e.g., *Mopalia*, *Placiphorella*), which are known to feed on both algae and small invertebrates. *Mopalia* consumes sessile invertebrates, such as barnacles, bryozoans, and hydroids. *Placiphorella* captures live microinvertebrates (particularly crustaceans) by trapping them beneath its head flap, a large anterior extension of the girdle (Figure 13.24C).

In monoplacophorans the radula consists of a ribbonlike membrane bearing a succession of transverse rows of 11 teeth each (a slender central tooth flanked on each side by 5 broader lateral teeth). Monoplacophorans are probably generalized deposit feeders that graze on minute organisms coating the substratum on which they live.

Cephalopods are predatory carnivores. Squid are some of the most voracious creatures in the sea, successfully competing with fishes. Octopuses are also active carnivores, preying primarily on crabs, bivalves, and gastropods. Some species of *Octopus* bore through the shells of molluscan prey in a fashion similar to that of gastropod drills. Some even drill and prey upon their close relatives, the chambered nautiluses. They do not use the radula to drill, but instead use a rasplike projection formed from the salivary papilla.

Using their impressive locomotor skills, most cephalopods hunt and catch active prey. Some octopuses, however, hunt "blindly," by tasting beneath stones with their highly sensitive suckers that are both mechano- and chemosensitive. In any event, once prey is captured and held by the arms, the cephalopod bites it with its horny beak (modified jaws) and injects a neurotoxin from modified salivary glands. This ability to quickly immobilize prey also helps prevent the soft-bodied cephalopod from being engaged in a potentially dangerous struggle.

Suspension feeding evolved in autobranch bivalves, and also several times in gastropods, and in most of these cases it involves modifications of the ctenidia that enabled the animal to trap particulate matter carried into the mantle cavity by the incoming respiratory water current. The lamellar nature of molluscan gills exapted them for extracting suspended food particles. Increasing the size of the gills and the degree of folding also increased the surface area available for trapping particulate material. In suspension feeders, at least some of the gill and mantle cilia, which otherwise serve to remove potentially clogging sediment from the mantle cavity (as pseudofeces), are preadapted to transport particulate matter from the gills to the mouth region.

While the collection of food on the gills has been adopted by autobranch bivalves and some groups of gastropods, other methods have also been employed. In the gill-less planktonic sea butterflies (pteropods), the ciliated "wings" or parapodia used for swimming (Figure 13.7D,E) also function as food-collecting surfaces or may cooperate with the mantle to produce large mucous sheets that capture small zooplankton. From the foot, ciliary currents carry mucus and food to the mouth. In some pteropods, the mucous sheet may be as large as 2 m across. Mucous sheet feeding is also employed by a few other gastropods, including the intertidal limpets Trimusculidae and the vermetids. Suspension-feeding gastropods include a few vetigastropods such as the sand-beach trochids (*Umbonium, Bankivia*), the hot-vent neomphalid (*Neomphalus*), some marine caenogastropods (Calyptraeidae, e.g., *Crepidula*; Vermetidae, e.g., *Vermetus*; Turritellidae, e.g., *Turritella*), and the freshwater Viviparidae (e.g., *Viviparus*). The ctenidial filaments in these filter feeders are much elongated, and the mantle waste rejection cilia have evolved into a food-collecting groove that runs to the mouth. The radula in suspension-feeding gastropods is somewhat reduced, serving mainly to pull mucus-bound food into the mouth. Some feed entirely by suspension feeding, others use browsing to supplement this method.

The wormlike shell of the vermetids is permanently affixed to the substratum, and while some adopt ciliary food collecting, others combine this with mucous net collecting or use the latter method exclusively. A special pedal gland in the reduced foot produces copious amounts of mucus that spreads into the water column as a sticky plankton trap. Periodically the net is hauled in by the foot and pedal tentacles, and a new one is quickly secreted. *Thylacodes arenarius*, a large Mediterranean vermetid, casts out individual threads up to 30 cm long, whereas the gregarious California species *Thylacodes squamigerus* forms a communal net shared by many individuals.

The radula apparently disappeared early in the course of bivalve evolution, and in living species there is no trace of this structure or even the buccal cavity that contained it. Most autobranch bivalves use their large ctenidia for suspension feeding, but the more primitive bivalves in the subclass Protobranchia are not suspension feeders but engage in a type of deposit-feeding microphagy. Protobranchs live in soft marine sediments and maintain contact with the overlying water either directly (e.g., *Nucula*) or by means of siphons (e.g., *Nuculana*, *Yoldia*). The two ctenidia are small, conforming to the primitive molluscan bipectinate plan of an elongated axis carrying a double row of lamellae (Figures 13.28A and 13.29). Protobranchs

feed by means of two pairs of large labial palps flanking the mouth. The two innermost palps are the short **labial palps**, and the two outermost palps are formed into tentacular processes called **proboscides** (each being called a **palp proboscis**), which can be extended beyond the shell (Figure 13.29). During feeding the proboscides are extended into the bottom sediments. Detrital material adheres to the mucus-covered surface of the proboscides and is then transported by cilia to the labial palps, which function as sorting devices. Low-density particles are carried to the mouth; heavy particles are carried to the palp margins and ejected into the mantle cavity.

In the suspension-feeding subclass Autobranchia, lateral cilia on the ctenidia generate a water current from which suspended particles are gleaned. Increased efficiency is achieved by various ctenidial modifications. The primary modification, seen in all living autobranch bivalves, has been the conversion of the original, small, triangular plates into V-shaped filaments with extensions on either side (Figures 13.28B and 13.30B). The arm of this V-shaped filament that is attached to the central axis of the ctenidium is called the descending arm; the arm forming the other half of the V is the ascending arm. The ascending arm is usually anchored distally by ciliary contacts or tissue junctions to the roof of the mantle, or to the visceral mass. Taken together, the two V-shaped filaments, with their double row of leaflets, form a W-shaped structure when seen in cross section.

Some pteriomorphian autobranch bivalves have **filibranch** ctenidia (e.g., mussels) wherein adjacent filaments are interlocked to one another by periodic clumps of specialized cilia, leaving long narrow slits in between (interfilament spaces) (Figure 13.30C,D). The spaces between the arms of the Ws are exhalant suprabranchial chambers, which merge with the exhalant area in the posterior mantle cavity to be discharged; the spaces ventral to the Ws are inhalant and communicate with the inhalant area of the mantle edge. Many other bivalves have **eulamellibranch** ctenidia, which are similar to the filibranch design but with neighboring filaments fused to one another by tissue junctions at numerous points along their length. This arrangement results in interfilament pores that are rows of ostia rather than the long narrow slits of filibranchs (Figure 13.30B,E,F). In addition, the ascending and descending halves of some filaments may be joined by tissue bridges that provide firmness and strength to the gill.

Both filibranch and eulamellibranch ctenidia are used to capture food. Water is driven from the inhalant to the exhalant parts of the mantle cavity by lateral cilia all along the sides of filaments in filibranchs, or by special lateral ostial cilia in eulamellibranchs (Figure 13.30E,F). As the water passes through the interfilament spaces, it flows through rows of frontolateral cilia, which flick particles from the water onto the surface of the filament facing into the current. These feeding cilia are called **compound cirri**; they have a pinnate structure that probably increases their catching ability. Mucus presumably plays some part in trapping the particles and keeping them close to the gill surface, although its precise role is uncertain. Bivalve ctenidia are not covered with a continuous sheet of mucus, as occurs in some other suspension-feeding invertebrates (e.g., certain gastropods, tunicates, amphioxus). Once on the filament surface, particles are moved by frontal cilia toward food groove on the free edges of the ctenidium, and then anteriorly to the labial palps. The palps sort the material by size and perhaps also by quality before passing the food to the mouth. Rejected particles fall off the gill or palp edges into the mantle cavity as **pseudofeces**. This "filtration" of water by bivalves is quite efficient. The American oyster (*Crassostrea virginica*), for example, can process up to 37 liters of water per hour (at 24°C) and can capture particles as small as 1 µm in size. Studies on the common mussels *Mytilus edulis* and *M. californianus* suggest that these bivalves maintain pumping rates of about 1 liter per hour per gram of (wet) body weight.

Members of the superfamily Tellinoidea (primarily Tellinidae and Semelidae) are deposit feeders, sucking up surface detritus with their long, mobile inhalant siphon (Figure 13.20G) and using the large labial palps to presort the particles before ingesting them.

Some members of the Anomalodesmata are known as septibranchs and are sessile predators, and unlike other autobranch bivalves, their gills are not used for feeding. Instead the ctenidia are very reduced and modified as a perforated but muscular septum that divides the mantle cavity into dorsal and ventral chambers (Figures 13.28C and 13.31A). The muscles are attached to the shell such that the septum can be raised or lowered within the mantle cavity. Raising the septum causes water to be sucked into the mantle cavity by way of the inhalant siphon; lowering the septum causes water to pass dorsally through the pores into the exhalant chamber. These movements also force hemolymph from mantle sinuses into the siphonal sinuses, thereby causing a rapid protrusion of the inhalant siphon, which can be directed toward potential prey (Figure 13.31B–D). In this fashion, small animals such as microcrustaceans are sucked into the mantle cavity, where they are grasped by muscular labial palps and thrust into the mouth; at the same time, the mantle tissue serves as the gas exchange surface.

While most pteriomorphians are restricted to epibenthic life, lacking siphons (Figure 13.21A,B), many heterodont bivalves live buried in soft sediments, where long siphons are utilized to maintain contact with the overlying water (Figures 13.8A and 13.20D–H).

Scaphopods consume foraminifera and other meiofaunal taxa, diatoms, zooplankton, and interstitial detritus. Two lobes flank the head, each bearing numerous (up to several hundred) long, slender tentacles called

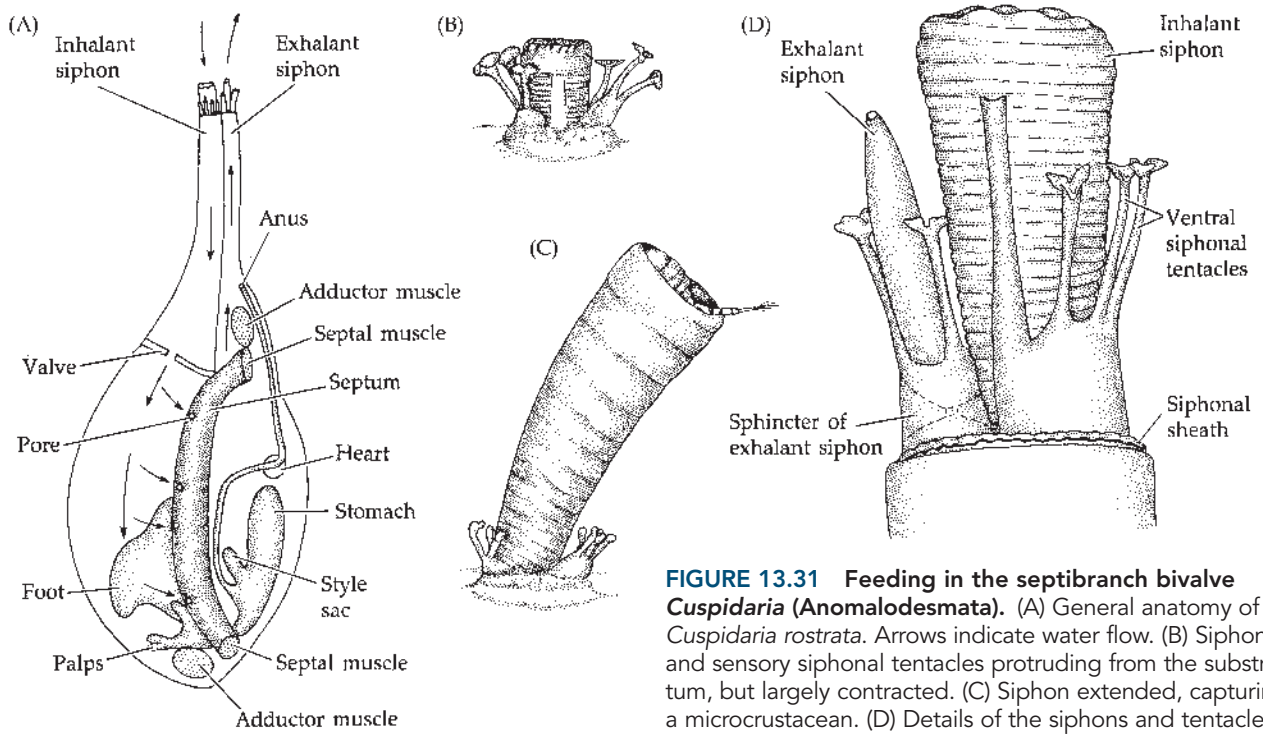

FIGURE 13.31 Feeding in the septibranch bivalve *Cuspidaria* (Anomalodesmata). (A) General anatomy of *Cuspidaria rostrata*. Arrows indicate water flow. captacula (Figures 13.9 and 13.13F). The captacula are extended into the substratum by metachronal beating of cilia on the small terminal bulb. Within the sediment organic particles and microorganisms adhere to the sticky terminal bulb; small food particles are transported to the mouth by way of ciliary tracts along the tentacles, while larger food items are transported directly to the mouth by muscular contraction of the captacula. A well-developed, large radula pulls the food into the mouth, perhaps partially macerating it in the process.

Several forms of symbiotic relationships intimately tied to the host's nutritional biology have evolved within molluscs. One of the most interesting of these relationships exists between many molluscs and sulfur-reducing and sulfur-oxidizing bacteria. These molluscs appear to derive a portion of their nutritional needs from bacteria, which usually reside on the host mollusc's gills. In some monoplacophorans (*Laevipilina antarctica*) and gastropods (*Lurifax vitreus*, *Hirtopelta*) the bacteria are housed in special cavities called bacteriocytes in the mantle cavity. This mollusc-bacteria symbiosis has been documented from a variety of sulfide-rich anoxic habitats, including deep-sea hydrothermal vents, where geothermally produced sulfide is present, and from other reduced sediments, where microbial degradation of organic matter leads to the reduction of sulfate to sulfide (e.g., anoxic marine basins, sea grass bed and mangrove swamp sediments, pulp mill effluent sites, sewage outfall areas).

Members of some bivalve families, in particular the Solemyidae, Nucinellidae, and Lucinidae, harbor sulfur-reducing bacteria in their enlarged gills that have the ability to directly oxidize sulfide. They do this by means of a special sulfide oxidase enzyme in the mitochondria. These bivalves inhabit reduced sediments where free sulfides are abundant. The ability to oxidize sulfide not only provides the bivalves with a source of energy to drive ATP synthesis, but also enables them to rid their body of toxic sulfide molecules that accumulate in such habitats. The nutrients obtained by this symbiosis are sufficient for the bivalve, so in solemyids the gut is reduced or, in a few species, absent.

Another notable partnership exists between giant clams (*Tridacna*) and their symbiotic zooxanthellae (the dinoflagellate *Symbiodinium*, which is now known to be composed of at least seven distinct clades). These clams live with their dorsal side against the substratum, and they expose their fleshy mantle to sunlight through the large shell gape. The mantle tissues harbor the zooxanthellae and have special lenslike structures that focus light on zooxanthellae living in the deeper tissues. A few other bivalves and certain sea slugs also maintain a symbiotic relationship with *Symbiodinium*. Among nudibranchs, several species of *Melibe, Pteraeolidia*, and *Berghia* harbor colonies of these dinoflagellates in "carrier cells" associated with their digestive glands. Experiments indicate that when sufficient light is available, host nudibranchs utilize photosynthetically fixed organic molecules produced by the alga to supplement their usual diet of prey. The dinoflagellates are probably not transmitted with the zygotes of the nudibranchs, each new generation thus requiring reinfection from the environment. A number of aeolid nudibranchs accumulate zooxanthellae from their cnidarian prey. Some of the dinoflagellates end up inside cells of the nudibranch's digestive gland, but many others are released in the slug's feces, from where they may reinfect cnidarians. An even more remarkable phenomenon occurs in some members of another group of sea slugs, the Sacoglossa (e.g., *Plakobranchus*). These sea slugs obtain functional chloroplasts from the green algae upon which they feed and incorporate them into their own tissues; the chloroplasts remain active for a period of time and produce photosynthetically fixed carbon molecules that are utilized by the hosts.

Still another unusual symbiosis occurs between an aerobic bacterium and the wood-boring marine shipworm bivalves (Teredinidae) (Figure 13.21D). Shipworms are capable of living on a diet of wood alone by harboring this cellulose-decomposing, nitrogen-fixing bacterium. The bivalve cultures the bacterium in a special organ associated with ctenidial blood vessels called the **gland of Deshayes**. The bacterium breaks down cellulose and makes its products available to its host. Nitrogen-fixing bacteria occur as part of the gut flora in many animals whose diet is rich in carbon but deficient in nitrogen (e.g., termites). However, shipworms are the only animals known to harbor a nitrogen fixer as a pure (single species) culture in a specialized organ (similar to the host nodule–*Rhizobium* symbiosis of leguminous plants).

In addition to these and a myriad of other feeding strategies of molluscs, some species (notably some bivalves, cephalopods, and sea slugs) probably obtain a substantial portion of their nutritional needs by direct uptake of dissolved organic material, such as amino acids, from seawater.

Digestion

Molluscs possess complete guts, a few of which are illustrated in Figure 13.32. The mouth leads inward to a buccal cavity, within which the radular apparatus and jaws (when present) are located (Figure 13.23). The esophagus is generally a straight tube connecting the foregut to the stomach. Various glands are often associated with this anterior gut region; some produce enzymes, and other glands, usually called salivary glands, secrete a lubricant over the radula. In many herbivorous species (e.g., certain eupulmonates, aplysiidans, and some cephalaspideans), a muscular **gizzard** (unrelated to the jaws) may be present for grinding up tough vegetable matter. The

gizzard may have chitinous, or even calcareous, plates or teeth. The stomach usually bears one or more ducts that lead to the large digestive gland (variously called the digestive diverticula, digestive caeca, midgut glands, liver, or other similar terms). Several sets of digestive glands may be present. The intestine leaves the stomach and terminates as the anus, which is typically located in the mantle cavity in or near the exhalant water flow.

Once food has entered the buccal cavity of most molluscs, it is carried in mucous strings into the esophagus and then to the stomach. In cephalopods and some predatory gastropods, chunks of food or whole prey are swallowed by muscular action of the esophagus. The food is stored in the stomach or in an expanded region of the esophagus called the "crop," as in octopuses and *Nautilus* and many gastropods. In many bivalves and gastropods, the stomach wall bears a chitinous **gastric shield** and a ciliated, ridged **sorting area** (Figure 13.33). The posterior stomach region (anterior in gastropods) is a **style sac**, which is lined with cilia and in autobranch bivalves and some gastropods contains a **crystalline style**. This structure, which functions to aid in digestion, is a rodlike matrix of proteins and enzymes (often amylase) that are slowly released as the projecting end of the style rotates and grinds against the gastric shield that protects the otherwise delicate stomach wall. The gastric cilia and rotating style wind up the mucus and food into a string and draw it along the esophagus to the stomach. The style is produced by special cells of the style sac. The style of some bivalves is enormous, one-third to one-half the length of the clam itself. Particulate matter is swept against the stomach's anterior sorting region, which sorts mainly by size. Small particles are carried into the digestive glands, which arise from the stomach wall. Larger particles are passed along ciliated grooves of the stomach to the intestine. In Protobranchia and in many gastropods, a crystalline

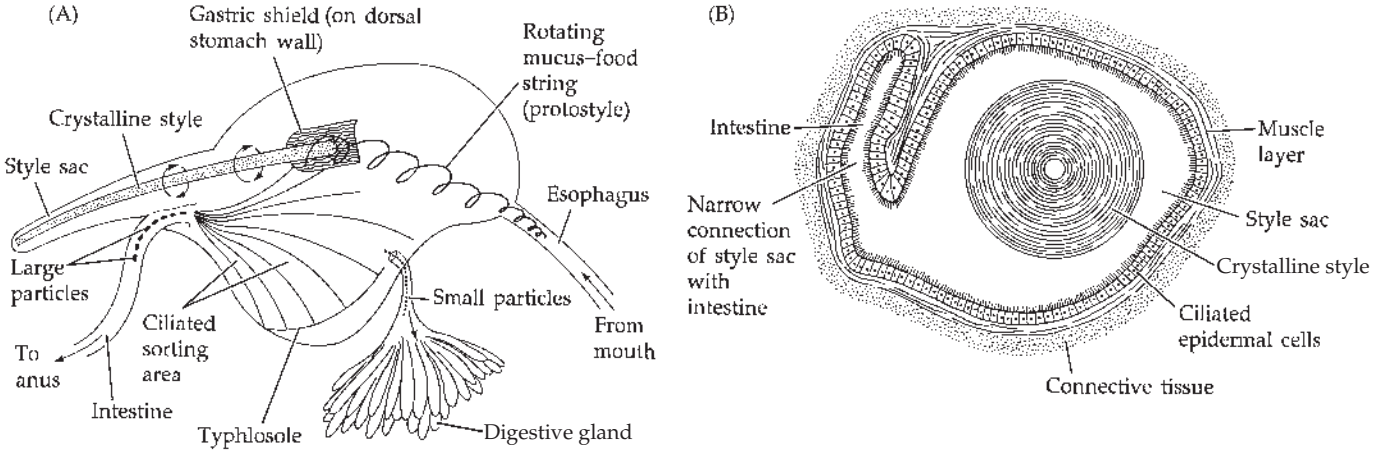

FIGURE 13.33 The molluscan stomach and style sac. (A) A generalized stomach and style apparatus of an autobranch bivalve. The crystalline style rotates against the gastric shield, releasing digestive enzymes and winding up the mucus-food string to assist in pulling it from the esophagus. Food particles are sorted in the ciliated, grooved sorting area: small particles are carried (in part by the typhlosole) to the digestive glands for digestion; large particles are carried to the intestine for eventual elimination. (B) A cross section of a style sac.

style is absent but there is often a style sac, which contains a rotating mass of mucus mixed with particles that is termed a **protostyle**.

Extracellular digestion takes place in the stomach and lumina of the digestive glands, while absorption and intracellular digestion occur in the digestive gland cells and the intestinal walls. Extracellular digestion is accomplished by enzymes produced in the foregut (e.g., salivary glands, esophageal pouches or glands, pharyngeal glands—sometimes called "sugar glands" because they produce amylase), the stomach, and the digestive glands. In primitive groups, intracellular digestion tends to predominate. In Solenogastres all digestive functions are accomplished in a uniform midgut lined by voluminous digestive and secretory cells. In most molluscs, ciliated tracts line the digestive glands and carry food particles to minute diverticula, where they are engulfed by phagocytic digestive cells of the duct wall. The same cells dump digestive wastes back into the ducts, to be carried by other ciliary tracts back to the stomach, from there to be passed out of the gut via the intestine and anus as fecal material. In most highly derived groups (e.g., cephalopods and many gastropods), extracellular digestion predominates. Enzymes secreted primarily by the digestive glands and stomach digest the food, and absorption occurs in the stomach, digestive glands, and intestine.

Circulation and Gas Exchange

Although molluscs are coelomate protostomes, the coelom is greatly reduced. The main body cavity is, in most species, an open circulatory space or hemocoel, which comprises several separate sinuses, and a network of vessels in the gills, where gas exchange takes place. The blood of molluscs contains various cells, including amebocytes, and is referred to as hemolymph. It is responsible for picking up the products of digestion from the sites of absorption and for delivering these nutrients throughout the body. It usually carries in solution the copper-containing respiratory pigment hemocyanin. Some molluscs use hemoglobin to bind oxygen, and many have myoglobin in the active muscle tissues, in particular those of the odontophore.

The heart lies dorsally within the **pericardial chamber** and includes a pair of atria (often called auricles) and a single ventricle. In monoplacophorans and in *Nautilus* there are two pairs of atria corresponding to two pairs of gills, while in many gastropods there is a single auricle (the left) that corresponds to the single gill. The atria receive the efferent branchial vessels, drawing oxygenated hemolymph from each ctenidium and passing it into the muscular ventricle, which pumps it anteriorly through a large anterior artery (the anterior or cephalic aorta). The anterior artery branches and eventually opens into various sinuses within which the tissues are bathed in oxygenated hemolymph. Return drainage through the sinuses eventually funnels the hemolymph back into the afferent branchial vessels. This basic pattern of molluscan circulation is shown diagrammatically in Figure 13.34, although it is modified to various degrees in different classes (Figure 13.35). In some cephalopods the circulatory system is secondarily closed (Figure 13.35C).

The majority of molluscs have ctenidia, but some have lost the ctenidia and rely either on secondarily derived gills or on gas exchange across the mantle or general body surface. In the primitive condition the ctenidium is built around a long, flattened axis projecting from the wall of the mantle cavity (Figure 13.30A). To each side of the axis are attached triangular or wedge-shaped filaments that alternate in position with filaments on the

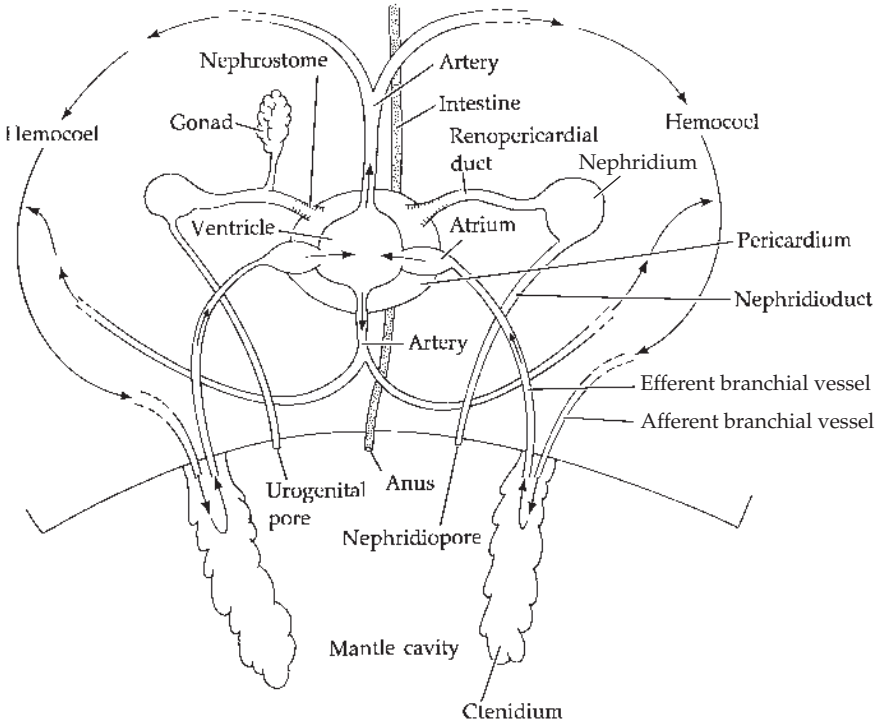

FIGURE 13.34 Hemolymph flow in a typical mollusc. Oxygenated hemolymph is pumped from the ventricle to the hemocoel, where it bathes the organs; eventually it drains into various channels and sinuses and then into the afferent branchial vessels, which enter the ctenidia. Oxygen is picked up in the ctenidia, and the hemolymph is then transported by the efferent branchial vessels to the left and right atria, through the ventricle, and then back to the hemocoel. Additional auxiliary pumping vessels occur in several taxa, particularly in active groups such as cephalopods.

opposite side of the axis. This arrangement, in which filaments project on both sides of the central axis, is called the **bipectinate condition**. There is one gill on each side of the mantle cavity, sometimes held in position by membranes that divide the mantle cavity into upper and lower chambers (Figure 13.28A,B). Lateral cilia on the gill draw water into the inhalant (ventral) chamber, from which it passes upward between the gill filaments to the exhalant (dorsal) chamber and then out of the mantle cavity (Figure 13.30A).

Two vessels run through each gill axis. The afferent vessel carries oxygen-depleted hemolymph into the gill, and the efferent vessel drains freshly oxygenated hemolymph from the gill to the atria of the heart, as noted above. Hemolymph flows through the filaments from the afferent to the efferent vessel. Ctenidial cilia move water over the gill filaments in a direction opposite to that of the flow of the underlying hemolymph in the branchial vessels. This countercurrent phenomenon enhances gas exchange between the hemolymph and water by maximizing the diffusion gradients of O_2 and CO_2 (Figure 13.30A). These presumed primitive bipectinate ctenidial gill conditions are expressed in several living groups, for example, in caudofoveates, chitons, protobranch bivalves, and some gastropods.

As a result of torsion, gastropods evolved novel ways to circulate water over the gills before it comes into contact with gut or nephridial discharges. Some vetigastropods with two bipectinate ctenidia may accomplish this by circulating water in across the gills, then past the anus and nephridiopore, and away from the body via slits or holes in the shell. This circulation pattern is used by the slit shells (Pleurotomariidae) and the minute Scissurellidae and Anatomidae (Figure 13.36), abalones (Haliotidae) (Figures 13.1D and 13.25A), and volcano (or keyhole) limpets (Fissurellidae) (Figure 13.16H,I). Some specialists regard the Pleurotomariidae as "living fossils" that reflect an early gastropod character state since gastropods bearing slits are found among early gastropod fossils. Most other gastropods have lost the right ctenidium and with it the right atrium; inhalant water enters on the left side of the head and then passes through the mantle cavity and straight out the right side, where the anus and nephridiopore open. Other gastropods have lost both ctenidia and utilize secondary respiratory regions—the mantle surface itself, expanded nephridial surfaces, or secondarily derived gills of one kind or another. Limpets of the genus *Patella* have rows of secondary gills in the mantle groove along each side of the body, superficially similar to the condition seen in chitons where multiple ctenidia are found.

In many gastropods one ctenidium is lost, e.g., in patellogastropods, some vetigastropods, and all neritimorphs and caenogastropods. In caenogastropods, the dorsal and ventral suspensory membranes seen in vetigastropod ctenidia are absent, and the gill is attached directly to the mantle wall by the gill axis. The gill filaments on the attached side have been lost, while those of the opposite side project freely into the mantle cavity. This arrangement of filaments on only one side of the central axis is referred to as the **monopectinate (or pectinobranch) condition** (Figure 13.14D). Some caenogastropods have evolved inhalant siphons by extension and rolling of the anterior mantle

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

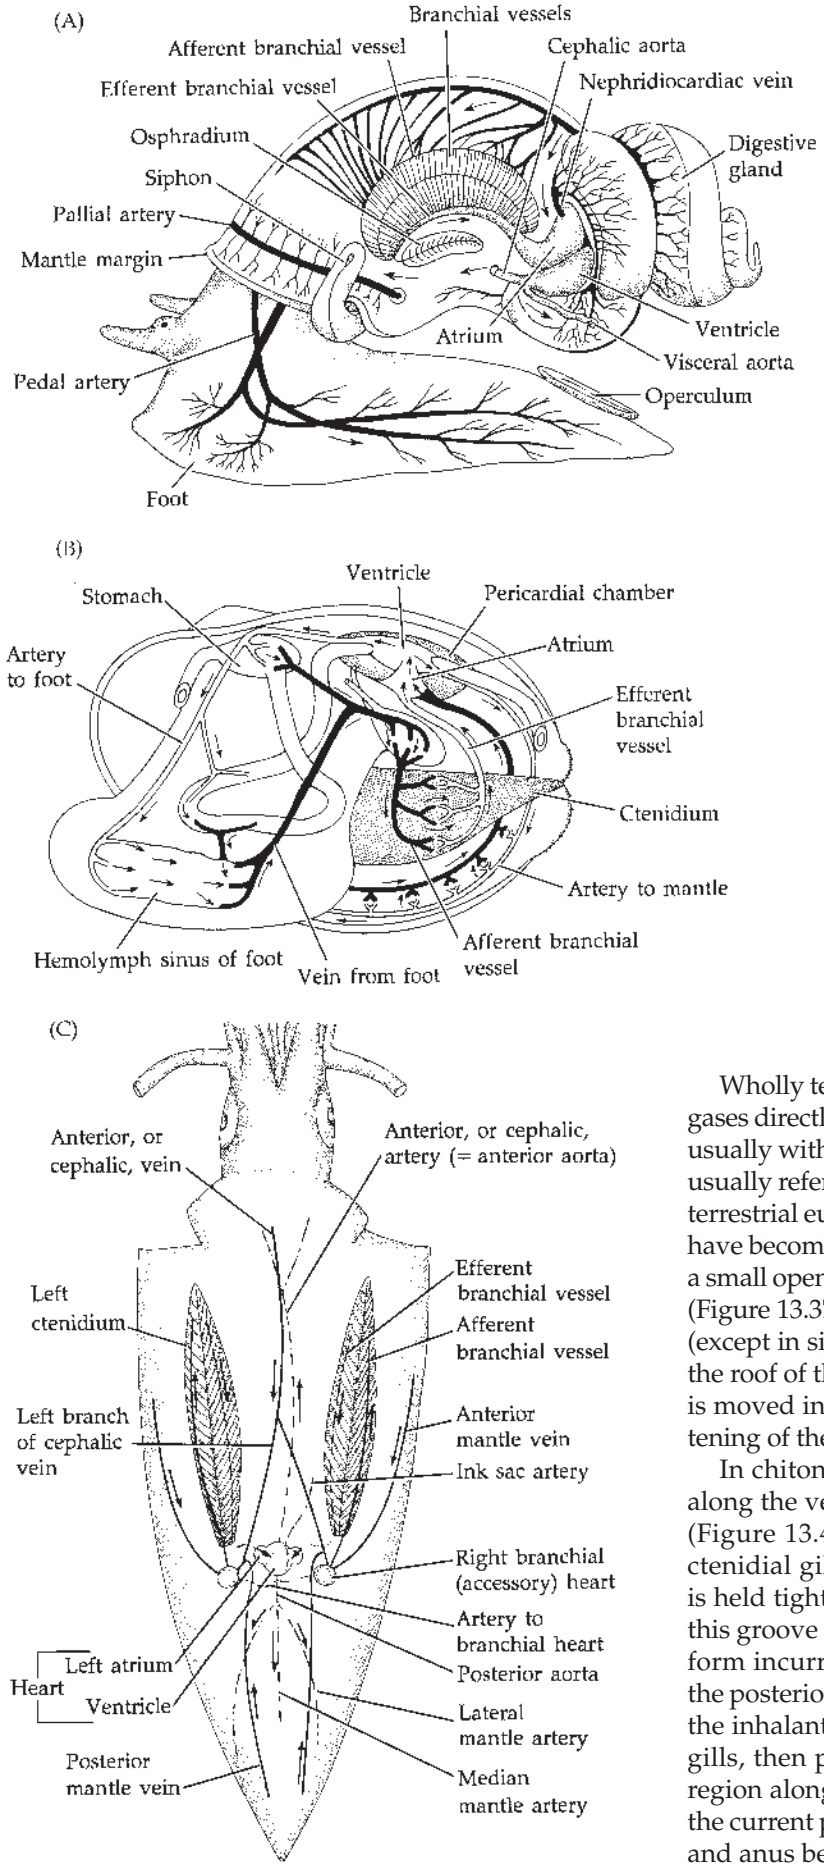

FIGURE 13.35 The circulatory system of three molluscs. (A) A neogastropod *Buccinum* (hemolymph sinuses not shown). (B) A eulamellibranch unionid bivalve (freshwater clam). (C) A squid, *Loligo*.

margin (Figures 13.1E and 13.40A). In these cases the margin of the shell may be notched or may be drawn out as a canal to house the siphon. The siphon provides access to surface water in burrowing species and may also function as a mobile, directional organ used in conjunction with the chemosensory osphradium.

All heterobranchs have lost the typical ctenidia, but some have a plicate, or folded, gill that is considered by some to be a reduced ctenidium and thought by others to be a secondary structure that has re-formed in much the same location as the original ctenidial gill. Trends toward detorsion, loss of the shell, and reduction of the mantle cavity occur in many heterobranchs, and the process has apparently occurred several times within this group. Some nudibranchs have evolved secondary dorsal gas exchange structures called **cerata** or, in others, secondary gills surrounding the anus (Figure 13.7F–J).

Wholly terrestrial gastropods lack gills and exchange gases directly across a vascularized region of the mantle, usually within the mantle cavity, the latter arrangement usually referred to as a **lung**. In marine, freshwater, and terrestrial eupulmonates, the edges of the mantle cavity have become sealed to the back of the animal except for a small opening on the right side called a **pneumostome** (Figure 13.37A) that is controlled by a sphincter muscle (except in siphonariid limpets). Instead of having gills, the roof of the mantle cavity is highly vascularized. Air is moved into and out of the lung by arching and flattening of the mantle cavity floor.

In chitons the mantle cavity is a groove extending along the ventral body margin and encircling the foot (Figure 13.4B). A large number of small bipectinate ctenidial gills lie laterally in this groove. The mantle is held tight against the substratum, largely enclosing this groove except on either side at the anterior end, to form incurrent channels, and in one or two places at the posterior end, to form excurrent areas. Water enters the inhalant region of the mantle groove lateral to the gills, then passes between the gills into the exhalant region along the sides of the foot. Moving posteriorly, the current passes over the gonopores, nephridiopores, and anus before exiting (Figure 13.4B).

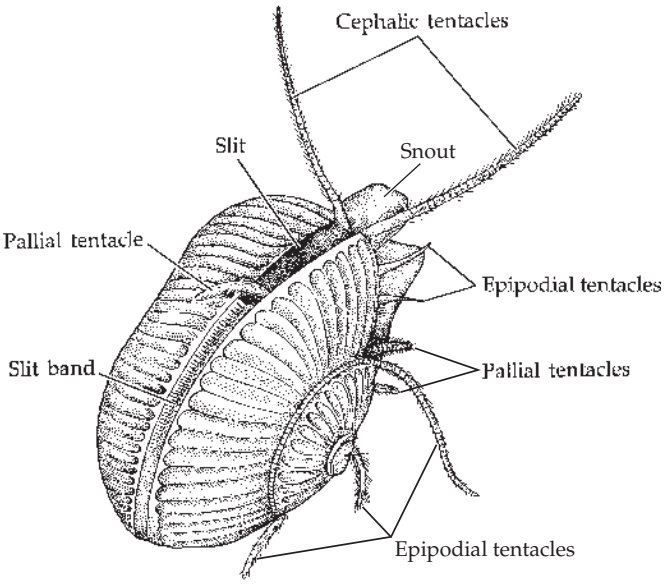

FIGURE 13.36 **The slit-bearing vetigastropod *Anatoma*.**

In bivalves the capacious mantle cavity allows the ctenidia to develop a greatly enlarged surface area, serving in most autobranch species for both gas exchange and feeding. Many of the morphological modifications of bivalve gills are described above. In addition to the folded, W-shaped ctenidial filaments seen in many bivalves (Figure 13.28B), some forms (e.g., oysters) have plicate ctenidia. A plicate ctenidium has vertical ridges or folds, each ridge consisting of several ordinary ctenidial filaments. So-called "principal filaments" lie in the grooves between these ridges, and their cilia are important in sorting particles from the ventilation and feeding currents. The plicate condition gives the ctenidium a corrugated appearance and further increases the surface area for feeding and gas exchange.

FIGURE 13.37 **Land snails and slugs (Heterobranchia: Eupulmonata).** (A) A terrestrial slug (*Arion lusitanicus*), showing the pneumostome that opens to the "lung" (Stylommatophora: Limacidae). (B) Terrestrial helicid snails (Stylommatophora: Helicidae) during summer dormancy in Sicily.

In spite of these modifications, the basic system of circulation and gas exchange in bivalves is similar to that seen in gastropods (Figure 13.35B). In most bivalves, the ventricle of the heart folds around the gut, so the pericardial cavity encloses not only the heart but also a short section of the digestive tract. The large mantle lines the interior of the valves and provides an additional surface area for gas exchange, which in some groups may be as important as the gills in this regard. For example, in lucinid bivalves where the ctenidial gills are packed with symbiotic bacteria, folds on the mantle act as a secondary gill, and in septibranchs, which have very reduced gills or lack them, the mantle surface is the principal area of gas exchange.

Most autobranch bivalves lack respiratory pigments in the hemolymph, although hemoglobin occurs in a few families and hemocyanin is found in protobranchs.

Scaphopods have lost the ctenidia, heart, and virtually all vessels. The circulatory system is reduced to simple hemolymph sinuses, and gas exchange takes place mainly across the mantle and body surface. A few ciliated ridges occur in the mantle cavity that may assist in maintaining water flow. A few tiny gastropods and at least one small monoplacophoran species lack a heart altogether.

No doubt associated with their large size and active lifestyle, cephalopods have a more developed circulatory system than other molluscs, and in the highly active decapodiforms (squid and cuttlefish) it is effectively closed, with many discrete vessels, secondary pumping structures, and capillaries (Figures 13.11C, 13.12B, and 13.35C). The result is increased pressure and efficiency of hemolymph flow and delivery. In most cephalopods, the pumping of blood into the ctenidia is assisted by muscular accessory branchial hearts, which boost the low venous pressure as the hemolymph enters the gills. The gills are not ciliated and their surface is highly folded, increasing their surface area for the greater gas exchange necessary to meet the demands of their high metabolic rate.

In the Solenogastres, gills are absent but the mantle cavity surface may be folded or form respiratory papillae. Caudofoveates have a single pair of bipectinate ctenidia in the mantle cavity. Monoplacophoran gills are well developed but weakly muscular and ciliated, with lamellae on only one side of the gill axis; they occur as three to six pairs, aligned bilaterally within the mantle groove. The gills of monoplacophorans are thought to be modified ctenidia that vibrate and ventilate the groove where gas exchange occurs.

Excretion and Osmoregulation

The basic excretory structures of adult molluscs are paired tubular metanephridia (often called kidneys or simply nephridia) that are primitively similar to those of annelids, but some larval forms have protonephridia. Typical nephridia are absent in aplacophorans. Three, six, or seven pairs of nephridia occur in monoplacophorans, two pairs in nautiloids, and a single pair in all other molluscs (although one is lost in all higher gastropods) (Figure 13.14). The nephrostome typically opens into the pericardial coelom via a renopericardial duct, and the nephridiopore discharges into the mantle cavity, often near the anus (Figures 13.14 and 13.34). The pericardial fluids ("primary urine") pass through the nephrostome and into the nephridium, where selective resorption occurs along the tubule wall until the final urine is ready to pass out the nephridiopore. The pericardial sac and heart wall act as selective barriers between the open nephrostome and the hemolymph in the surrounding hemocoel and in the heart. Mollusc nephridia are rather large and saclike, and their walls are often greatly folded. In many species, afferent and efferent nephridial vessels carry hemolymph to and from the nephridial tissues (Figure 13.38). Sometimes a bladder is present just before the nephridiopore, or a ureter may form a duct to carry urine well beyond the nephridiopore.

In many molluscs urine formation involves pressure filtration, active secretion, and active resorption. Aquatic molluscs excrete mostly ammonia, and most marine species are osmoconformers. In freshwater species the nephridia are capable of excreting a hyposmotic urine by resorbing salts and by passing large quantities of water. Terrestrial gastropods conserve water by converting ammonia to uric acid. Land snails are capable of surviving a considerable loss of body water, which is brought on in large part by evaporation and the production of the metabolically expensive slime trail. They often absorb water from the urine in the ureter. In many gastropods (e.g., neritimorphs, caenogastropods, and heterobranchs), torsion is accompanied by loss of the adult right nephridium; in neritimorphs and caenogastropods, a small remnant contributes to part of the gonoduct. Some gastropods have lost the direct connection of the nephrostome to the pericardial coelom. In such cases the nephridium is often very glandular and served by afferent and efferent hemolymph vessels, and wastes are removed from the circulatory fluid.

In bivalves, the two nephridia are located beneath the pericardial cavity and are folded in a long U shape. In autobranch bivalves, one arm of the U is glandular and opens into the pericardial cavity; the other arm often forms a bladder and opens through a nephridiopore in the suprabranchial cavity. In protobranchs, the unfolded walls of the tube are glandular throughout. The nephridiopores may be separate from or joined with the ducts of the reproductive system. In the latter case, the openings are called urogenital pores.

In patellogastropods, vetigastropods, and some other molluscs, the gonoduct fuses with the renopericardial canal, and the nephridiopore functions as a

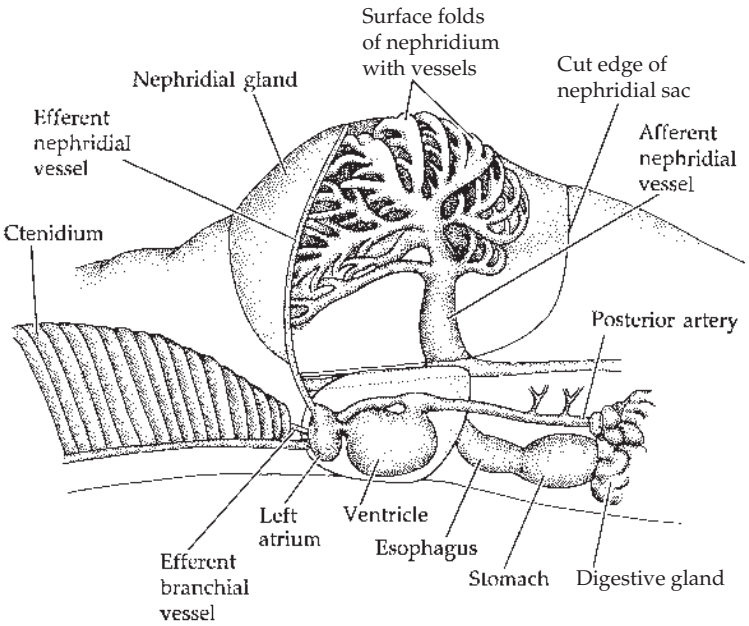

FIGURE 13.38 The nephridium and nearby organs of *Littorina* (cutaway view). The nephridial sac has been slit open.

urogenital pore discharging both excretory wastes and gametes. In some cases, as in one monoplacophoran, a few bivalves, and some vetigastropods, the urogenital pore may become glandular. In many bivalves and chitons the nephridium and gonad have separate ducts.

In monoplacophorans and chitons, the nephridia open into the exhalant regions of the mantle grooves; in scaphopods, the paired nephridia open near the anus. In most gastropods the nephridiopores open directly into the mantle cavity, but in some, such as stylommatophoran eupulmonates, there is an elongate ureter that in some opens outside the enclosed lung (mantle cavity).

Cephalopods retain the basic nephridial plan, in which the nephridia drain the pericardial coelom by way of renopericardial canals and empty via nephridiopores into the mantle cavity. However, the nephridia bear enlarged regions called **renal sacs**. Before reaching the branchial heart, a large vein passes through the renal sac, wherein numerous thin-walled evaginations, called **renal appendages**, project off the vein. As the branchial heart beats, hemolymph is drawn through the renal appendages, and wastes are filtered across their thin walls into the nephridia. The overall result is an increase in excretory efficiency over the simpler arrangement present in other molluscs.

The fluid-filled nephridia of cephalopods are inhabited by a variety of commensals and parasites. The epithelium of the convoluted renal appendages provides an excellent surface for attachment, and the renal pores provide a simple exit to the exterior. Symbionts identified from cephalopod nephridia include viruses, fungi, ciliate protists, dicyemids (all the members of this phylum live exclusively in the renal sac of benthic cephalopods—see Chapter 10), trematodes, larval cestodes, and juvenile nematodes.

Nervous System

The molluscan nervous system is derived from the basic protostome plan of an anterior circumenteric arrangement of ganglia and paired ventral nerve cords. In molluscs, the more ventral and medial of the two pairs of nerve cords are called the **pedal cords** (or ventral cords); they innervate the muscles of the foot. The more lateral pair of nerves are the **visceral cords** (or lateral cords); they serve the mantle and viscera. Transverse commissures interconnect these longitudinal nerve cord pairs, creating a ladderlike nervous system. This basic plan is seen in the aplacophorans and polyplacophorans (Figure 13.39). The molluscan nervous system lacks any trace of segmentally arranged ganglia.

In aplacophorans, monoplacophorans, and polyplacophorans, ganglia are poorly developed (Figure 13.39). A simple nerve ring surrounds the anterior gut, often with small cerebral ganglia on either side. Each cerebral ganglion, or the nerve ring itself, issues small nerves to the buccal region and gives rise to the pedal and the visceral nerve cords. Most other molluscs have more well-defined ganglia. Their nervous system is built around three pairs of large ganglia that interconnect to form a partial or complete nerve ring around the gut (Figures 13.40 and 13.41). Two pairs, the cerebral and pleural ganglia, lie dorsal or lateral to the esophagus, and one pair, the pedal ganglia, lies ventral to the gut, in the anterior part of the foot. In cephalopods, bivalves, and some neogastropods and heterobranch gastropods, the cerebral and pleural ganglia are often fused. From the cerebral ganglia, peripheral nerves innervate, when present, the tentacles, eyes, statocysts, and general head surface, as well as buccal ganglia, with special centers of control for the buccal region, radular apparatus, and esophagus. The pleural

ganglia give rise to the visceral cords, which extend posteriorly, supplying peripheral nerves to the viscera and mantle. The visceral cords eventually join a pair of esophageal (= intestinal, = pallial) ganglia and from there continue to terminate in paired visceral ganglia. The esophageal ganglia or associated nerves innervate the gills and osphradium, and the visceral ganglia serve organs in the visceral mass. The pedal ganglia also give rise to a pair of pedal nerve cords that extend posteriorly and provide nerves to muscles of the foot.

As described previously, due to torsion, the posterior portion of the gastropod nervous system is twisted into a figure eight, the condition known as **streptoneury** (Figure 13.40). In addition to twisting the nervous system, torsion brings the posterior ganglia forward. In many advanced gastropods this

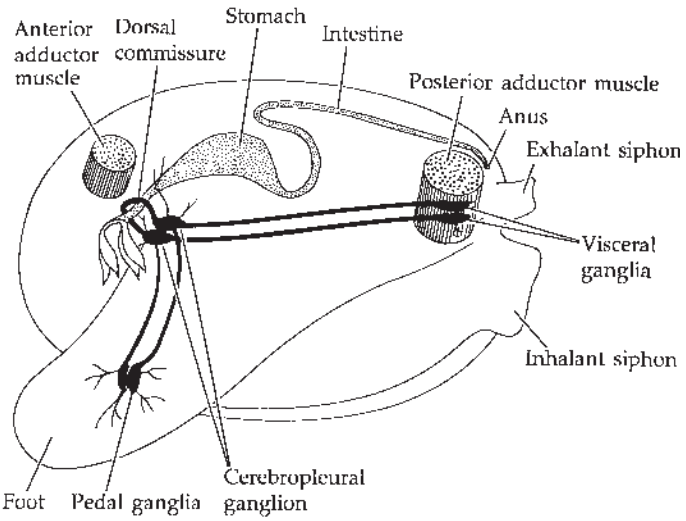

FIGURE 13.41 The reduced and concentrated nervous system of a typical autobranch bivalve.

anterior concentration of the nervous system is accompanied by a shortening of some nerve cords and fusion of ganglia. In most detorted gastropods the nervous system displays a secondarily derived bilateral symmetry and more or less untwisted visceral nerve cords—the condition known as **euthyneury** (Figure 13.40).

In bivalves, the nervous system is clearly bilaterally symmetrical, and fusion has usually reduced it to three large, distinct pairs of ganglia. Anterior cerebropleural ganglia give rise to two pairs of nerve cords, one extending posterodorsally to the visceral ganglia, the other leading ventrally to the pedal ganglia (Figure 13.41). The two cerebropleural ganglia are joined by a dorsal commissure over the esophagus. The cerebropleural ganglia send nerves to the palps, anterior adductor muscle, and mantle. The visceral ganglia issue nerves to the gut, heart, gills, mantle, siphon, and posterior adductor muscle.

The degree of nervous system development within the Cephalopoda is unequaled among invertebrates. The paired ganglia seen in other molluscs are not recognizable in cephalopods, where extreme cephalization has concentrated ganglia into lobes of a large brain encircling the anterior gut (Figure 13.42A). In addition to the usual head nerves originating from the dorsal part of the brain (more or less equivalent to the cerebral ganglia), a large optic nerve extends to each eye via a massive optic lobe. In most cephalopods, much of the brain is enclosed in a cartilaginous cranium. The pedal lobes supply nerves to the funnel, and anterior divisions of the pedal ganglia (called brachial lobes) send nerves to each of the arms and tentacles, an arrangement suggesting that the funnel and tentacles are derived from the molluscan foot. Octopuses may be the "smartest" living invertebrates, for they can quickly learn complex memory-dependent tasks. Squid and cuttlefish (Decabrachia) have a rapid escape behavior that depends on a system of giant motor fibers that control powerful and synchronous contractions of the mantle muscles. The command center of this system is a pair of very large first-order giant neurons in the lobe of the fused visceral ganglia. Here, connections are made to second-order giant neurons that extend to a pair of large stellate ganglia. At the stellate ganglia, connections are made with third-order giant neurons that innervate the circular muscle fibers of the mantle (Figure 13.42D). Other nerves extend posteriorly from the brain and terminate in various ganglia that innervate the viscera and structures in the mantle cavity.

For several decades neurobiologists have utilized the giant axons of loliginid squid as an experimental system for the study of nerve physiology and mechanics, and much of our fundamental knowledge of how nerve cells work is based on squid neurobiology. The sea hare *Aplysia* and some eupulmonate snails have also been used in the same fashion, and although they lack giant axons, they possess exceptionally large neurons and ganglia that can be easily impaled with microelectrodes to discover the physiological secrets of such systems.

Sense Organs

With the exception of aplacophorans, molluscs possess various combinations of sensory tentacles, photoreceptors, statocysts, and osphradia. **Osphradia** are patches of sensory epithelium, located on or near the base of the gills or on the mantle wall (Figures 13.40B and 13.43A,B). They are chemoreceptors, and their cilia can also assist in mantle cavity ventilation in some caenogastropods. Little is known about the biology of osphradia, and their morphology and histology differ markedly within the phylum and even within some classes such as the gastropods.

In vetigastropods, a small osphradium is present on the base of each gill; in those gastropods that possess one gill, there is only one osphradium, and it lies on the mantle cavity wall anterior and ventral to the attachment of the gill itself. Osphradia are reduced or absent in gastropods that have lost ctenidial gills, that possess a highly reduced mantle cavity, or that have taken up a strictly pelagic existence. Osphradia are best developed in benthic predatory and scavenging neogastropods and some other caenogastropods.

Most gastropods have one pair of sensory cephalic tentacles, but eupulmonates and many sea slugs possess two pairs. Many vetigastropods also have epipodial tentacles on the margin of the foot or mantle, and epipodial sense organs may also be present on the margin of the foot (Figure 13.5A,C). The cephalic tentacles may bear eyes as well as tactile and chemoreceptor cells. Many nudibranchs have a pair of branching or folded anterior dorsal chemoreceptors called **rhinophores** (Figure 13.7F,G) that are modified cephalic tentacles.

The patellogastropod limpets have simple pigment-cup eyes, while the remaining gastropods have more complex eyes with a lens and often a cornea (Figure 13.44A,B,D). Most gastropods have a small eye at the base of each cephalic tentacle, but in some, such as the conch *Strombus* and some neogastropods, the eyes are enlarged and elevated on long stalks. The stylommatophoran and systellommatophoran pulmonates have eyes placed on the tips of optic tentacles and, in stylommatophorans, these tentacles are also olfactory organs.

Gastropods typically produce a mucopolysaccharide slime trail as they crawl. In many species the trail contains chemical messengers that other members of the species "read" by means of their excellent chemoreception. These chemical messengers may be simple trail markers, so one animal can follow or locate another, or they may be alarm substances that serve to warn others of possible danger on the path ahead. For example, when the carnivorous cephalaspidean sea slug *Navanax*

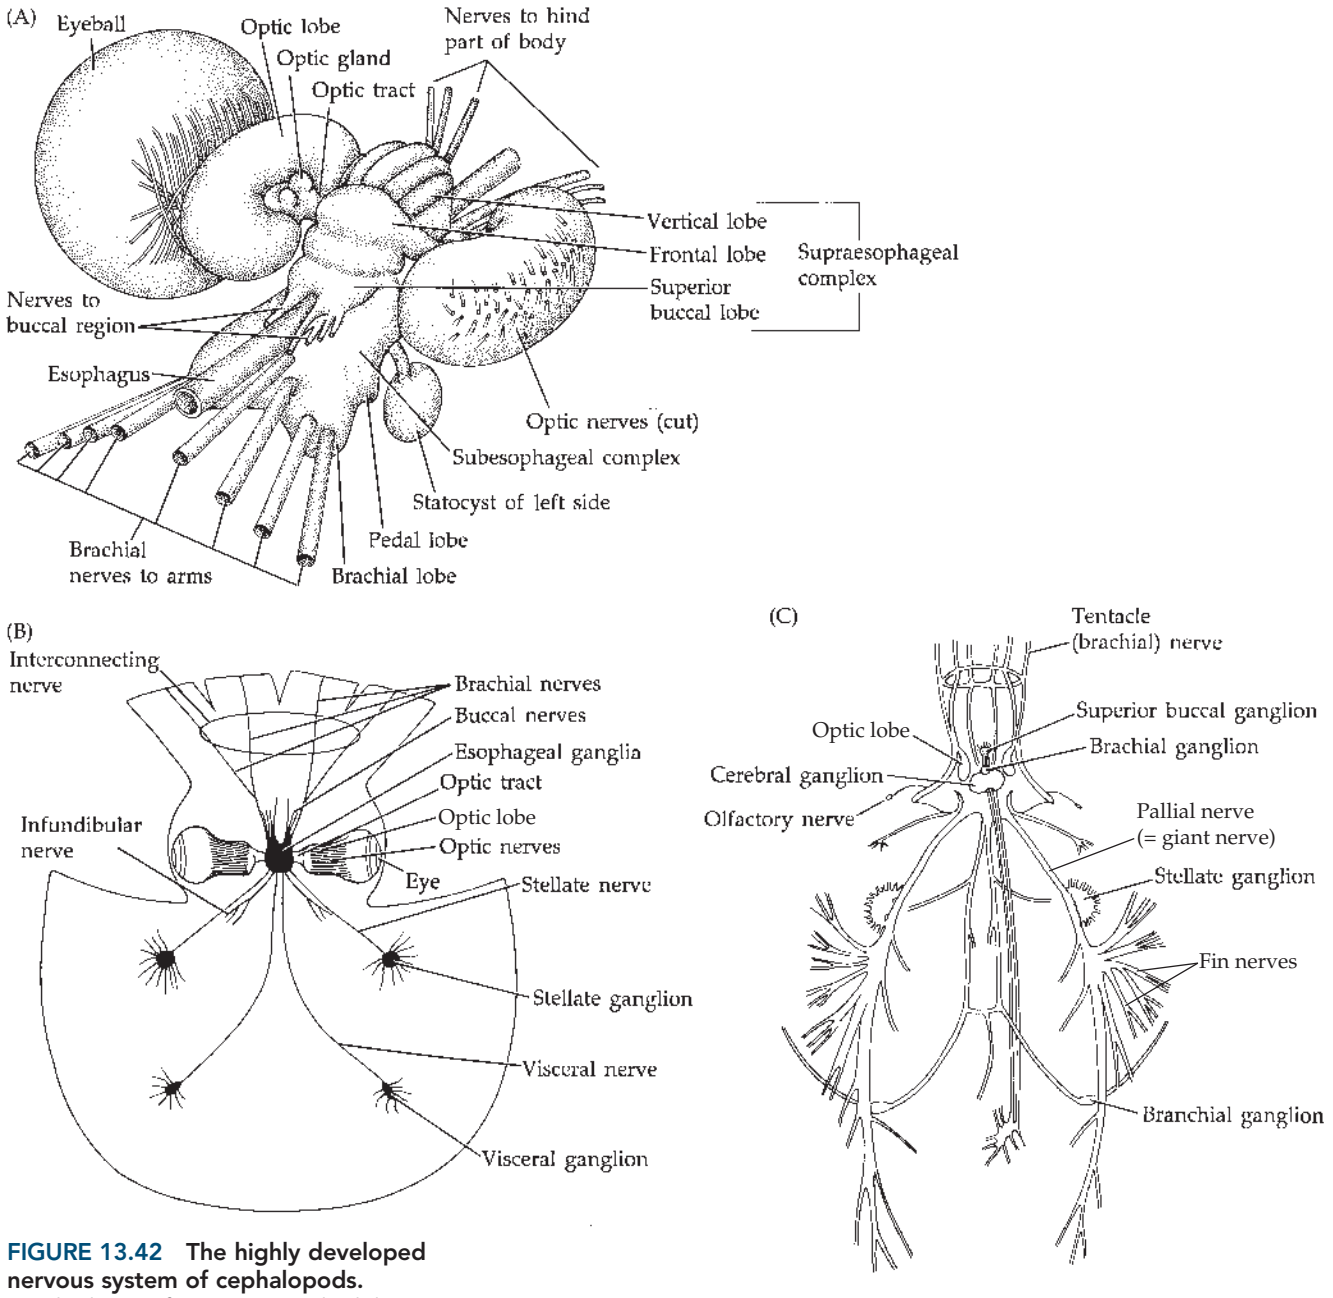

FIGURE 13.42 The highly developed nervous system of cephalopods.
(A) The brain of an octopus. The lobes of the supraesophageal complex approximately correspond to the cerebral and buccal ganglia of other molluscs, while the subesophageal complex comprises the fused pedal and pleurovisceral ganglia. About 15 structurally and functionally distinct pairs of lobes have been identified in the brain of octopuses. (B) Nervous system of an octopus. (C) Nervous system of a squid (*Loligo*). (D) Giant fiber system of a squid. Note that the first-order giant neurons possess an unusual cross connection and that the third-order giant neurons are arranged so that motor impulses can reach all parts of the mantle-wall musculature simultaneously (because impulses travel faster in thicker axons).

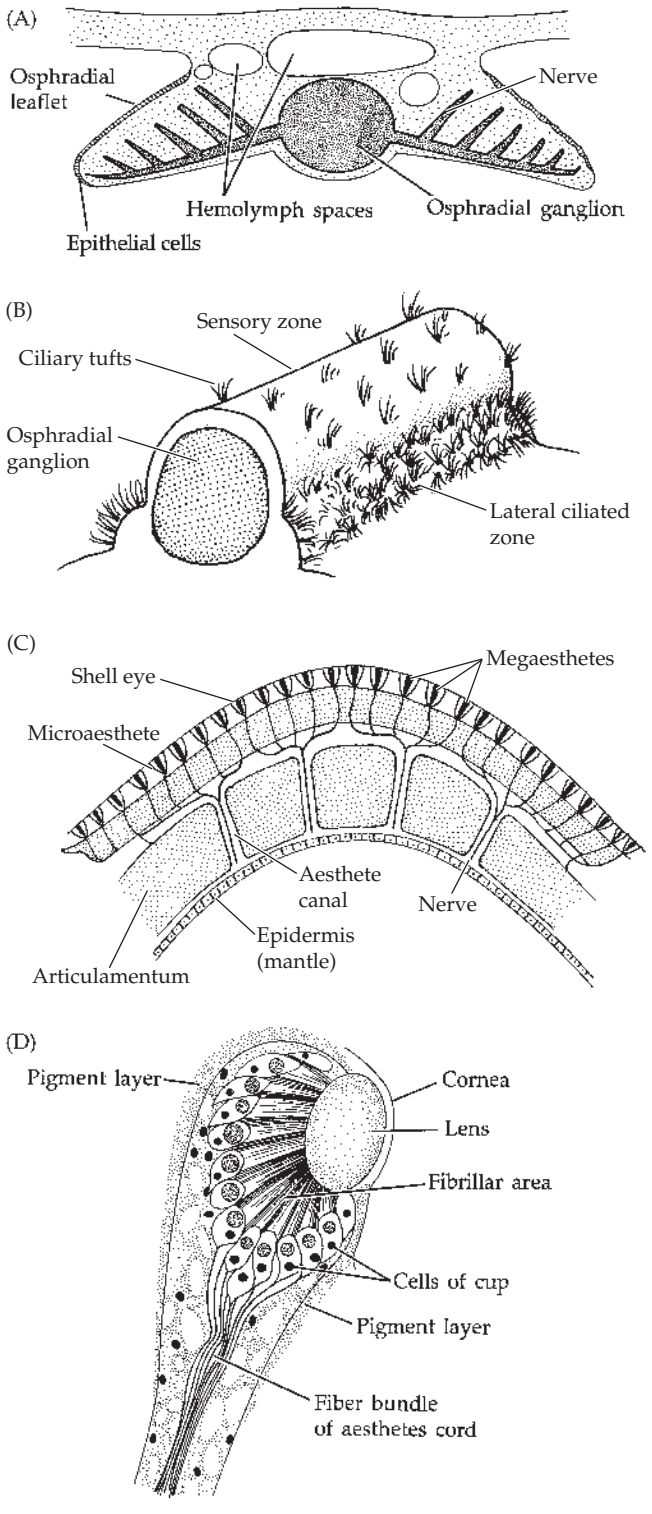

FIGURE 13.43 Two sensory organs of molluscs: osphradia and aesthetes. (A) Cross section of a bipectinate osphradium of the caenogastropod *Ranella* showing two leaflets. (B) Part of the osphradium of a littorinimorph caenogastropod such as *Littorina*. (C) One valve of a polyplacophoran (*Tonicia*). is attacked by a predator, it quickly releases a yellow chemical mixture on its trail that causes other members of the species to abort their trail-following activity. Laboratory experiments have shown that at least one nudibranch (*Tritonia tetraquetra*) possesses geomagnetic orientation to the Earth's magnetic field.

Motile gastropods usually possess a pair of closed statocysts near the pedal ganglia in the anterior region of the foot that contain either a single large **statolith** or several **statoconia** (much smaller particles).

Scaphopods lack the eyes, tentacles, and osphradia typical of the epibenthic and motile molluscan groups. The captacula may function as tactile (as well as feeding) structures. Sense organs are found on the anterior mantle edge surrounding the ventral aperture and at the dorsal water intake opening.

Bivalves have most of their sensory organs along the middle lobe of the mantle edge where they are in contact with the external environment (Figure 13.15C). These receptors may include mantle tentacles, which can contain both tactile and chemoreceptor cells. Such tentacles are commonly restricted to the siphonal areas, but in some swimming clams (e.g., *Lima*, *Pecten*) they may line the entire mantle margin. Paired statocysts usually occur in the foot near the pedal ganglia and are of particular importance in georeception by burrowing bivalves. Mantle eyes may also be present along the mantle edge or on the siphons and have evolved independently in a number of bivalve groups. In spiny oysters (*Spondylus)* and pectinid scallops, these eyes are "mirror eyes" with a reflective layer (the **tapeum**) behind paired retinas. This layer reflects light back into the eye, giving these bivalves a separate focal image on each retina—one from the lens and the other from the mirror (Figure 13.44C). The bivalve osphradium lies in the exhalant chamber, beneath the posterior adductor muscle.

Chitons lack statocysts, cephalic eyes, and tentacles. Instead, they rely largely on three special sensory structures. These are the anterior **Schwabe organs** in lepidopleuridan chitons, the **adanal sensory structures** in the posterior portion of the mantle cavity, and the **aesthetes**, which are a specialized system of photoreceptors unique to the class Polyplacophora. Aesthetes typically occur in high numbers across the dorsal surface of the shell plates. They are mantle cells that extend into the minute vertical canals (megapores and micropores) in the upper tegmentum of the shell (Figure 13.43C,D). The canals and sensory endings terminate beneath a cap on the shell surface. Little is known about the functioning of aesthetes, although the megaesthetes are known to mediate light-regulated behavior. In some (e.g., Chitonidae), they may be modified as simple lensed image-forming eyes; the lenses are made of aragonite, the same mineral that makes up chiton

for more ebook/ testbank/ solution manual request email 960126734@qq.com

shells. The outer mantle surface of the girdle of many chitons is liberally supplied with tactile and photoreceptor cells (Figure 13.43D).

Like the rest of their nervous systems, the sense organs of cephalopods are highly developed. The eyes are superficially similar to those of vertebrates (Figure 13.44E), and these two types of eyes are often cited as a classic example of convergent evolution. The eye of a coleoid cephalopod such as *Octopus* sits in a socket associated with the cartilaginous cranium. The cornea, iris, and lens arrangement is much like that of vertebrate eyes. Also, as in vertebrates, the lens is suspended by ciliary muscles, but it has a fixed shape and focal length. An iris diaphragm controls the amount of light entering the eye, and the pupil is a horizontal slit. The

retina comprises closely packed, long, rodlike photoreceptors whose sensory ends point toward the front of the eye; hence the cephalopod retina is of the direct type rather than the indirect type seen in vertebrates. The rods connect to retinal cells that supply fibers to the large optic ganglia at the distal ends of the optic nerves. Unlike the corneas of vertebrates, the coleoid cornea probably contributes little to focusing, because there is almost no light refraction at the corneal surface. The coleoid eye accommodates to varying light conditions by changes in the size of the pupil and by migration of the retinal pigment. Coleoid eyes form distinct images (although octopuses are probably quite nearsighted), and experimental work suggests that they do not see colors other than as different shades of gray, although they can detect polarized light. In addition, coleoids can discriminate among objects by size, shape, and vertical versus horizontal orientation. The eyes of *Nautilus* are rather primitive relative to the eyes of coleoids. They lack a lens and are open to the water through the pupil. They are thought to function in the same way that a pinhole camera does.

Coleoids have complex statocysts that provide information on static body position and on body motion. Those of *Nautilus* are relatively simple. In addition, the arms of coleoids are well supplied with chemosensory and tactile cells, especially on the suckers of benthic octopuses, which have extremely good chemical and textural discrimination capabilities. Nautilidae are the only cephalopods with osphradia.

Cephalopod Coloration and Ink

Coleoid cephalopods are noted for their striking pigmentation and dramatic color displays. In nature, their highly dynamic skin coloration (and texture) changes, to allow rapid camouflage and intraspecies communication. The integument contains many pigment cells, or chromatophores, most of which are under nervous control. Such chromatophores can be rapidly expanded or contracted individually by means of tiny muscles attached to the periphery of each cell. Contraction of these muscles pulls out the cell and its internal pigment into a flat plate, thereby displaying the color; relaxation of the muscles causes the cell and pigment to concentrate into a tiny, inconspicuous dot. Because these chromatophores are displayed or concealed by muscle action, their activity is extremely rapid, and coleoid cephalopods can change color (and pattern) almost instantaneously. Chromatophore pigments are of several colors—black, yellow, orange, red, and blue. The chromatophore color may be enhanced by deeper layers of iridocytes that both reflect and refract light in a prismatic fashion. Some species of cuttlefish and many octopuses are capable of closely mimicking their background coloration (Figure 13.12E) as well as producing vivid contrasting colors (Figure 13.12F,G). Many epipelagic squid show a dark-above, light-below countershading similar to that seen in pelagic fishes. Most coleoids also undergo color changes in relation to behavioral rituals, such as courtship and aggression. In octopuses, many color changes are accompanied by modifications in the surface texture of the body, mediated by muscles beneath the skin—something like elaborate, controlled "gooseflesh."

In addition to the color patterns formed by chromatophores, some coleoids are bioluminescent. When present, the light organs, or photophores, are arranged in various patterns on the body, and in some cases they even occur on the eyeball. The luminescence is sometimes produced by symbiotic bacteria, but in other cases it is autogenic. The photophores of some species have a complex reflector and focusing-lens arrangement, and some even have an overlying color filter or chromatophore shutter to control the color or flashing pattern. Most luminescent species are deep-sea forms, and little is known about the role of light production in their lives. Some shallow-water sepiolids appear to use the photophores to create countershading, so as to appear less visible to predators (and prey) from below and above. Others living below the photic zone may use their glowing or flashing patterns as a means of communication, the signals serving to keep animals together in schools or to attract prey. The flashing may also play a role in mate attraction and in avoiding predation. The fire squid, *Lycoteuthis*, can produce several colors of light: white, blue, yellow, and pink. The members of at least one genus of squid, *Heteroteuthis*, secrete a luminescent ink. The light comes from luminescent bacteria cultured in a small gland near the ink sac, from which ink and bacteria are ejected simultaneously.

In most coleoid cephalopods, a large ink sac is located near the intestine (Figure 13.32H). An ink-producing gland lies in the wall of the sac, and a duct runs from the sac to a pore into the rectum. The gland secretes a brown or black fluid that contains a high concentration of melanin pigment and mucus; the fluid is stored in the ink sac. When alarmed, the animal releases the ink through the anus and mantle cavity and out into the surrounding water. The cloud of inky material hangs together in the water, forming a "dummy" image that serves to confuse predators. It may also serve as an "ink screen" obscuring the squid or its bioluminescence trail in the deep sea. The alkaloid nature of the ink may also act to deter predators, particularly fishes, and may interfere with their chemoreception.

Like virtually all other aspects of coleoid biology, the abilities to change color and to defend against predators are part and parcel of their active hunting lifestyles. In the course of their evolution, coleoid cephalopods abandoned the protection of an external shell, becoming more efficient swimmers but also exposing their fleshy bodies to predators. The evolution of camouflage and ink production, coupled with

for more ebook/ testbank/ solutionmanual request email 9601267344@qq.com

high mobility and complex behavior, played a major role in the success of these animals in their radical modification of the basic molluscan body plan.

Reproduction

Primitively, molluscs are mostly gonochoristic, with a pair of gonads that discharge their gametes to the water, either through the nephridial plumbing or through separate ducts. In these free-spawnning species, fertilization is external and development is indirect. Many molluscs with separate gonoducts that store and transport the gametes also have various means of internal fertilization. In these forms, direct and mixed life history patterns have evolved.

Caudofoveata are gonochoristic, and Solenogastres are hermaphroditic (Figure 13.45). In both aplacophoran groups the paired gonads discharge gametes by way of short gonopericardial ducts into the pericardial chamber, from which they pass through gametoducts to the mantle cavity. In the Solengastres fertilization is internal and the young are sometimes brooded, while in the Caudofoveata the gametes are discharged into the surrounding seawater, where fertilization occurs.

Monoplacophorans possess two pairs of gonads, each with a gonoduct connected to a nephridium (Figures 13.3D and 13.14E). One tiny monoplacophoran species, *Micropilina arntzi,* is a hermaphrodite and broods its embryos in its mantle cavity.

Most chitons are gonochoristic, although a few hermaphroditic species are known. In chitons, the two gonads are fused and situated medially in front of the pericardial cavity (Figure 13.4F). Gametes are transported directly to the outside by two separate gonoducts. The gonopores are located in the exhalant region of the mantle groove, one in front of each nephridiopore. Fertilization is external but can occur in the mantle cavity of the female. The eggs are enclosed within a spiny, buoyant membrane (hull)—with a striking case of coevolution in which the sperm head has elongated to be able to reach the egg surface—and are released into the sea individually or in strings. A few chitons brood their embryos in the mantle groove, and in one species (*Calloplax vivipara*) development takes place entirely within the ovary.

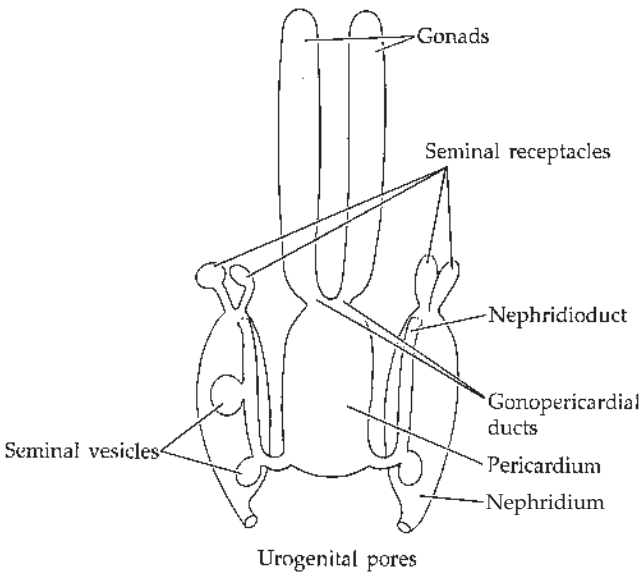

FIGURE 13.45 **A solenogaster urogenital system.**

In living gastropods, one gonad has been lost and the remaining one is usually located with the digestive gland in the visceral mass. The gonoduct is developed in association with the right nephridium in patellogastropods and vetigastropods (Figure 13.46A), while in neritimorphs and caenogastropods a vestige of the right nephridium is incorporated in the oviduct. In cases where the right nephridium is still functional in transporting excretory products, as in the patellogastropods and vetigastropods, the gonoduct is properly called a urogenital duct, because it discharges both gametes and urine.

Gastropods may be gonochoristic or hermaphroditic, but even in the latter case usually only a single gonad (an ovotestis) exists, although a few heterobranchs have separate male and female gonads (e.g., *Omalogyra* and the mathildid *Tuba valkyrie*), while others are protandric. The commitment of the right nephridial plumbing entirely to serving the reproductive system was a major event in gastropod evolution. The isolation of the reproductive tract allowed its independent evolution, without which the great variety of reproductive and developmental patterns in gastropods may never have been possible.

In many gastropods with isolated reproductive tracts, the female system bears a ciliated fold or tube that forms a vagina and oviduct (or pallial oviduct). During development, the tube extends inward from the mantle wall and connects with the genital duct. The oviduct may bear specialized structures for sperm storage or egg case secretion. An organ for storing received sperm, the seminal receptacle, often lies near the ovary at the proximal end of the oviduct. Eggs are fertilized at or near this location prior to entering the long secretory portion of the oviduct. Many female systems also have a copulatory bursa, usually at the distal end of the oviduct, where sperm are received during mating. In such cases the sperm are later transported along a ciliated groove in the oviduct to the seminal receptacle, near where fertilization takes place. The secretory section of the oviduct may be modified as an albumin gland and a mucous or capsule gland. Many heterobranchs lay fertilized eggs in jellylike mucopolysaccharide masses or strings produced by these glands. Most terrestrial eupulmonates produce a small number of large, individual, yolky eggs, which are often provided with calcareous shells. Other eupulmonates brood their embryos internally and give birth to juveniles. Many

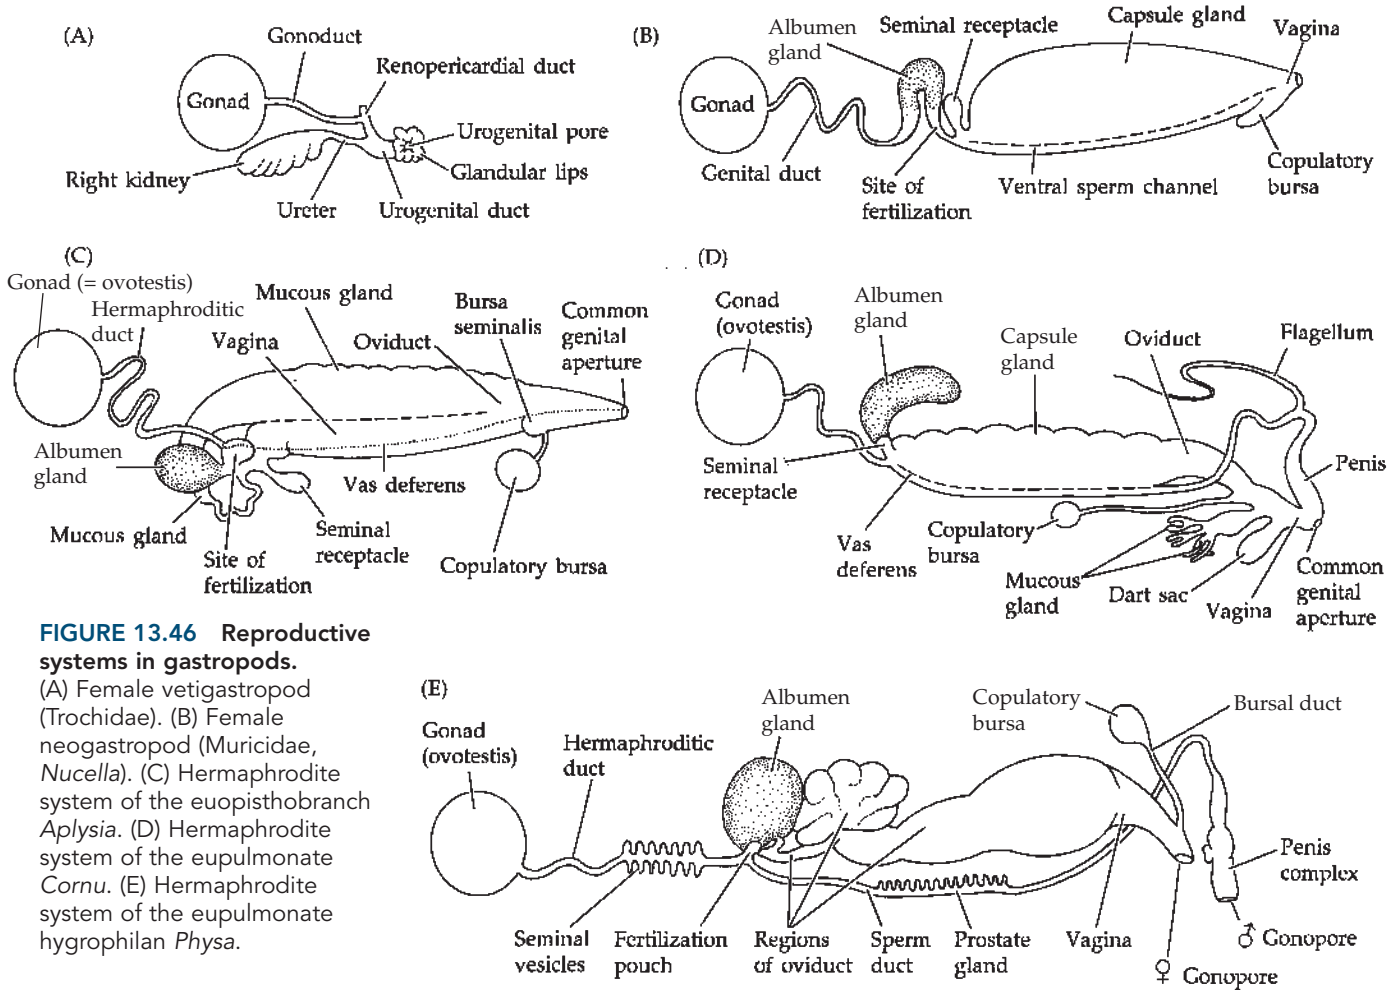

FIGURE 13.46 Reproductive systems in gastropods. (A) Female vetigastropod (Trochidae). (B) Female neogastropod (Muricidae, *Nucella*). (C) Hermaphrodite system of the euopisthobranch *Aplysia*. (D) Hermaphrodite system of the eupulmonate *Cornu*. (E) Hermaphrodite system of the eupulmonate hygrophilan *Physa*.

caenogastropods produce egg capsules in the form of leathery or hard cases that are attached to objects in the environment, thereby protecting the developing embryos. A ciliated groove is often present to conduct the soft egg capsules from the female gonopore down to a gland in the foot, where they are molded and attached to the substratum.

The male genital duct, or vas deferens, often includes a prostate gland for production of seminal secretions. In many gastropods the proximal region of the vas deferens functions as a sperm storage area, or seminal vesicle. In many caenogastropods, neritimorphs, and the so-called "lower heterobranchs," the males have an external penis to facilitate transfer of sperm (Figures 13.6 and 13.47), and internal fertilization takes place prior to formation of the egg case. The penis is a long extension of the body wall, usually arising behind the right cephalic tentacle. In these groups with a cephalic penis, most of the glandular parts of the reproductive system lie within the mantle cavity or may extend back alongside the nephridium. In most euthyneurans, these parts of the reproductive system have migrated into the body cavity and the penis has become a retractile, internal structure. Sperm transfer in some gastropods involves the use of **spermatophores**, either involving a penis or without one, as in the cerithiomorph groups and some others. In some, large sterile parasperm are used to transport the normal sperm.

With both simultaneous and sequential hermaphrodite gastropods, copulation is the rule—either with one individual acting as the male and the other as the female, or with a mutual exchange of sperm between the two. Sedentary species, such as territorial limpets and slipper shells, are often protandric hermaphrodites. In slipper shells (e.g., *Crepidula fornicata*), individuals may stack one atop the other (Figure 13.48), with the more recently settled individuals being males on top of the stack, females on the bottom. Each male (Figure 13.47B) uses its long penis to inseminate the females (Figure 13.47C) below. Males that are in association with females tend to remain male for a relatively long period of time. Eventually, or if isolated from a female, the male develops into a female. Female slipper shells cannot switch back to males, because the masculine reproductive system degenerates during the sex change.

Most eupulmonates are simultaneous hermaphrodites, although protandric hermaphrodites sometimes occur. In most simultaneous hermaphrodite euthyneurans a single complex gonad, the ovotestis, produces both eggs and sperm (Figures 13.46C–E and 13.47D),

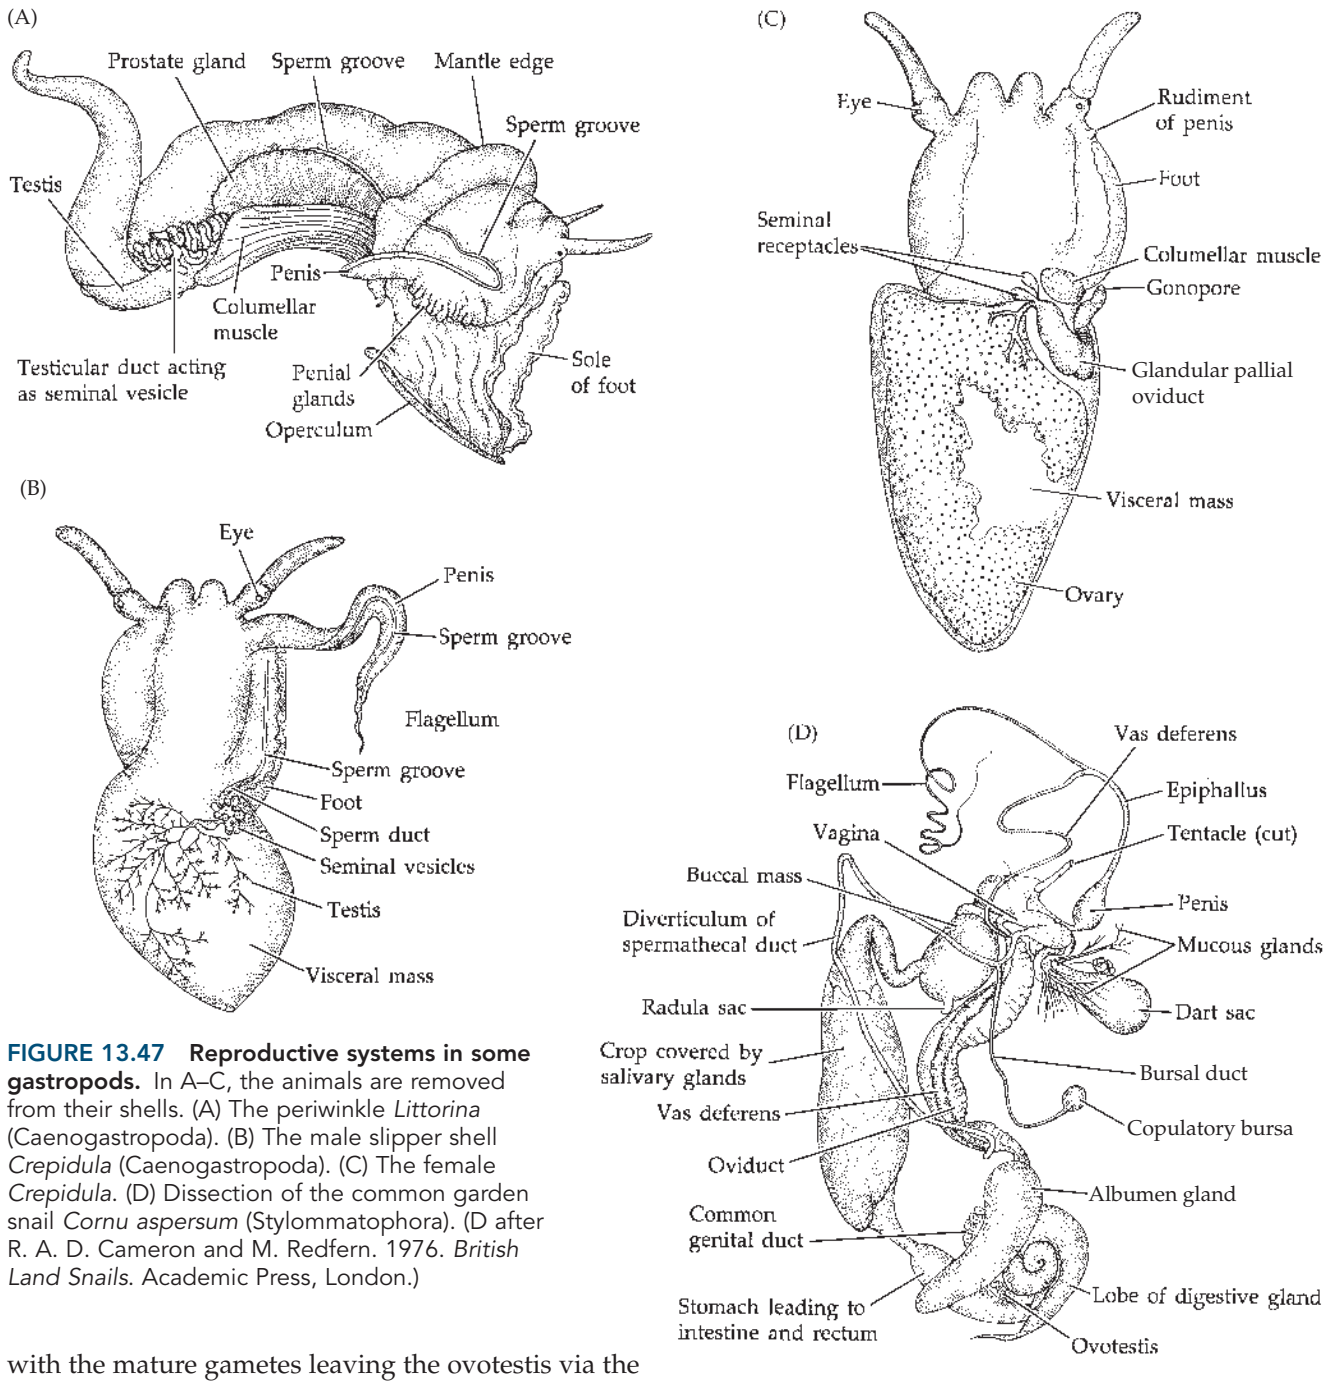

FIGURE 13.47 Reproductive systems in some gastropods. In A–C, the animals are removed from their shells. (A) The periwinkle *Littorina* (Caenogastropoda). (B) The male slipper shell *Crepidula* (Caenogastropoda). (C) The female *Crepidula*. (D) Dissection of the common garden snail *Cornu aspersum* (Stylommatophora). (D after R. A. D. Cameron and M. Redfern. 1976. *British Land Snails*. Academic Press, London.)

with the mature gametes leaving the ovotestis via the hermaphroditic duct. Euthyneuran reproductive systems are amazingly complex and varied in their plumbing and structure; they may have separate male and female gonopores or only a single common gonopore (Figure 13.46D,E).

Distinct precopulatory behaviors occur in a few groups of gastropods. These courtship routines are best documented in land eupulmonates and include behaviors such as oral and tentacular stroking, and intertwining of the bodies. In some eupulmonates (e.g., the common garden snail, *Cornu*, formerly *Helix*) the vagina contains a dart sac, which secretes a calcareous harpoon. As courtship reaches its crescendo and a pair of snails is intertwined, one will drive its dart into the body wall of the other. The dart is coated with mucus that contains a hormonelike substance that enhances the shooter's paternity.

Most bivalves are gonochoristic and retain the primitively paired gonads. However, the gonads are large and closely invested with the viscera and with each other, so an apparently single gonadal mass results. The gonoducts are simple tubes, and fertilization is usually external, although some marine and most freshwater species brood their embryos for a time. In protobranch bivalves, the gonoducts join the nephridia, and gametes are released through urogenital pores. In autobranch bivalves, the gonoducts open into the

mantle cavity separately from the nephridiopores. Hermaphroditism occurs in some bivalves, including shipworms and some species of cockles, oysters, scallops, anomalodesmatans, and others. Oysters of the genus *Ostrea* are sequential hermaphrodites, and most are capable of switching sex in either direction. Shipworms (Teredinidae) remain confined to the wood they colonize as larvae, and this has led to some interesting reproductive strategies, from broadcast spawning to spermcasting, larval brooding, and extreme sexual size dimorphism with male dwarfism. Some shipworms engage in pseudocopulation, a form of direct fertilization where groups of neighboring individuals simultaneously inseminate one another via their siphons (the only part of the animal extending beyond the burrow), and they are the only bivalves known to do so. This has led to copulatory behaviors such as siphon wrestling and the removal of a rival's spermatozoa from the siphons of a recipient.

Cephalopods are almost all gonochoristic, with a single gonad in the posterior region of the visceral mass (Figures 13.11C, 13.12B, and 13.49). The testis releases sperm to a coiled vas deferens, which leads anteriorly to a seminal vesicle. Here various glands assist in packaging the sperm into elaborate spermatophores, which are stored in a large reservoir called **Needham's sac**. From there the spermatophores are released into the mantle cavity via a sperm duct. In females the oviduct terminates in one oviducal gland in squid, and two in octopuses. This gland secretes a protective membrane around each egg.

The highly developed nervous system of cephalopods has facilitated the evolution of some very sophisticated precopulatory behaviors, which culminate in the transfer of spermatophores from the male to the female. Because the oviducal opening of females is deep within the mantle chamber, male coleoids use one of their arms as an intromittent organ to transfer the spermatophores. These modified arms are called **hectocotyli** (Figures 13.12D and 13.49B). In squid and cuttlefish the right or left fourth arm is used; in octopuses it is the right third arm. In *Nautilus* four small arms form a conical organ, the **spadix**, that functions in sperm transfer. Hectocotylus arms have special suckers, spoonlike depressions, or superficial chambers for holding spermatophores during the transfer, which may be a brief or a very lengthy process.

Each spermatophore comprises an elongate sperm mass, a cement body, a coiled and "spring-loaded" ejaculatory organ, and a cap. The cap is pulled off as the spermatophore is removed from the Needham's sac in squid or by uptake of seawater in octopuses. Once the cap is removed, the ejaculatory organ everts, pulling the sperm mass out with it. The sperm mass adheres by means of the cement body to the seminal receptacle or mantle wall of the female, where it disintegrates and liberates sperm for up to two days.

Precopulatory rituals in coleoid cephalopods usually involve striking changes in coloration, as the male tries to attract the female (and discourage other males in the

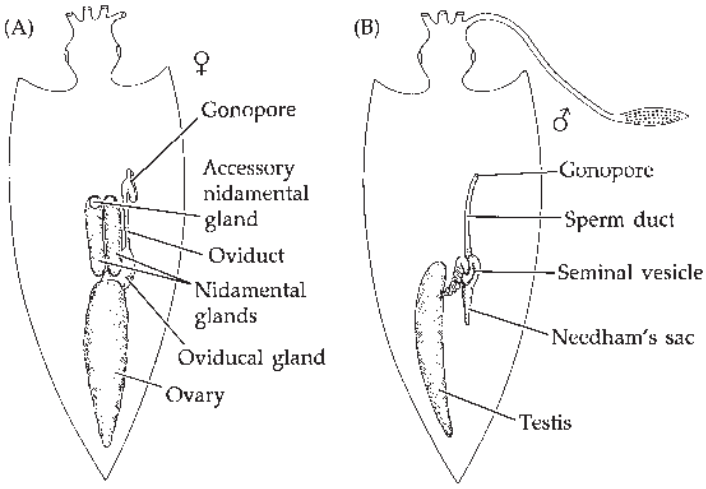

FIGURE 13.49 **Reproductive systems in a coleoid cephalopod, the squid *Loligo*.** (A) Female. (B) Male.

for more ebook/ testbank/ solution manual request email 9601267344@qq.com

area). Male squid often seize the female partner with the tentacles, and the two swim head-to-head through the water. Eventually the male's hectocotylus grabs a spermatophore and inserts it into the mantle chamber of his partner, near or in the oviducal opening. Mating in octopuses can be a savage affair. The exuberance of the copulatory embrace may result in the couple tearing at each other with their sharp beaks, or even strangulation of one partner by the other as the former's arms wrap around the mantle cavity of the latter, cutting off ventilation. In many octopuses (e.g., *Argonauta*, *Tremoctopus*) the tip of the hectocotylus arm may break off and remain in the female's mantle chamber.[8]

As the eggs pass through the oviduct, they are covered with a capsulelike membrane produced by the oviducal gland. Once in the mantle cavity, various kinds of **nidamental glands** may provide additional layers or coatings on the eggs. In squid like *Doryteuthis*, which migrate to shallow water to breed, the nidamental glands coat the eggs within an oblong gelatinous mass, each containing about 100 eggs. The female holds these egg cases in her arms and fertilizes them with sperm ejected from her seminal receptacle. The egg masses harden as they react with seawater and are then attached to the substratum. The adults die after mating and egg laying. Cuttlefish deposit single eggs and attach them to seaweed or other substrata. Many open-ocean pelagic coleoids have floating eggs, and the young develop entirely in the plankton. Octopuses usually lay grapelike egg clusters in dens in rocky areas, and many species care for the developing embryos by protecting them and by aerating and cleaning them by flushing the egg masses with jets of water. Octopuses and squid tend to grow quickly to maturity, reproduce, and then die, usually within a year or two. The chambered nautilus, however, is long-lived (perhaps to 25–30 years), slow growing, and able to reproduce for many years after maturity.

One of the most astonishing reproductive behaviors among invertebrates occurs in members of the pelagic octopod genus *Argonauta*, known as the paper nautiluses. Female argonauts use two specialized arms to secrete and sculpt a beautiful, coiled, calcareous shell-like egg case into which eggs are deposited (Figure 13.17B). The thin-walled, delicate shell is carried by the female and serves as her temporary home and as a brood chamber for the embryos. The much smaller male often cohabits the egg case with the female.

Development

Development in molluscs is similar in many fundamental ways to that of the other spiralian protostomes. Most molluscs undergo typical spiral cleavage, with the mouth and stomodeum typically developing from the blastopore, and the anus forming as a new opening on the gastrula wall (protostomous). Cell fates are also typically spiralian, including a 4d mesentoblast.

By the end of the 64-cell stage, the distinctive molluscan cross is typically formed by a group of apical micromeres ($1a^{12}$–$1d^{12}$ cells and their descendants, with cells $1a^{112}$–$1d^{112}$ forming the angle between the arms of the cross) (Figure 13.50). This configuration of blastomeres appears to be just one of several patterns found in lophotrochozoans. As detailed studies are conducted on more and more species, the phylogenetic implications of these variations are being evaluated.

Development may be direct, mixed, or indirect. During indirect development, the free-swimming trochophore larva that develops is remarkably similar to that seen in annelids (Figure 13.51). Like the annelid larva, the molluscan trochophore bears an apical sensory plate with a tuft of cilia and a girdle of ciliated cells—the prototroch—just anterior to the mouth.

In some free-spawning molluscs (e.g., Polyplacophora and Caudofoveata), the trochophore is the only larval stage, and it metamorphoses directly into the juvenile (Figure 13.51C). Solenogasters and protobranch bivalves usually have a so-called "test cell larva," or pericalymma where a bell-shaped larval test encloses parts of the developing embryo. But in other groups (e.g., gastropods and autobranch bivalves), the trochophore is followed by a uniquely molluscan larval stage called a veliger (Figure 13.52). The **veliger larva** may possess a foot, shell, operculum, and other adult-like structures. The most characteristic feature of the veliger larva is the swimming organ, or **velum**, which consists of two large ciliated lobes developed from the trochophore's prototroch. In some species the velum is also a feeding organ

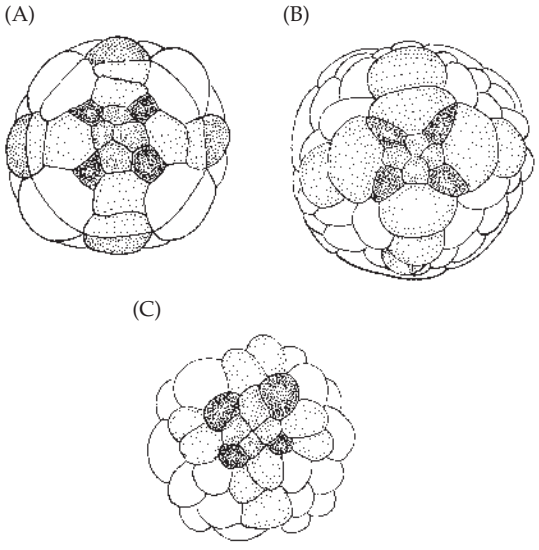

FIGURE 13.50 The "molluscan cross" of developing embryos. (A) Gastropoda (*Lymnaea*). (B) Polyplacophora (*Stenoplax*). (C) Solenogastres (*Epimenia*).

[8]The detached arm was mistakenly first described as a parasitic worm and given the genus name *Hectocotylus* (hence the origin of the term)

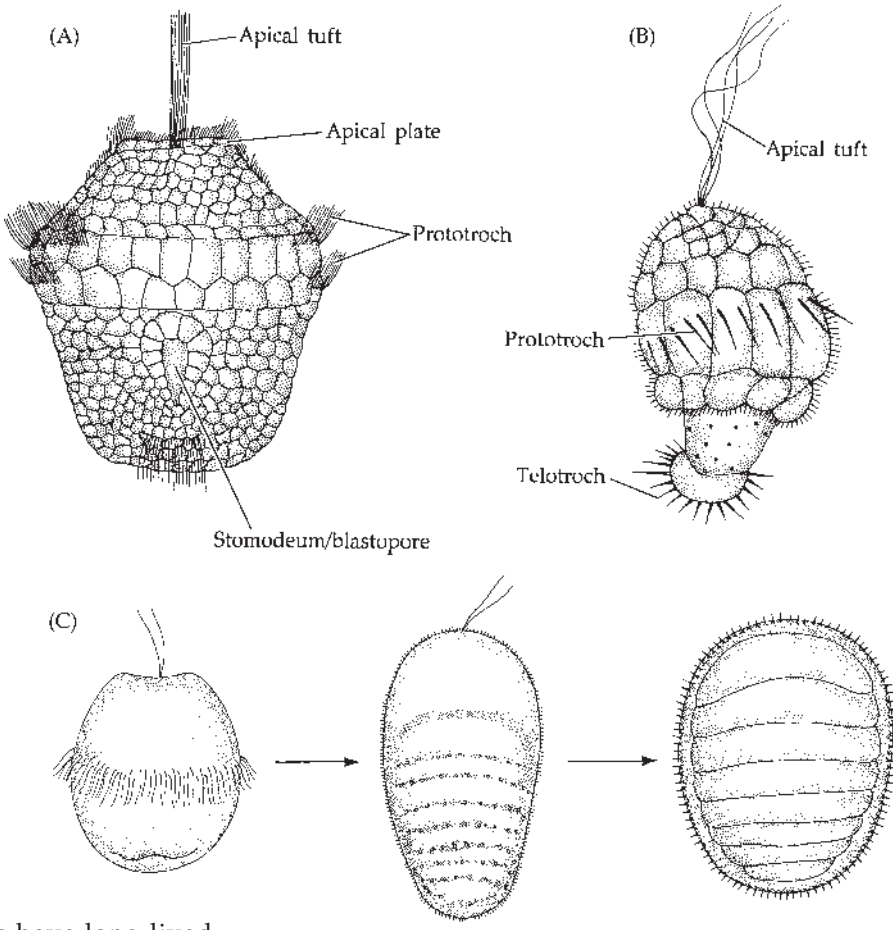

FIGURE 13.51 Molluscan trochophore larvae. (A) Generalized molluscan trochophore larva. (B) Trochophore of a solengaster aplacophoran. (C) Metamorphosis of a polyplacophoran from trochophore to juvenile.

and is subdivided into four, five, or even six separate lobes (Figure 13.52C). Feeding (planktotrophic) veligers capture particulate food between opposed prototrochal and metatrochal bands of cilia on the edge of the velum, others are non-feeding (lecithotrophic) and live on yolk reserves. Eventually eyes and tentacles appear, and the veliger transforms into a juvenile, settles to the bottom, and assumes an adult existence.

Like gastropods, some bivalves have long-lived planktotrophic veligers, whereas others have short-lived lecithotrophic veligers. Many widely distributed species have very long larval lives that allow dispersal over great distances. A few bivalves have mixed development and brood the developing embryos in the suprabranchial cavity through the trochophore period; then the embryos are released as veliger larvae. Some marine and freshwater clams have direct development, as for example in the freshwater family Sphaeriidae where embryos are brooded between the gill lamellae and juveniles shed into the water when development is completed. Several unrelated marine groups have independently evolved a similar brooding behavior (e.g., philobryids such as *Lissarca miliaris*, some archiheterodonts and galeommatoideans, etc.).

In the freshwater clams (Unionidae), the embryos are also brooded between the gill lamellae, where they develop into highly modified veligers adapted for a parasitic phase on fishes, thereby facilitating dispersal. These parasitic larvae are called **glochidia** (Figure 13.52E). They attach to the skin or gills of the host fish by a sticky mucus, hooks, or other attachment devices. Most glochidia lack a gut and absorb nutrients from the host by means of special phagocytic mantle cells. The host tissue often forms a cyst around the glochidium. Eventually the larva matures, breaks out of the cyst, drops to the bottom, and assumes its adult life.

Among gastropods, only patellogastropods and vetigastropods rely on external fertilization and retain a free-swimming trochophore larva. All other gastropods suppress the trochophore or pass through it quickly before hatching. In many groups embryos hatch as veligers (e.g., many neritimorphs, caenogastropods and heterobranchs). Some of these gastropods have planktotrophic veligers that may have brief or extended (to several months) free-swimming lives. Others have lecithotrophic veligers that remain planktonic only for short periods (sometime less than a week). Planktotrophic veligers feed by use of the velar cilia, whose beating drives the animal forward and draws minute planktonic food particles into contact with the shorter cilia of a food groove. Once in the food groove, the particles are trapped in mucus and carried along ciliary tracts to the mouth.

Almost all eupulmonates and many caenogastropods have direct development, and the veliger stage is passed in the egg case, or capsule. Upon hatching, tiny snails crawl out of the capsule into their adult habitat. In some neogastropods (e.g., certain species of *Nucella*), the encapsulated embryos cannibalize their siblings, a phenomenon called **adelphophagy**; consequently, only one or two juveniles eventually emerge from each capsule.

Werner. 1955. *Helgol Wiss Meeresunters* 5: 169–217. https://hmr.biomedcentral.com/articles/10.1007/BF01610508)

It is usually during the veliger stage that gastropods undergo torsion (see the previous section Torsion, or "How the Gastropod Got its Twist"), when the shell and visceral mass twist relative to the head and foot (Figures 13.18 and 13.53). As we have seen, this phenomenon is still not fully understood, but it has most probably played a major role in gastropod evolution.

Cephalopods produce large, yolky, telolecithal eggs. Development is always direct, the larval stages having been lost entirely during evolution of the yolk-laden

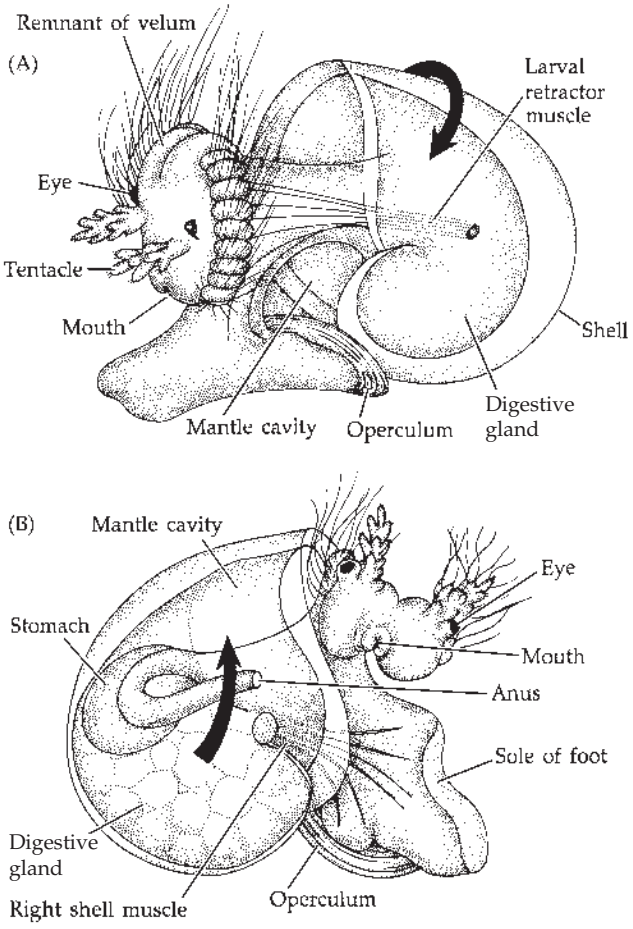

FIGURE 13.53 Settled larva of the abalone (*Haliotis*) undergoing torsion. (A) Left-side view after about 90° of torsion, with mantle cavity on the right side. (B) Torsion continues as the mantle cavity and its associated structures twist forward over the head.

embryo that develops within the egg case. Early cleavage is meroblastic and eventually produces a cap of cells (a discoblastula) at the animal pole, without remnants of the spiral cleavage typical of other molluscs. The embryo grows in such a way that the mouth opens to the yolk sac, and the yolk is directly "consumed" by the developing animal (Figure 13.54).

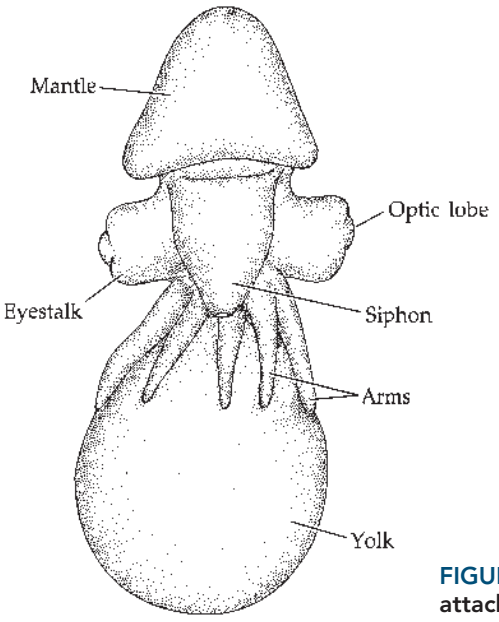

FIGURE 13.54 Juvenile coleoid cephalopod attached to and consuming its sac of yolk.

Molluscan Evolution and Phylogeny

The phylogenetic details of molluscan evolution have yet to be thoroughly elucidated. The phylum is highly diverse, and many named taxa below the class level are known to be polyphyletic or paraphyletic. The existence of a good fossil record (primarily of shells) has been both a blessing and a curse, as efforts to trace the evolutionary history of molluscs have often been frustrated by the limited and sometimes confusing data molluscan shells have provided.

Until fairly recently, the idea of a "hypothetical ancestral mollusc" (HAM) was popular, the nature of which derived largely from early work of the eminent British biologist and "Darwin's Bulldog," T. H. Huxley. Detailed and sometimes highly imaginative descriptions of this hypothetical ancestral mollusc were proposed by various workers, even including speculations on its physiology, ecology and behavior (see Lindberg and Ghiselin 2003). The usefulness of HAM in molluscan evolutionary studies was questioned as zoology moved into an era of explicit phylogenetic analysis (i.e., cladistics). Thus, most workers now avoid the pitfalls of a priori construction of a hypothetical ancestor and instead analyze the evolutionary history of molluscs by phylogenetic inference. Although morphological analyses of molluscan relationships have differed in some details, the phylogenetic relationships resulting from this work have been similar. In contrast, more recent molecular analyses of molluscan relationships have produced several alternative trees depending on the molecular data type and analytical methods.. The phylogeny summarized here (Figure 13.55) is one of the possible scenarios of molluscan evolution. The characters used to construct the cladogram are enumerated in the figure legend and briefly summarized in the following discussion. The nodes on the cladogram have been lettered to facilitate the discussion.

Exactly where the molluscs arose within the lophotrochozoan clade, along with their kinship to the other phyla, are still matters of debate. While some workers treat them as descendant from a segmented ancestor, most do not. We support the idea that molluscs arose from a nonsegmented precursor. Some molecular studies (see the References) have suggested the Brachiozoa (Brachiopoda and Phoronida) as the sister group of the molluscs, with the annelids nested outside of the Mollusca + Brachiozoa. This placement is

for more ebook/ testbank/ solution manuals requests email 9601267344@qq.com

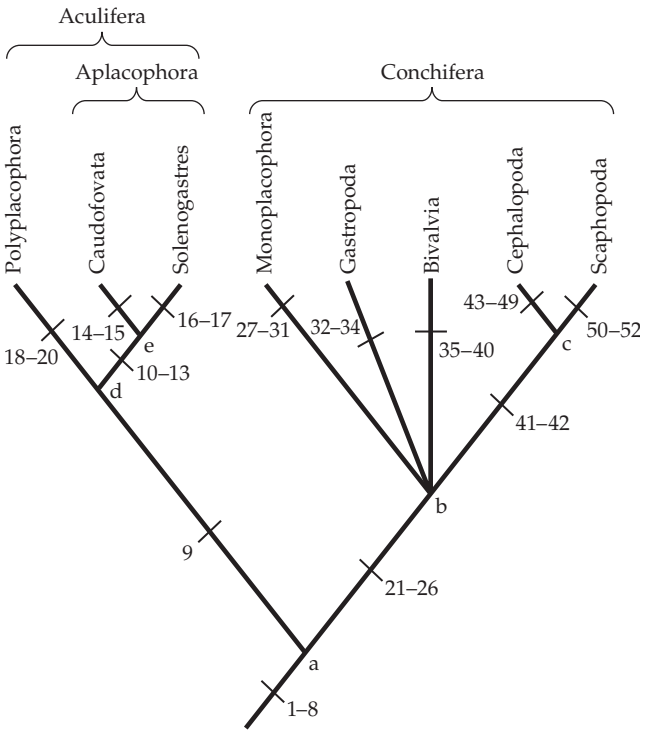

FIGURE 13.55 A cladogram depicting a conservative view of the phylogeny of the Mollusca. This cladogram is based on current hypotheses; see Sigwart and Lindberg (2015) and Ponder et al. (2020) for alternative molluscan phylogenies. The numbers on the cladogram indicate suites of synapomorphies for each hypothesized line or clade.

Phylum Mollusca at node a: (1) reduction of the coelom and development of an open hemocoelic circulatory system; (2) dorsal body wall forms a mantle; (3) extracellular production of calcareous sclerites (and/or shell) by mantle shell glands; (4) ventral body wall muscles develop as muscular foot (or foot precursor); (5) radula; (6) chambered heart with separate atria and ventricle; (7) increase in gut complexity, with large digestive glands; (8) ctenidia.

Aculifera (Aplacophora + Polyplacophora) node d: (9) sclerites.

Aplacophora (Caudofoveata + Solenogastres) node e: (10) vermiform body; (11) foot reduced; (12) gonads empty into pericardial cavity, exiting to mantle cavity via U-shaped gametoducts; (13) without nephridia.

Caudofoveata: (14) calcareous sclerites of the body wall form imbricating scales; (15) complete loss of foot.

Solenogastres: (16) posterior end of reproductive system with copulatory spicules; (17) loss of ctenidia.

Polyplacophora: (18) shell with 8 plates (and with 8 shell gland regions), articulamentum layer, and aesthetes; (19) multiple ctenidia; (20) expanded and highly cuticularized mantle girdle that "fuses" with shell plates.

Conchifera node b: (21) presence of a well-defined single shell gland region and larval shell (protoconch); (22) shell univalve (of a single piece; note that the bivalve shell is derived from the univalve condition); (23) shell of basically 3 layers (periostracum, prismatic layer, lamellar or crossed layer); (24) mantle margin of 3 parallel folds, each specialized for specific functions; (25) statocysts; (26) viscera concentrated dorsally.

Monoplacophora: (27) 3–6 pairs of ctenidia; (28) 3–7 pairs of nephridia; (29) 8 pairs of pedal retractor muscles; (30) 2 pairs of gonads; (31) 2 pairs of heart atria.

Gastropoda: (32) torsion; (33) cephalic tentacles; (34) operculum.

Bivalvia: (35) bivalve shell and its associated mantle and (in autobranch bivalves) ctenidial modifications; (36) loss of radula; (37) byssus (autobranchs); (38) lateral compression of body; (39) adductor muscles; (40) ligament.

Cephalopod-scaphopod lineage node c: (41) ano-pedal flexure; (42) new neuroanatomical features, including cerebral ganglia fusion and position.

Cephalopoda: (43) expansion of the coelom and closure of the circulatory system; (44) septate shell; (45) ink sac (in coleoids); (46) siphuncle; (47) beaklike jaws; (48) foot modified as prehensile arms/tentacles and funnel (= siphon); (49) development of large brain.

Scaphopoda: (50) tusk-shaped, shell open at both ends; (51) loss of heart and ctenidia; (52) captacula.

surprising, as molluscs have spiral cleavage while the brachiopods have radial cleavage; however both radial and spiral cleavage patterns are present in phoronids—see Chapter 16. In addition, the molluscan coelom is formed through schizocoely, while the brachiopods are characterized by enterocoely.

The major steps in the evolution of what we generally think of as a "typical" mollusc—that is, a shelled mollusc—also remain controversial. Previous scenarios have often argued that the first step took place after the origin of the aplacophorans, perhaps as molluscs adapted to active epibenthic lifestyles. These steps centered largely on the elaboration of the mantle and mantle cavity, the refinement of the ventral surface as a well-developed muscular foot, and the evolution of a consolidated dorsal shell gland and solid shell(s) in place of independent calcareous sclerites.

The description of a solenogaster larva by Pruvot in 1890, in which the dorsal surface was said to bear seven transverse bands of sclerites (described as "composite plates," reminiscent of chitons), led some workers to postulate that aplacophorans and polyplacophorans might be sister groups; this relationship was confirmed by several phylogenomic studies (e.g., Kocot et al. 2011, Smith et al. 2011). However, the discovery from Silurian deposits in England of a possible aplacophoran fossil having seven dorsal shell plates (*Acaenoplax hayae*), as well as "footless" chitons (*Kulindroplax perissokomos* and *Phthipodochiton thraivensis*), has further confused the polarity of the aplacophoran-chiton character transformation. Adding to the confusion, there are fundamental differences between the shells of polyplacophorans and those of all other molluscs, an observation suggesting that the chitons and aplacophorans may stand alone as a unique radiation off the early

molluscan line. Three hypotheses have been offered to explain this "shell problem" in molluscan evolution: (1) The multiplate shell may have been ancestral, the single-shell condition having evolved by coalescence of plates. (2) The single shell may have been ancestral, and the multiplate forms arose by subdivision of the single shell. (3) The single-shell and multishell designs arose independently from a shell-less ancestor, perhaps by way of sclerite consolidation. The presence of eight pairs of pedal retractor muscles in both polyplacophorans and monoplacophorans has been taken as evidence in favor of the first explanation. Acceptance of the first hypothesis suggests that the ancestor at node *a* in the cladogram in Figure 13.55 was a multivalved chitonlike creature. Acceptance of the second hypothesis implies that the ancestor at node *a* was a univalved, monoplacophoran-like ancestor. The third hypothesis postulates that the ancestor at node *a* lacked a solid shell altogether.

The primitive mantle and foot arrangement was probably somewhat similar to that in living polyplacophorans or monoplacophorans—that is, a large flattened sole was surrounded by a mantle groove. Because of their small size, the first molluscs probably did not require specialized respiratory structures, and gas exchange was through the dorsal epidermis. However, with the origin of the cuticle-covered mantle or dorsal shell covering this surface, posterior, specialized respiratory structures (ctenidia) originated and became associated with excretory and reproductive pores in a posterior mantle cavity. This arrangement would have been modified at least twice; in both the polyplacophorans and monoplacophorans, the mantle cavity became continuous with the expanded mantle groove alongside the foot, and the ctenidia multiplied and extended anteriorly in the mantle groove. Secondary modifications of the shape of the foot and other features in bivalves and scaphopods allowed most of these animals to exploit infaunal life in soft sediments, and both of these taxa are highly adapted to sediment burrowing. However, these modifications are clearly convergent, and scaphopods share other characters, including ano-pedal flexure, with cephalopods. Gastropods also undergo ano-pedal flexure, but according to some molecular studies this could be convergent. Scaphopods are also the last class of molluscs to appear in the fossil record (about 427 Ma, Silurian).

Monoplacophorans share the character of a single (univalve) shell with other molluscs (other than bivalves and chitons). They also share a similar shell structure and a host of other features. The only synapomorphies defining the monoplacophorans seem to be their repetitive organs (multiple gills, nephridia, pedal muscles, gonads, and heart atria). The question of whether this multiplicity arose uniquely in the monoplacophorans or represents a symplesiomorphic retention of ancestral features from some unknown metameric ancestor (below node *a* on the cladogram) has not been resolved and will likely require developmental studies on monoplacophorans to finally settle the question.

The bivalve line in the cladogram is defined by the presence of two shell valves, adductor muscles, reduction of the head region, decentralization of the nervous system and associated reduction or loss of certain sensory structures, and expansion of the mantle cavity.

Cephalopods are highly specialized molluscs and possess a number of complex synapomorphies. Primitive shelled cephalopods are represented today by about six species of *Nautilus* and *Allonautilus*, although thousands of fossil species of shelled cephalopods have been described. This highly successful molluscan class probably arose about 497 million years ago. The palcephalopods underwent a series of radiations during the Paleozoic but were largely replaced by the ammonites after the Devonian period (358 Ma). The ammonites, in turn, became extinct around the Cretaceous-Tertiary boundary (66 Ma). The origin of the coleoid cephalopods (octopuses, squid, and cuttlefish) is obscure, possibly dating back to the Devonian. They diversified mainly in the Mesozoic and became a highly successful group by exploiting a very new lifestyle, as we have seen.

The issue of ancestral metamerism in molluscs has been debated since the discovery of the first living monoplacophoran (*Neopilina galatheae*) in 1952. However, monoplacophorans are not the only molluscs to express serial replication or to have repeated organs reminiscent of metamerism (or "pseudometamerism," as some prefer to call it). Polyplacophorans have many serially repeated gills in the mantle groove and also typically possess eight pairs of pedal retractor muscles and eight shell plates. The two pairs of heart atria, nephridia, and ctenidia in *Nautilus* (and two pairs of retractor muscles in some fossil forms) have also been regarded by some workers as primitive metameric features.

The presence of organ repetition in some molluscs has been used to argue a close relationship to annelids. Recent molecular studies have included an unresolved relationship between molluscs, annelids, nemerteans, and brachiozoans (Dunn et al. 2014), while Kocot et al. (2017) suggested a resolved clade of brachiozoans, annelids, and nemerteans as the sister taxon of the molluscs. Laumer et al. (2019) also recovered a clade of brachiozoans, annelids, and nemerteans; this was also the first analysis to include the bryozoans, which grouped with the brachiozoans, thus supporting the monophyly of the lophophorates. The analysis of brachiopod, mollusc, and annelid genomes by Luo et al. (2015) placed the brachiopods as the sister taxon of the molluscs; this analysis did not include nemertean or bryozoan genomes. These molecular analyses suggest that organ repetition in molluscan groups is the result of independent convergent evolution, and is not

for more ebook/ testbank/ solution manuals requests email 9601267344@qq.com

ancestral, and that the genetic/evolutionary potential for serial repetition of organs is not uncommon and occurs in other nonannelid bilaterian phyla as well, e.g., Nemertea and Chordata. We regard organ repetition in the molluscs as independent convergent evolution of this characteristic.

The origin of molluscs themselves remains enigmatic. The excellent fossil record of this phylum extends back some 500 million years and suggests that the origin of the Mollusca probably lies in the Precambrian. Indeed, the late Precambrian fossil *Kimberella quadrata*, once thought to be a cnidarian, has been argued to have molluscan features, including perhaps a shell and muscular foot. However, recent examination of hundreds of specimens now suggests that *Kimberella* more likely belongs to an extinct lophotrochozoan group.

Chapter Summary

The phylum Mollusca is probably the most morphologically diverse of all animal phyla, and with ~73,000 described living species it is second only to the phylum Arthropoda in diversity. Molluscs are spiralian protostomes, with species ranging in size from microscopic, to giant squid reaching at least 13 m in length (including the tentacles), to octopuses weighing over 40 kg. The classification of Mollusca is complex, with eight classes that include two classes of spiculate, wormlike aplacophorans; the deep-sea, limpet-shaped monoplacophorans; eight-plated chitons (polyplacophorans); limpets, snails, and slugs (gastropods); clams, mussels, and their relatives (bivalves); tusk shells (scaphopods); and octopuses, squid, and nautiluses (cephalopods). Molluscs have radiated in every environment on Earth, from the deepest seas to high mountains. But despite this enormous diversity, all molluscs share a suite of defining characters that include (but are not limited to) bilateral symmetry (lost in gastropods), reduced coelom (the principal body cavity being the hemocoel), viscera concentrated dorsally as a "visceral mass," body covered by a cuticular epidermal sheet called the mantle (which has shell glands that secrete sclerites or shells), distinctive gills known as ctenidia (which may be lost or modified), a buccal feeding structure called the radula (except in bivalves), and spiral cleavage (except in cephalopods), and some groups have a trochophore larva, while bivalves and gastropods have a unique veliger larva.

CHAPTER 14

Phylum Nemertea

The Ribbon Worms

Members of the phylum Nemertea (Greek, "a sea nymph"), or Rhynchocoela (Greek *rhynchos*, "snout"; *coel*, "cavity"), are commonly called ribbon worms. Figure 14.1 illustrates a variety of body forms within this taxon and the major features of their anatomy. These unsegmented vermiform animals are usually flattened dorsoventrally and are moderately cephalized; they possess highly extensible bodies and strong regeneration powers. Many ribbon worm species are rather drab in appearance, but others are brightly colored or distinctively marked (e.g., the tropical eastern Pacific species *Baseodiscus punnetti*, above).

There are about 1,300 accepted, described species of nemerteans. They range in length from a few millimeters to several meters. Many can stretch easily to several times their contracted lengths (one specimen of *Lineus longissimus* reportedly measured 30 m in length). They are predominately benthic marine animals. A few, however, are planktonic, and some are symbiotic in molluscs, ascidians, or other marine invertebrates. A few freshwater and terrestrial species are known, the latter having some species distributed mostly on islands around the world.

Many features of the nemertean body plan (Box 14A) are similar to the conditions seen in flatworms (Platyhelminthes), and historically the two taxa were often grouped together as triploblastic acoelomate Bilateria. However, we now understand that nemerteans are truly coelomate and that they are closely related to annelids, molluscs, and the lophophorate phyla. Similarities with the flatworms are reflected in the overall architecture of the nervous systems, the types of sense organs, and the protonephridial excretory structures. However, in other respects ribbon worms are more similar to the previously mentioned spiralian phyla. Nemerteans possess a through gut with an anus

BOX 14A Characteristics of the Phylum Nemertea

1. Marine, freshwater, or terrestrial
2. Triploblastic, coelomate, bilaterally symmetrical unsegmented worms (one species externally "segmented")
3. Digestive tract complete, with anterior mouth and posterior anus
4. With protonephridia (a few deep-sea pelagic species lacking excretory systems)
5. With a bilobed cerebral ganglion that surrounds proboscis apparatus (not the gut), and two or more longitudinal nerve cords connected by transverse commissures
6. With two or three layers of body wall muscles arranged in various ways
7. With a unique proboscis apparatus lying dorsal to the gut and surrounded by a coelomic hydrostatic chamber called the rhynchocoel
8. With a closed circulatory system; some species with hemoglobin
9. Most gonochoristic; cleavage holoblastic; early development typically spiralian, and either direct or indirect, some with a pilidium larva
10. Asexual reproduction by fragmentation not uncommon

(a complete, one-way digestive tract), a closed circulatory system that is coelomic in nature, and an eversible proboscis surrounded by a hydrostatic cavity called the rhynchocoel. The circulatory system and the rhynchocoel are both coelomic cavities. The structure of the proboscis apparatus is unique to nemerteans and represents a novel synapomorphy that distinguishes the Nemertea from all other invertebrate taxa.

Taxonomic History and Classification

The earliest report of a nemertean was that of William Borlase (1758), who described his specimen as "the sea long-worm" and categorized it "among the less perfect kind of sea animals." For nearly a century, most authors placed the ribbon worms with the turbellarian flatworms, although other writers suggested that they were allied to annelids (including sipunculans), nematodes, and even molluscs and insects. It was during this period that Georges Cuvier (1817) described a particular ribbon worm and called it *Nemertes*, from which the phylum name was eventually derived. However, it was not until 1851 that substantial evidence for the distinctive nature of the ribbon worms was published by the German zoologist Max Schultze, who described the functional morphology of the proboscis, established the presence of nephridia and an anus, and discussed many other features of these animals. Schultze even proposed the basis for classifying these worms, which is still largely employed today by most authorities. Interestingly, he persisted in considering them to be turbellarians (today a paraphyletic grouping of the free-living Platyhelminthes), but he coined the names Nemertina and Rhynchocoela. The American anatomist Charles Minot separated the nemerteans from the flatworms in 1876, but it was not until the mid-twentieth century that the unique combination of characters displayed by the ribbon worms was fully accepted. Since that time they have been treated as a valid phylum. Then it took until the mid-1980s for James M. Turbeville, who studied their ultrastructure, to determine that nemerteans are more closely related to the coelomate protostomes than to platyhelminths, a result later corroborated by molecular sequence data and by their early cleavage pattern.

Classification

Since the publication of Schultze's classic accounts, the primary effort of nemertean taxonomists has been to refine the details of his scheme, which has generated surprisingly few controversies. The classification scheme used here is mostly based on the traditional one established by Wesley Coe in 1943 and refined with molecular phylogenetic analyses.

For most of the last 100 years, the classification system of nemerteans has largely followed that of the Dutch biologist Gerarda Stiasny-Wijnhoff (1936), which accepted as classes Schultze's (1851) division of nemerteans into Anopla and Enopla. Stiasny-Wijnhoff further divided Anopla into Palaeonemertea and Heteronemertea, and Enopla into Hoplonemertea and Bdellonemertea. Hoplonemertea was further subdivided into Monostilifera and Polystilifera. Recent molecular phylogenetic studies of nemerteans found a basal division between Palaeonemertea and Neonemertea, but Hubrechtiidae, formerly in Palaeonemertea, appears nested within Neonemertea, as the sister group of the remaining Heteronemertea. This extended Heteronemertea, including Hubrechtiidae, constitute the clade Pilidiophora (see the Classification section). Furthermore, all molecular analyses have contradicted the ordinal status of Bdellonemertea (*Malacobdella*), which is deeply nested within Hoplonemertea (and in the order Monostilifera).

We therefore follow a system in which the phylum is subdivided into two main clades, Palaeonemertea and Neonemertea (which we rank as classes), the latter divided into two subclasses, Pilidiophora (including the traditional order Heteronemertea and the family Hubrechtiidae) and Hoplonemertea (= Enopla of older classifications). The principal anatomical features used to distinguish between these clades include proboscis armature, mouth location relative to the position of the cerebral ganglion, gut shape, layering of the body wall

muscles, position of the longitudinal nerve cords, and several larval features. We rely on a recent proposal by nearly all active workers on nemerteans for this taxonomy (Strand et al. 2018), but recognize and rank Neonemertea as the sister group of Palaeonemertea.

CLASSIFICATION OF NEMERTEA (= RHYNCHOCOELA)

CLASS PALAEONEMERTEA Unarmed nemerteans (Figure 14.1B). Proboscis not armed with stylets and not morphologically specialized into 3 regions. Mouth separate from proboscis pore and located directly below or somewhat posterior to cerebral ganglion. Two or 3 layers of body wall muscles, from external to internal either circular-longitudinal or circular-longitudinal-circular; dermis thin and gelatinous, or absent; longitudinal nerve cords epidermal, dermal, or intramuscular within the longitudinal layer; cerebral organs and ocelli frequently lacking. Palaeonemerteans are marine, primarily littoral forms. There are no designated orders in this class. (e.g., *Carinina*, *Carinoma*, *Cephalothrix*, *Tubulanus*)

CLASS NEONEMERTEA Unarmed or armed nemerteans with separate or fused mouth and proboscis pores. Because Hubrechtiidae was formerly placed in Palaeonemertea, most characters within Neonemertea are variable.

SUBCLASS PILIDIOPHORA Unarmed nemerteans with separate mouth and proboscis pores and with a pilidium larva (when present) and the proboscis musculature bilaterally arranged.

ORDER HETERONEMERTEA With different types of body wall structure and nervous system in Hubrechtiidae and the remaining heteronemerteans, as historically hubrechtiids were regarded as a "transitional stage" between palaeonemerteans and basal heteronemerteans. Except for hubrechtiids, with characters as those of palaeonemerteans, heteronemerteans have 3 layers of body wall muscles, from external to internal longitudinal-circular-longitudinal; dermis usually thick, partly fibrous; longitudinal nerve cords intramuscular, between outer longitudinal and middle circular layers; cerebral organs and ocelli usually present; development indirect (Figure 14.1A,D–F). Primarily marine littoral forms, but a few freshwater species are known. (e.g., *Baseodiscus*, *Cerebratulus*, *Hubrechtia*, *Hubrechtella*, *Lineus*, *Micrura*, *Nemertoscolex*, *Paralineus*)

SUBCLASS HOPLONEMERTEA Typically armed nemerteans (Figure 14.1C,G). Proboscis usually armed with distinct stylets and morphologically specialized into 3 regions (except in *Malacobdella*); mouth and proboscis pore usually united into a common aperture; mouth located anterior to cerebral ganglion; longitudinal nerve cords within mesenchyme, internal to body wall muscles. With marine, freshwater, and terrestrial species; many marine species symbiotic with or parasitic upon other invertebrates.

ORDER MONOSTILIFERA Stylet apparatus consists of a single main stylet and 2 or more sacs housing accessory (replacement) stylets; proboscis apparatus is unarmed and opens into foregut in *Malacobdella*, which has a trunk with a large posterior sucker and a convoluted gut that lacks lateral diverticula. Most species are marine and benthic, but freshwater, terrestrial, and parasitic forms are known; *Malacobdella* species are commensal in the mantle cavities of marine bivalves and, in one species, a freshwater gastropod. (e.g., *Amphiporus*, *Annulonemertes*, *Carcinonemertes*, *Emplectonema*, *Geonemertes*, *Malacobdella*, *Ovicides*, *Paranemertes*)

ORDER POLYSTILIFERA Stylet apparatus consists of many small stylets borne on a basal shield. All species are marine, either benthic or pelagic. (e.g., *Drepanophorus*, *Nectonemertes*, *Pelagonemertes*, *Phallonemertes*, *Punnettia*)

The Nemertean Body Plan

The nemertean body plan is especially interesting, since it presents characteristics of both coelomates (e.g., the closed circulatory system and rhynchocoel) and acoelomates (e.g., the parenchyma and protonephridial system). In Chapter 3 we discussed some of the limitations of the acoelomate body plan, and we will see the results of these constraints in our examination of the flatworms (Chapter 17). Even though it is now clear that nemerteans have true coelomic cavities, these worms have relatively solid bodies. Thus, they are at least functionally acoelomate. Recall that many of the problems inherent in acoelomate architecture are related to restricted internal transport capabilities. The presence of a circulatory system in nemerteans has largely eased this problem; and the functional anatomy of many other systems is related directly or indirectly to the presence of this circulatory system. For example, nemertean protonephridia are usually intimately associated with the blood, from which wastes are drawn, rather than with the mesenchymal tissues as are flatworm protonephridia.

The increased capabilities for internal circulation and transport have allowed a number of developments that would otherwise be impossible. First, the circulatory system provides a solution to the surface-to-volume dilemma, and as a result nemerteans tend to be much larger and more robust than flatworms, having been largely relieved of the constraints of relying on diffusion for internal transport and exchange. Second, the digestive tract is complete and somewhat regionally specialized. With a one-way movement of food materials through the gut, and a circulatory system to absorb and distribute digested products, the anterior region of the gut has been freed to specialize for feeding and ingestion. Third, since the animal does not have to rely on

for more ebook/ testbank/ solution manuals requests: email 9601267374@qq.com

diffusion for transport through a loosely organized mesenchyme, that general body area is available for the development of other structures, notably the well-developed layers of muscles. In summary, the presence of a circulatory system in concert with these other changes has resulted in relatively large, active animals, capable of more complex activities than seen in the acoelomate metazoans.

This general body plan is enhanced by the presence of the unique proboscis apparatus (which usually functions in prey capture), the distinctly anterior location of the mouth, and well-developed cephalic sensory organs for prey location. Thus, while variation exists, the "typical" nemertean may be viewed as an active benthic hunter/tracker that moves among nooks and crannies preying on other invertebrates or even on some vertebrate prey and vertebrate remains.

Body Wall

The body wall of nemerteans comprises an epidermis, a dermis, relatively thick muscle layers surrounding the gut and other internal organs, and a mesenchyme of varying thickness (Figure 14.2). The epidermis is a ciliated columnar epithelium (Figure 14.2C). Mixed among the columnar cells are sensory cells (probably tactile), mucous gland cells, and basal replacement cells that may extend beneath the epidermis. Below the epidermis is the dermis, which varies greatly in thickness and composition. In some ribbon worms (e.g., the palaeonemerteans) the dermis is extremely thin or composed of only a homogeneous gel-like layer; in others (e.g., the heteronemerteans), it is typically quite thick and densely fibrous and usually includes a variety of gland cells. Beneath the dermis are well-developed layers of circular and longitudinal muscles. The organization of these muscles varies among taxa and may occur in either a two- or three-layered plan (Figure 14.3). The layering arrangement may also vary to some degree along the body length of individual animals. Internal to the muscle layers is a dense mesenchyme, although in some nemerteans the muscle layers are so thick that they nearly obliterate this inner mass. The mesenchyme

includes a gel matrix and often a variety of loose cells, fibers, and dorsoventrally oriented muscles. Figure 14.3 depicts cross-sectional views of representatives of the three main clades, showing mesenchyme thickness, muscles, placement of longitudinal nerve cords, major longitudinal blood vessels, and other features.

Support and Locomotion

In the absence of any rigid skeletal elements, the support system of nemerteans is provided by the muscles and other tissues of the body wall and by the hydrostatic qualities of the mesenchyme. These features permit dramatic changes in both length and cross-sectional shape and diameter, characteristics that are closely associated with locomotion and accommodation to cramped quarters. Most very small benthic ribbon worms are propelled by the action of their epidermal cilia. A slime trail is produced by the body wall mucous glands and provides a lubricated surface over which the worm slowly glides. Small nemerteans commonly live among the interstices of filamentous algae, under tidepool rocks, or in the spaces of other irregular surfaces such as those found in mussel beds, sand, mud, or pebble bottoms. Larger epibenthic ribbon worms and most of the burrowing forms employ peristaltic waves of the body wall muscles to propel them over moist surfaces or through soft substrata. Some of the larger forms (e.g., *Cerebratulus*) use undulatory swimming as a secondary means of locomotion, and perhaps as an escape reaction to benthic predators. Fully pelagic nemerteans (certain polystiliferan hoplonemerteans) generally drift or swim slowly. Some of the terrestrial forms produce a slime sheath through which they glide by ciliary action, and some use their proboscis for rapid escape responses.

Feeding and Digestion

Most ribbon worms are active predators on small invertebrates, but some are able to capture live fish, or even active invertebrates like small cephalopods. Some are scavengers, feeding on all sorts of decaying animal matter, including large vertebrates, and still others feed on plant material (at least under laboratory conditions). There is evidence to suggest that species of the commensal genus *Malacobdella*, which inhabit the mantle cavity of bivalve molluscs, feed largely on phytoplankton captured from their host's feeding and gas exchange currents. Field observations indicate that

for more ebook/ testbank/ solution manuals requests: email 9601267344@qq.com

the diets of predatory forms may be either extremely varied or quite restricted, depending on the species. Some species are capable of tracking prey over long distances, whereas others must locate food by direct contact. Distance prey location and assessment of food acceptability are almost certainly chemotactic responses. Ribbon worms that actually hunt and track can recognize the trails left by potential prey, and they fire their proboscis along the trail ahead of them to capture food (Figure 14.4). Similar reactions are elicited when infaunal nemerteans encounter burrows in which potential prey might be located. Surface hunters that live in intertidal areas generally forage during high tides or at night and thus avoid the threats of desiccation and visual predators. However, members of some marine genera (e.g., *Tubulanus, Paranemertes, Amphiporus*) may frequently be seen during low tides on foggy mornings, gliding over the substratum in search of prey. The rapid expulsion of their proboscis and successful prey capture can be a memorable moment of high drama for tide pool enthusiasts.

The behavior involved in the capture and ingestion of live prey is significantly different from that associated with scavenging on dead material. In predation, the proboscis is employed both in capturing prey and in moving it to the mouth for ingestion. The proboscis is everted and wrapped around the victim (Figure 14.4). The prey is not only physically held by the proboscis, but may also be subdued or killed by its toxic secretions. In the Pacific species *Paranemertes peregrina*, which feeds primarily on nereid polychaetes, the glandular epithelium of the everted proboscis secretes a potent neurotoxin. Nemerteans with an armed proboscis (Hoplonemertea) actually use the stylets to pierce the prey's body (often numerous times) to introduce the toxin. Once captured, the prey is drawn to the mouth by retraction and manipulation of the proboscis; it is usually swallowed whole. The mouth is expanded and pressed against the food, and swallowing is accomplished by peristaltic action of the body wall muscles aided by ciliary currents in the anterior region of the gut. Scavenging, in contrast, usually does not involve the proboscis. The worm simply ingests the food directly by muscular action of body wall and foregut. In some predatory hoplonemerteans (those in which the lumen of the proboscis is connected with the anterior gut lumen), the foregut itself may be everted for feeding on animals too large to be swallowed whole. In such cases, fluids and soft tissues are generally sucked out of the prey's body. Annelids and amphipod crustaceans seem to be favorite food items for many predatory nemerteans.

Courtesy of S. Stricker

FIGURE 14.4 ***Paranemertes peregrina*** **(Hoplonemertea: Monostilifera) capturing a nereid polychaete.** The proboscis is coiled around the polychaete.

Species of the hoplonemertean genus *Carcinonemertes* are ectoparasites (egg predators) on brachyuran crabs. Different species inhabit different regions of the host's body, but all migrate to the egg masses on gravid female crabs and feed on the yolky eggs. In high numbers, these egg predators can kill all of the embryos in the host's clutch. Some studies have reported up to 99% infestation rates of *Carcinonemertes errans* on the commercially important Pacific Dungeness crab (*Metacarcinus magister*), with up to 100,000 worms per host. This parasite has been implicated in past collapses of the central California Dungeness crab fishery. Several species of *Ovicides* (Carcinonemertidae) live on the abdomens of hydrothermal vent crabs in the Pacific, and *Nemertoscolex parasiticus* (Heteronemertea) lives in the coelomic fluid of the thalassematid annelid *Echiurus echiurus.*

The proboscis apparatus The proboscis apparatus is a complex arrangement of tubes, muscles, and hydraulic systems and contains a glandular epithelium with a role in prey capture (Figure 14.5). The glandular proboscis epithelium of most Palaeonemertea and Pilidiophora also contains specialized gland cells, which produce unique secretory granules with an internal hollow threadlike tubule (core) capable of extrusion, that are termed pseudocnidae. The term *pseudocnidae* refers to the superficial similarity of these structures with cnidae of Cnidaria and historically have been referred to as nematocysts, rhabdites, or barbs. The proboscis itself is an elongate, eversible, blind tube and either is associated with the foregut or opens through a separate proboscis pore. The proboscis, which can be branching in some species, may be regionally specialized and may bear stylets in various arrangements in the so-called "enoplan" nemerteans (today's Hoplonemertea) (Figure 14.5E–H). Nemertean stylets are nail-shaped structures that typically reach lengths of 50–200 μm. Each calcified stylet is composed of a central organic matrix surrounded by an inorganic cortex composed of calcium phosphate. The stylets are formed within large epithelial cells called styletocytes. Because growing ribbon worms must replace

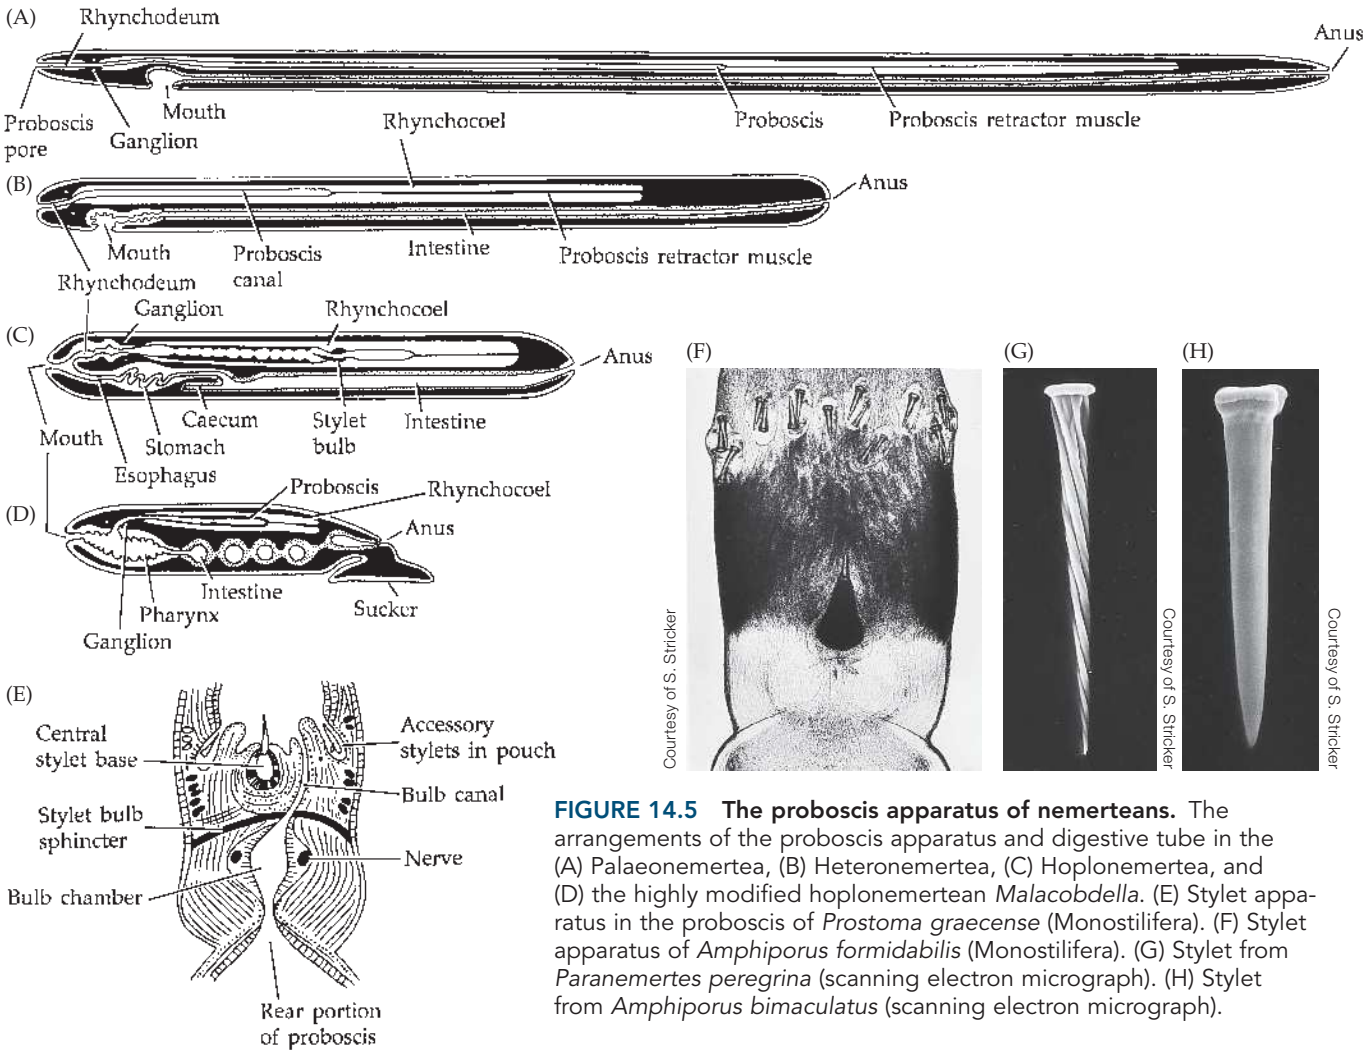

FIGURE 14.5 The proboscis apparatus of nemerteans. The arrangements of the proboscis apparatus and digestive tube in the (A) Palaeonemertea, (B) Heteronemertea, (C) Hoplonemertea, and (D) the highly modified hoplonemertean *Malacobdella*. (E) Stylet apparatus in the proboscis of *Prostoma graecense* (Monostilifera). (F) Stylet apparatus of *Amphiporus formidabilis* (Monostilifera). their stylets with new larger ones, and because they often lose the stylet during prey capture, new stylets are continuously produced in reserve stylet sacs and stored until needed, whereupon they are transported and affixed in their proper final position.

The basic structure and action of the proboscis are most easily described where the apparatus is entirely separate from the gut. As shown in Figure 14.5A,B, the proboscis pore leads from the outside directly into the anterior proboscis lumen, called the rhynchodeum, the lining of which is continuous with the epidermis. Posterior to the rhynchodeum, the lumen continues as the proboscis canal that is surrounded by the muscular wall of the proboscis itself; these muscles are derived from the muscles of the body wall. The proboscis is surrounded by a closed, fluid-filled, coelomic space called the rhynchocoel, which in turn is surrounded by additional muscle layers. The inner blind end of the proboscis is connected to the posterior wall of the rhynchocoel by a proboscis retractor muscle. In a few taxa (e.g., *Gorgonorhynchus*), there is no retractor muscle, and eversion and retraction are accomplished hydrostatically. In hoplonemerteans the proboscis shares the opening with the digestive system (Figure 14.5C,D).

Eversion of the proboscis (Figure 14.6) is accomplished by contraction of the muscles around the rhynchocoel; this increases the hydrostatic pressure within the rhynchocoel itself, squeezing on the proboscis and causing its eversion. The everted proboscis moves with the muscles in its wall; the proboscis is retracted back inside the body by the coincidental relaxation of the muscles around the rhynchocoel and contraction of the proboscis retractor muscle. The retracted proboscis may extend nearly to the posterior end of the worm, and usually only a portion of it is extended during eversion.

Digestive system Nemerteans have a complete through gut with an anus (Figures 14.6 and 14.7). Associated with the one-way movement of food from mouth to anus we find various degrees of regional specialization (both structural and functional) in the guts of ribbon worms. The mouth leads inward to an ectodermally derived foregut (stomodeum) consisting of a bulbous buccal cavity, sometimes a short esophagus,

for more ebook/ testbank/ solution manuals requests: email 9601267344@qq.com

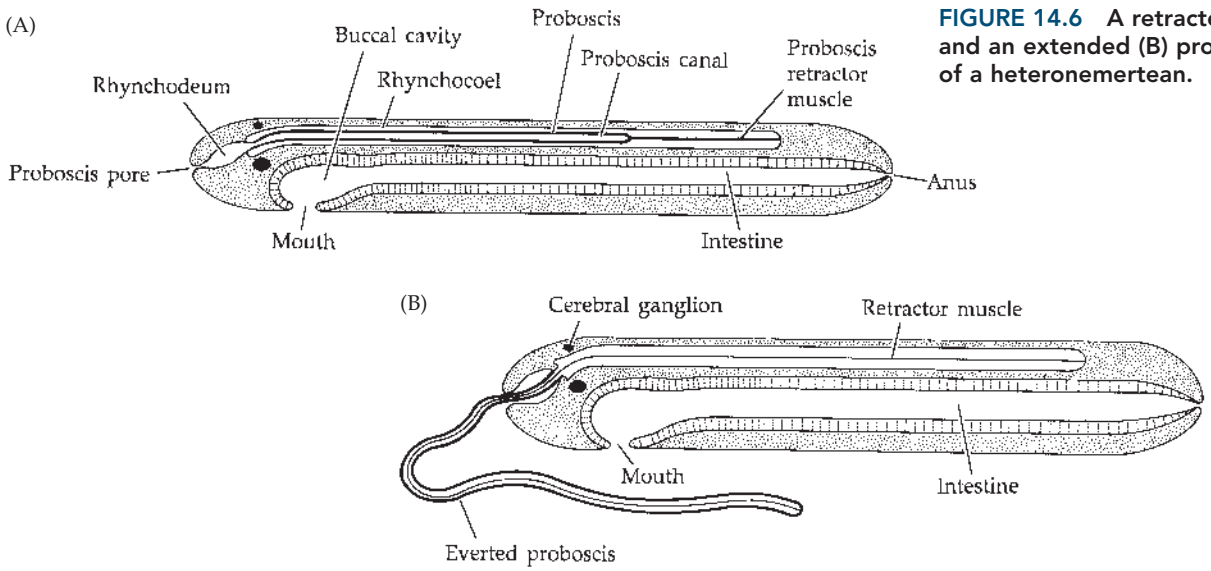

FIGURE 14.6 **A retracted (A) and an extended (B) proboscis of a heteronemertean.**

and a stomach. The stomach leads to an elongate intestine or midgut, which is more or less straight but usually bears numerous lateral diverticula. In *Malacobdella*, the intestine is loosely coiled and lacks diverticula; diverticula are also lacking in the strange "segmented" *Annulonemertes*. At the posterior end of the intestine is a short ectodermally derived hindgut (proctodeum) or rectum, which terminates in the anus. Elaborations on this basic plan are common in certain taxa and may include various ceca arising from the stomach or from the intestine at its junction with the foregut.

The entire digestive tube is ciliated, the foregut more densely than the midgut. The gut epithelium is basically columnar, mixed with gland cells. The foregut contains a variety of mucus-producing cells, sometimes multicellular mucous glands, and occasionally enzymatic gland cells in the stomach region. The midgut is lined with vacuolated ciliated columnar cells; these are phagocytic and bear microvilli, greatly increasing their surface area. Enzymatic gland cells are abundantly mixed with the ciliated cells of the midgut. The hindgut typically lacks gland cells. Food is moved through the digestive tract by cilia and by the action of the body wall muscles; there are usually no muscles in the gut wall itself, except in the foregut of some heteronemerteans.

The process of digestion in nemerteans is a two-phase sequence of protein breakdown. The first step involves the action of endopeptidases released from gland cells into the gut lumen. This extracellular digestion is quite rapid and is followed by phagocytosis (and probably pinocytosis) of the partially digested material by the ciliated columnar cells of the midgut. Protein digestion is completed intracellularly by exopeptidases within the food vacuoles of the midgut epithelium. Lipases have been discovered in at least one species (*Lineus ruber*), and carbohydrases are known in the omnivorous commensal *Malacobdella*. Food is stored primarily in the form

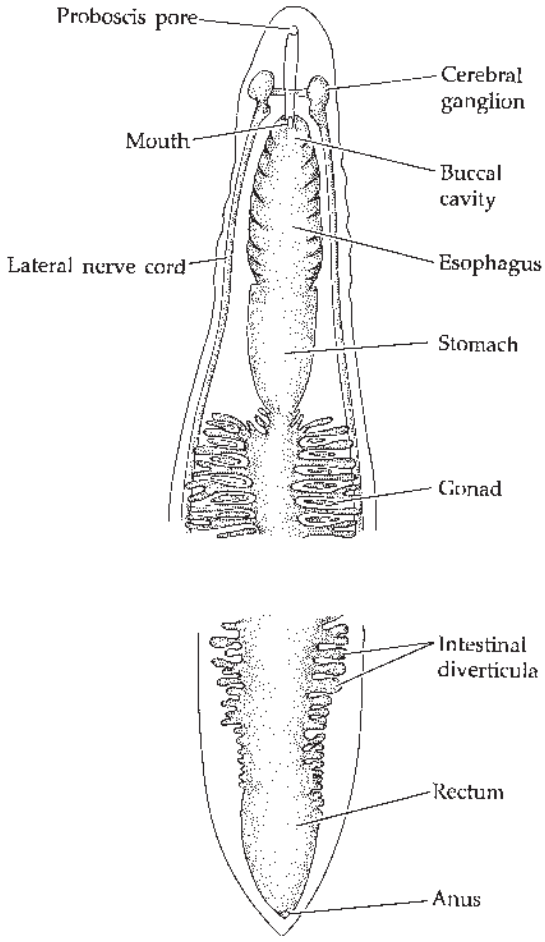

FIGURE 14.7 **A nemertean digestive system.** Anterior and posterior regions of the gut of *Carinoma* (Palaeonemertea) (ventral view).

of fats, and to a much lesser extent as glycogen, in the wall of the midgut. Transportation of digested materials throughout the body is accomplished by the circulatory system, which absorbs these products from the cells lining the intestine. Indigestible materials are moved through the gut and out the anus.

Circulation and Gas Exchange

We have mentioned briefly the evolutionary and adaptive significance of the circulatory system in nemerteans and its general relationship to other systems and functions. This closed system consists of vessels and thin-walled spaces called lacunae (Figure 14.2B). There is a good deal of variation in the architecture of nemertean circulatory systems (Figure 14.8). The simplest arrangement occurs in certain palaeonemerteans in which a single pair of longitudinal vessels extends the length of the body, connecting anteriorly by a cephalic lacuna and posteriorly by an anal lacuna. Elaboration on this basic scheme may include transverse vessels between the longitudinal vessels, enlargement and compartmentalization of the lacunar spaces, and the addition of a middorsal vessel. The walls of the blood vessels are only slightly contractile, and general body movements generate most of the blood flow. There is no consistent pattern to the movement of blood through the system; it may flow either anteriorly or posteriorly in the longitudinal vessels, and currents often reverse directions.

The blood consists of a colorless fluid in which various cells are suspended. These cells can include pigmented corpuscles (yellow, orange, green, red), at least some of which contain hemoglobin, and a variety of so-called lymphocytes and leukocytes of uncertain function. The anatomical association of the circulatory system with other structures, as well as the composition of the blood, suggest several circulatory functions. Although conclusive evidence is lacking, the circulatory system appears to be involved with the transport of nutrients, gases, neurosecretions, and excretory products. Some intermediary metabolism probably occurs in the blood, as several appropriate enzymes have been identified in solution. The blood may also serve as an aid to body support through changes in hydrostatic pressure within the vessels and lacunar spaces. There is some evidence to support the idea that the blood may also function in osmoregulation.

Gas exchange in nemerteans is epidermal and does not involve any special structures. Oxygen and carbon dioxide diffuse readily across the moist body surface, which is usually covered with mucous secretions. Some robust forms (e.g., *Cerebratulus*) augment this passive exchange of gases across the skin with regular irrigation of the foregut, where there is an extensive system of blood vessels. In those species in which hemoglobin occurs, this pigment probably aids in oxygen transport or storage within the blood.

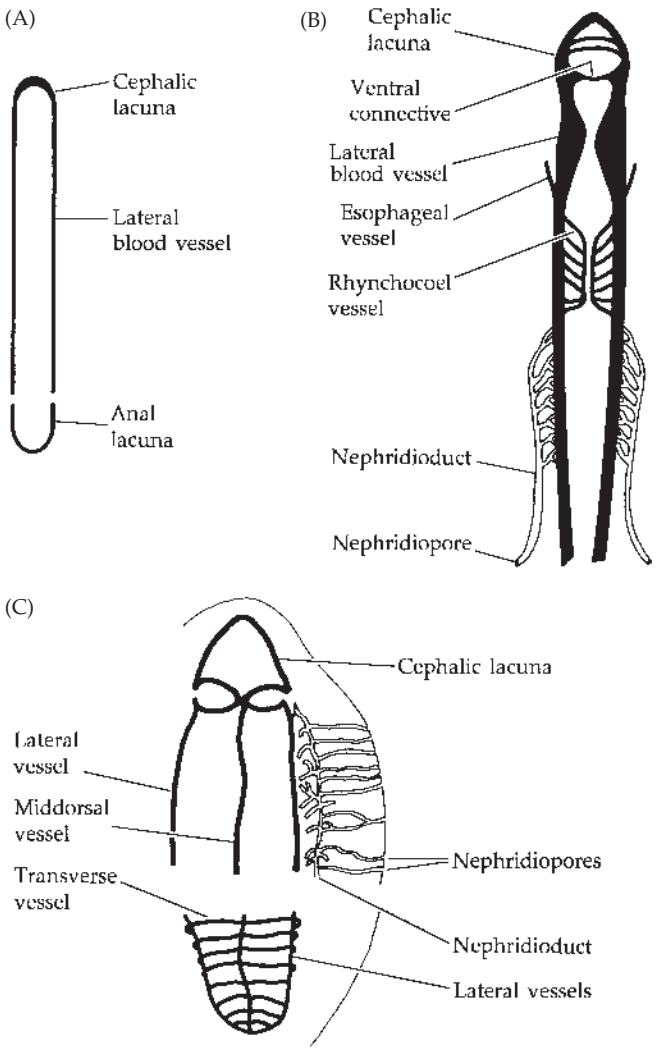

FIGURE 14.8 Nemertean circulatory systems. (A) The simple circulatory loop of *Cephalothrix* (Palaeonemertea) consists of a pair of lateral blood vessels connected by cephalic and anal lacunae. (B) The complex circulatory system of *Tubulanus* (Palaeonemertea). Note the intimate association of the nephridial system with the lateral blood vessels. (C) The circulatory system of *Amphiporus* (Hoplonemertea: Monostilifera) includes a middorsal vessel and numerous transverse vessels.

Excretion and Osmoregulation

The excretory system of most nemerteans consists of two to thousands of flame bulb protonephridia (Figures 14.8 and 14.9) similar to those found in free-living flatworms. However, apparently the deep-sea pelagic hoplonemerteans lack protonephridia altogether. The flame bulbs are usually intimately associated with the lateral blood vessels or less commonly with other parts of the circulatory system. The nephridial units are often pressed into the blood vessel walls, and in some instances the walls are actually broken down such that the nephridia are bathed directly in blood. In the simplest case, a single pair of flame bulbs leads to two nephridioducts, each with its own laterally placed

for more ebook/ testbank/ solution manuals requests: email 9601267374@qq.com

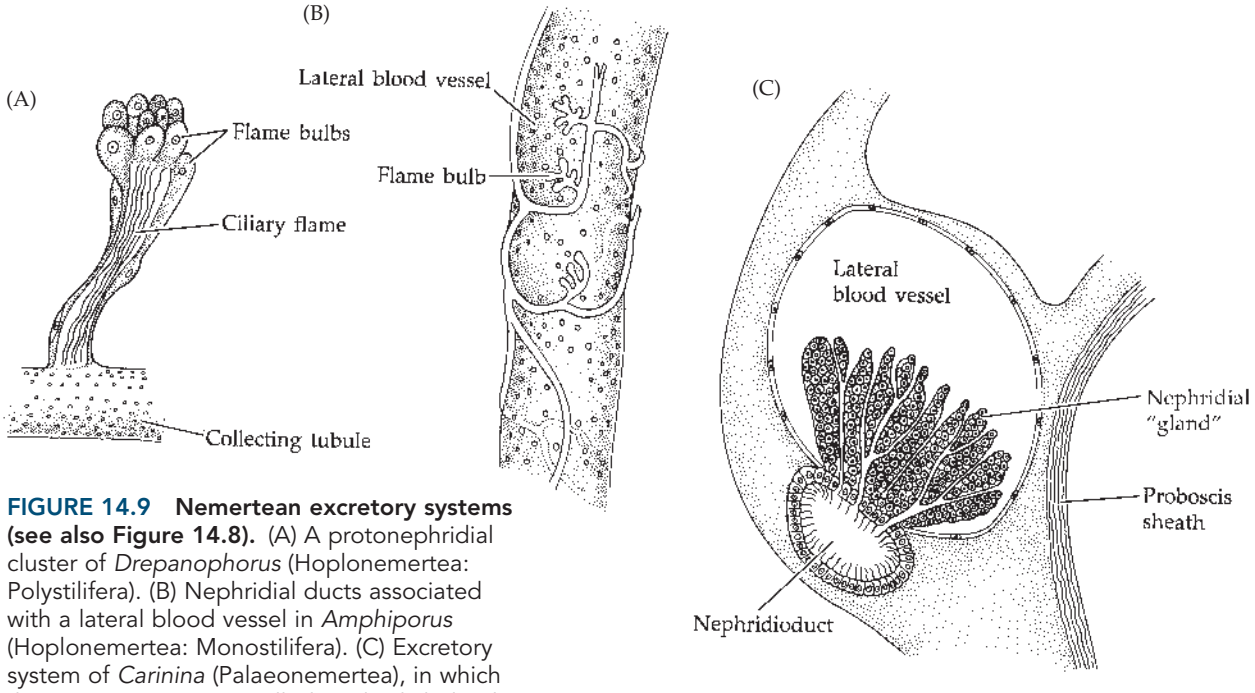

FIGURE 14.9 Nemertean excretory systems (see also Figure 14.8). (A) A protonephridial cluster of *Drepanophorus* (Hoplonemertea: Polystilifera). (B) Nephridial ducts associated with a lateral blood vessel in *Amphiporus* (Hoplonemertea: Monostilifera). (C) Excretory system of *Carinina* (Palaeonemertea), in which the secretory units (so-called nephridial gland) project into the lumen of the lateral blood vessel.

nephridiopore. More complex conditions include rows of single flame bulbs or clusters of flame bulbs with multiple ducts. In some species, the walls of the nephridioducts are syncytial and lead to hundreds or even thousands of pores on the epidermis. The most elaborate conditions occur in certain terrestrial nemerteans where approximately 70,000 clusters of flame bulbs (six to eight in each cluster) lead to as many surface pores. In some heteronemerteans (e.g., *Baseodiscus*), the excretory system discharges into the foregut.

The functioning of nemertean protonephridia in the excretion of metabolic wastes has not been well studied. The close association of the flame bulbs with the circulatory system suggests that nitrogenous wastes (probably ammonia), excess salts, and other metabolic products are removed from the blood as well as from the surrounding mesenchyme by the nephridia. If such is the case, it explains again the significance of the circulatory system in overcoming surface-to-volume problems and the constraints of simple diffusion on body size. Relatively active animals produce large amounts of metabolic wastes. Dependence on diffusion alone would seriously limit any increase in body bulk, but the transport of these wastes from the tissues to the protonephridial system by circulatory vessels greatly eases this limitation. One of the most remarkable evolutionary achievements of the nemerteans has been their ability to grow to great size, particularly in length, without segmentation or the development of a large body cavity.

There is some morphological and experimental evidence that the protonephridia also play an important role in osmoregulation, especially in freshwater and terrestrial ribbon worms. It is in some of these forms, which are subjected to extreme osmotic stress, that the most elaborate excretory systems are found, and these systems are probably associated with water balance. Furthermore, it appears that there may be a very complex interaction between the nervous system (neurosecretions), the circulatory system, and the nephridia to facilitate osmoregulatory mechanisms, but the details remain to be studied. Some members of Heteronemertea and Hoplonemertea have invaded fresh water and must combat water influx from their strongly hypotonic surroundings. Members of some genera (e.g., *Geonemertes, Microplana*) are terrestrial, although restricted to moist shady habitats where they avoid serious problems of desiccation. In addition, they tend to cover their bodies with a mucous coat that reduces water loss. Those forms that inhabit marine subtidal or deep-water environments, or are endosymbiotic (one genus of Heteronemertea and several genera of Hoplonemertea), face little or no osmotic stress. But the many species found intertidally do face periods of exposure to air and to lowered (or elevated) salinities. Their soft bodies are largely unprotected, and they are relatively intolerant of fluctuations in environmental conditions. Intertidal nemerteans rely strongly on behavioral attributes to survive periods of potential osmotic stress and remain in moist areas during low tide periods. Burrowing in soft, water-soaked substrata or living among algae or mussel beds, in cracks and crevices, or in other areas that retain seawater at low tide are lifestyles illustrating how habitat preference and behavior prevent exposure to stress.

In addition, most intertidal nemerteans are somewhat negatively phototactic, and many restrict their activities to night hours or to foggy or overcast mornings and evenings. A marine meiofaunal species from North Carolina lives in sediments at about 1 m depth above high tide level, probably relying on the water that fills the interstices of sand by capillarity.

Nervous System and Sense Organs

The basic organization of the nemertean nervous system reflects a relatively active lifestyle. Nemerteans are cephalized, especially in the anterior placement of the mouth and feeding structures, and we find related concentrations of sensory and other nervous elements in the head. The central nervous system of ribbon worms consists of a complex cerebral ganglion from which arises a pair of ganglionated, longitudinal (lateral) nerve cords (Figure 14.10A). The cerebral ganglion is formed of four attached lobes that encircle the proboscis apparatus (not the gut, as in many other invertebrates). Each side of the cerebral ganglion includes a dorsal and a ventral lobe; the two sides are attached to one another by dorsal and ventral connectives. Several pairs of sensory nerves provide input directly to the cerebral ganglion from various cephalic sense organs. The main longitudinal nerve cords arise from the ventral lobes of the cerebral ganglion and pass posteriorly; they attach to each other at various points by branched transverse connectives and terminally by an anal commissure. The longitudinal nerves also give rise to peripheral sensory and motor nerves along the length of the body. Elaboration on this basic plan includes additional longitudinal nerve cords, frequently a middorsal one arising from the dorsal commissure of the cerebral ganglion, and a variety of connectives, nerve tracts, and plexus.

As noted in the classification scheme, the positions of the major longitudinal nerve cords vary among the nemertean orders (Figure 14.3). These changes in the position of the nerve cords from epidermal to mesenchymal correspond to general increases in body complexity and tendencies toward specialization. Most workers agree that these differences reflect a plesiomorphic (epidermal) to apomorphic (subepidermal) trend among these taxa.

Ribbon worms possess a variety of sensory receptors, many of which are concentrated at the anterior end and associated with an active, typically hunting lifestyle and with other aspects of their natural history. Nemerteans are very sensitive to touch. This tactile sensitivity plays a role in food handling, avoidance responses, locomotion over irregular surfaces, and mating behavior. Several types of modified ciliated epidermal cells are scattered over the body surface (especially abundant at the anterior and posterior ends) and are presumed to have a tactile function. The cells occur either singly or in clusters; some of the latter types are located in small depressions and can be thrust out from the body surface.

The eyes of ribbon worms are located anteriorly and number from two to several hundred; they can be arranged in various patterns (Figure 14.10B). Most of these ocelli are of the inverted pigment-cup type, similar to those seen in flatworms, although a few species possess lensed eyes. As discussed in Chapter 3, these types of eyes typically are sensitive to light intensity and light direction. They help the nemerteans avoid bright light and potential exposure to predators or environmental stresses.

Much of the sensory input important to nemerteans is chemosensory. These worms are very sensitive to dissolved chemicals in their environment and employ this sensitivity in food location, probably mate location, substratum testing, and general water analysis. Probably all nemerteans respond to contact with chemical stimuli, and many are capable of distance chemoreception of materials in solution. At least three different nemertean structures have been implicated (some through speculation) in the initiation of chemotactic responses: cephalic slits or grooves, cerebral organs, and frontal glands (= cephalic glands) (Figures 14.10B–D). **Cephalic slits** are furrows of variable depth that occur laterally on the heads of many ribbon worms (see also Figure 14.1E). These furrows are lined with a ciliated sensory epithelium supplied with nerves from the cerebral ganglion. Water is circulated through the cephalic slits and over this presumably chemosensory epithelial lining.

Most nemerteans possess a pair of the remarkably complex **cerebral organs** (Figure 14.10C). The core of each cerebral organ is a ciliated epidermal invagination (the cerebral canal), which is expanded at its inner end. These canals lead laterally to pores within the cephalic slits (when present) or else directly to the outside via separate pores on the head. The inner ends of the canals are surrounded by nervous tissue of the cerebral ganglion, and by glandular tissue, and they are often intimately associated with lacunar blood spaces. Cilia in the cerebral canal circulate water through the open portion of the organ; this activity intensifies in the presence of food. Nemerteans presumably use this mechanism when hunting and tracking prey or in other chemotactic responses. The association of the cerebral canals with glandular, nervous, and circulatory structures has led some workers to suggest an endocrine and/or neurosecretory function for the cerebral organs. Other suggestions have included auditory, gas exchange, excretory, and tactile activities. Cerebral organs are absent in several genera, including the symbiotic *Carcinonemertes* and *Malacobdella,* and in the pelagic hoplonemerteans.

In the region anterior to the cerebral ganglion, large **frontal glands** open to the outside through a pitlike frontal sense organ (Figure 14.10D). These structures receive nerves from the cerebral ganglion and appear

(D) Clusters of frontal glands occur in the anterior end of a hoplonemertean (longitudinal section).

to be chemosensory, but solid evidence for this suggestion is lacking. Finally, statocysts also occur in some nemerteans, including pelagic forms where geotaxis is an obvious advantage.

Reproduction and Development

Asexual processes Many nemerteans show remarkable powers of regeneration, and nearly all species can regenerate at least posterior portions of the body, while the ability to regenerate the head may have evolved multiple times within the phylum. Those with the greatest regenerative abilities are certain species of *Lineus*, which engage in a remarkable form of asexual reproduction on a regular basis by undergoing multiple transverse fission events into numerous fragments. The fragments are often extremely small, and the process is sometimes referred to simply as **fragmentation**. The small pieces often form mucous cysts within which the new worms regenerate; larger pieces grow into new animals without the protection of cysts. In some nemerteans only anterior fragments can regenerate into new worms.

Sexual reproduction Nemerteans show remarkable variation in reproductive and developmental strategies. Most ribbon worms are gonochoristic, although protandric and even simultaneous hermaphrodites are known. The reproductive system of nemerteans

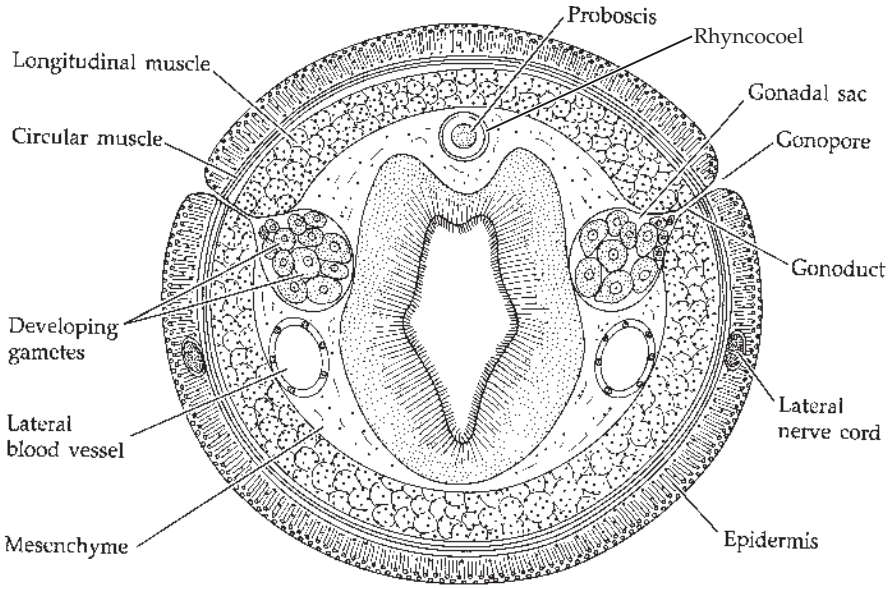

FIGURE 14.11 Arrangement of gonads in the palaeonemertean *Carinina* (cross section). Note the position of a pair of gonads in the mesenchyme. See also Figure 14.7.

has gonads that are simply specialized patches of mesenchymal tissue arranged serially along each side of the intestine, alternating with the midgut diverticula (Figure 14.11). In *Malacobdella* and a few others, the gonads are more or less packed within the mesenchyme (Figure 14.1H). In most nemerteans the development of gonads occurs along nearly the entire length of the body, but in a few species they are restricted to certain regions, usually toward the anterior end. The gonads begin to enlarge and hollow just prior to the onset of breeding activities. Specialized cells in the walls of the rudimentary ovaries and testes proliferate eggs and sperm into the lumina of the enlarging gonadal sacs. In females additional special cells are responsible for yolk production. There is evidence that maturation is under neurosecretory hormonal control, at least in some species. The secretions are probably from the cerebral organ complex.

With the proliferation of gametes, the gonadal sacs expand to almost fill the area between the gut and the body wall. When the animals are nearly ready to spawn, mating behavior is initiated and the worms become increasingly active. As mentioned earlier, mate location probably depends on chemotactic responses. The same is apparently true of spawning itself, at least for some species, because the presence of a ripe conspecific stimulates the release of gametes from other mature individuals. Experimental evidence indicates that physical contact is not necessary for such a spawning response; thus, some sort of pheromone is probably involved. In nature, however, spawning usually occurs in concert with actual physical contact; tactile responses evidently follow chemotactic mate location. During such mating activities, veritable knots of scores of worms may writhe in a mucus-covered mating mass. The coordinated release of ripe gametes under such conditions ensures successful fertilization. The gametes are extruded through temporary pores or through ruptures in the body wall. Rupture occurs by contraction of the body wall muscles or of special mesenchymal muscles surrounding the gonads.

Fertilization is often external, either free in the seawater or in a gelatinous mass of mucus produced by the mating worms. In the latter situation, actual egg cases are frequently formed, and part or all of the embryonic development occurs within them (Figure 14.12). Internal fertilization occurs in certain nemerteans. In some cases the sperm are released into the mucus surrounding the mating worms, and then they move into the ovaries of the females; once fertilized, the eggs are usually deposited in egg capsules, where they develop, although some Antarctic species brood with cocoons. Some terrestrial species are ovoviviparous; the embryos are retained within the body of the female and development is fully direct—an obvious advantage for surviving on land. Ovoviviparity is also known in a few other nemerteans, including deep-sea pelagic forms. Since the population densities of these pelagic worms are extremely low, they must presumably capitalize

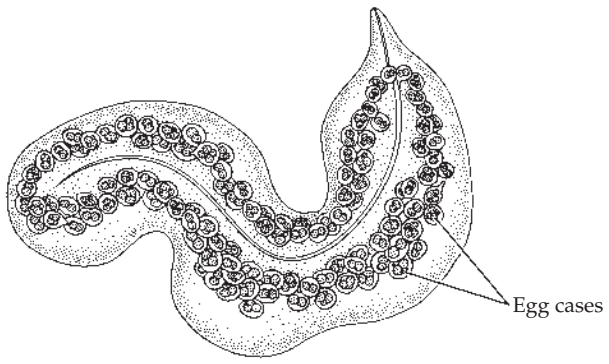

FIGURE 14.12 Egg cases in the heteronemertean *Lineus ruber*.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

on the relatively infrequent encounters of males and females and ensure successful fertilization. In a few cases the males are equipped with suckers, which are used to clasp the female, or, rarely, with a protrusible penis, which is used to transfer sperm.

Regardless of the method of fertilization, development through the gastrula is similar among most of the nemerteans studied to date. Cleavage is holoblastic and spiral, producing either three (*Tubulanus*) or, more typically, four quartets of micromeres. A coeloblastula forms, and this often shows the rudiments of an apical ciliary tuft associated with a slight thickening of the blastula wall at or near the animal pole. Gastrulation is usually by invagination of the macromeres and the fourth micromere quartet to produce a coelogastrula. In at least one genus (*Prostoma*, a hermaphroditic freshwater form), gastrulation is by unipolar ingression of the vegetal macromeres; this movement produces a stereogastrula, which later hollows. Mesoderm may originate in several ways, and in some cases the processes are poorly understood. In *Cerebratulus lacteus*, one of the best-studied nemerteans developmentally, ectomesoderm is derived from two blastomeres (3a and 3b), which give rise to the extensive array of the larval muscle cells. *Cerebratulus lacteus* also possesses a true mesentoblast (4d), which gives rise to a pair of small mesodermal bands, and scattered mesenchymal cells. This dual origin of the mesoderm, as both ectomesoderm and endomesoderm, appears to be a condition present in all spiralians. The gut is formed by all the fourth quartet micromeres as well as the vegetal macromeres (4A, 4B, 4C, 4D). Unraveling the embryogenesis of nemerteans has led to the discovery that the rhynchocoel is formed by schizocoely, and it therefore represents a true coelomic cavity.

Developmental strategies are also varied among nemerteans. Members of Palaeonemertea and Hoplonemertea undergo direct development within egg cases. The embryos in these groups develop gradually to juvenile worms without any abrupt metamorphosis (Figure 14.13) but may have multiple invaginations and shedding of a transitory larval epidermis. These embryos are nourished by yolk until they hatch, whereupon they commence feeding. This is especially true of the palaeonemerteans, in which the proboscis apparatus is not fully formed at hatching (the proboscis of heteronemerteans and *Malacobdella* is functional at the time of hatching).

A recent study of embryogenesis of the palaeonemertean *Carinoma tremaphoros* has shown large squamous cells covering the entire larval surface except for the apical and posterior regions. Although apical and posterior cells continue to divide, in the large surface cells cleavage is arrested and they form a contorted preoral belt. Based on the position, cell lineage, and fate, it has been suggested that this belt corresponds to the prototroch of other trochozoans.

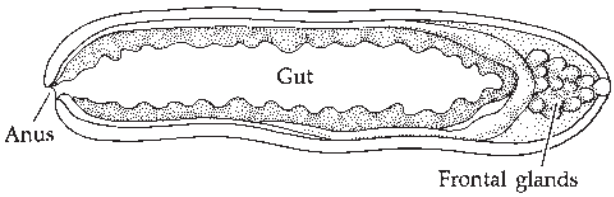

FIGURE 14.13 Hatching form produced by direct development in *Prosorhochmus*, a monostiliferan hoplonemertean.

Members of the subclass Pilidiophora undergo a bizarre and fascinating pattern of indirect development. Most species in this clade produce a free-swimming, planktotrophic larva called the **pilidium** (Figure 14.14). At this stage the gut is incomplete, consisting of a mouth located between a pair of flaplike ciliated lobes, a stomodeal foregut, and a blind intestine; the anus forms later as a proctodeal invagination. Interestingly, the intestinal diverticula of nemerteans do not form as evaginations of the gut wall but are produced by medial encroachments of mesenchyme, which press in the gut wall, thus creating the diverticula. As the pilidium swims and feeds, a series of invaginations in the larval ectoderm (Figure 14.14B) eventually pinch off internally to produce the presumptive adult ectoderm. Perhaps the most striking characteristic of the pilidium is the way the juvenile worm develops inside the larva from a series of isolated rudiments, called the imaginal discs. The paired cephalic discs, cerebral organ discs, and trunk discs originate as invaginations of larval epidermis and subsequently grow and fuse around the larval gut to form the juvenile (Figure 14.14C). The fully formed juvenile ruptures the larval body and, more often than not, devours the larva during catastrophic metamorphosis. In this way, the animal prepares for benthic life before it faces the rigors of settlement. When development is completed, the larval skin is shed and the juvenile assumes its life on the sea floor. Pilidia from different species vary in shape, size, and color. Modifications of pilidial development include **Desor's larva** in *Lineus viridis*, **Schmidt's larva** in *Lineus ruber*, and **Iwata's larva** in several *Micrura* species. Development of Desor's and Schmidt's larva is encapsulated, while the others have planktonic lecithotrophic development. In all of these cases, the pilidial lobes are lacking, the blastocoel is reduced, the larva does not feed, but similar to the canonical pilidium, the juvenile develops via imaginal discs.

Nemertean Phylogeny

The fossil record is, unfortunately, of little use in establishing the origin of nemerteans in geological time, and only one species of crown-group Nemertea, *Archisymplectes rhothon*, has been suggested based on multiple fossils from the Pennsylvanian of Illinois and

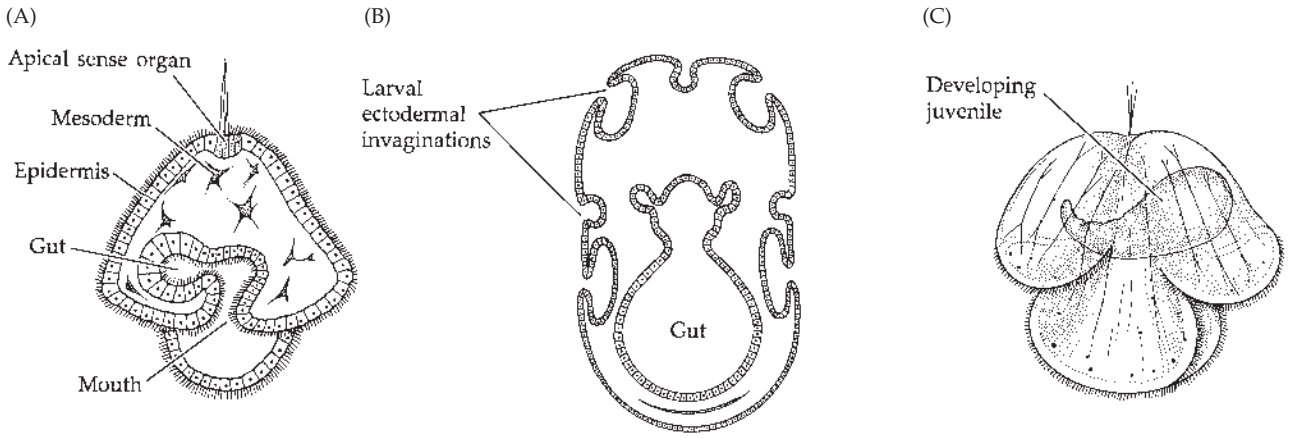

FIGURE 14.14 Development of a pilidium larva. (A) Pilidium larva (sagittal section). (B) A pilidium larva (transverse section) during invagination of larval ectoderm to form adult skin. (C) Late pilidium larva with juvenile formed within.

the Mississippian of Montana (Carboniferous). But, nemerteans obviously diverged sometime after the origin of the spiralian bilateral condition. Although now viewed to be part of the spiralian clade, related to other phyla with trochophore larvae, nemerteans had long been considered to be related to flatworms (Chapter 17). However, this idea is refuted by the discovery of the coelomic nature of the nemertean rhynchocoel and blood vessels, which place them closer to other phyla of coelomate spiralians. An older view is that nemerteans arose from an early archoöphoran "turbellarian" stock, perhaps sharing common ancestry with the macrostomid flatworms. The nemerteans and free-living platyhelminths display a number of similarities including protonephridia, types of ocelli, certain histological characteristics (especially of the epidermis), and the general organization of the nervous system. Furthermore, various ciliated slits and depressions among free-living flatworms resemble the cephalic slits and similar structures of the nemerteans. Some flatworms possess frontal (cephalic) glands long thought to be homologous to those of ribbon worms, but these could be symplesiomorphic for Spiralia or they could be convergences.

Their mode of early egg cleavage also places nemerteans as clear members of the clade Spiralia, and interpretations of the arrested cells of some embryos suggest a relationship to phyla with trochophore larvae—a relationship otherwise unsupported by any other anatomical characters. This is why their phylogenetic placement had been in flux for quite some time. However, molecular data strongly suggest a relationship to Mollusca, Annelida, and the lophophorate phyla (and probably also the Entoprocta).

The phylogenetic relationships among the various taxa of Nemertea have been examined in detail in the past few years and now include a phylogenomic analysis using hundreds of genes (Figure 14.15). These new studies are largely congruent with some of the traditional classifications, but they have found paraphyly of the former class Anopla, and they include some important rearrangements, such as the placement of the monospecific family Hubrechtiidae (*Hubrechtia desiderata*) as the sister group of the remaining Heteronemertea and not as a member of Palaeonemertea, as well as the placement of the former monogeneric order Bdellonemertea (*Malacobdella*) within the order Monostilifera. The former result is not really that surprising, as species of Hubrechtiidae have a mosaic of palaeonemertean and heteronemertean characters and some authors have considered them a "transitional stage" between palaeonemerteans and basal heteronemerteans. Furthermore, the new evolutionary tree implies that certain characters found in the former Anopla are actually symplesiomorphies for Nemertea, including the unarmed proboscis and the separate openings of the mouth and proboscis. Within Hoplonemertea, Monostilifera appear divided into two clades, Cratenemertea and Distromatonemertea, whereas Polystilifera splits into the clades Pelagica and Reptantia.

One of the principal structural trends among the nemerteans is the internalization of the major longitudinal nerve cords. We assume that the earliest ribbon worms possessed epidermal nerve cords, as do some modern palaeonemerteans. Palaeonemerteans and pilidiophorans retain the plesiomorphic feature of the placement of the mouth posterior to the cerebral ganglion. The relatively simple and unarmed proboscis and the placement of the nerve cords external to the mesenchyme suggest further that these clades retain the plesiomorphic character states among the ribbon worms. Pilidiophorans acquired indirect development, the unique formation of the double larval and adult

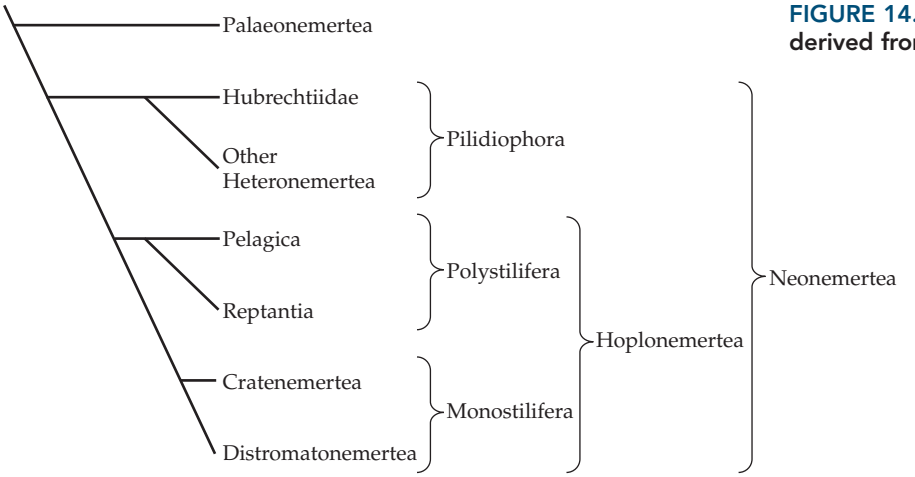

FIGURE 14.15 **Phylogeny of Nemertea derived from recent analyses of molecular data.**

ectoderm during metamorphosis, and the evolution of their unique arrangement of body wall muscles. The encapsulation, and thus functionally direct development, of those heteronemerteans with a Desor larva is almost certainly a secondary abandonment of free pilidial larval life.

The hoplonemerteans show some distinct changes from the groups mentioned so far. Most notable are the regional specialization and armature of the proboscis, the mesenchymal position of the nerve cords, and the placement of the mouth in a more anterior position. *Malacobdella*, formerly constituting the Bdellonemertea, is a specialized offshoot of Monostilifera that displays significant modification for an endosymbiotic lifestyle, including simplification of the proboscis, coiling and increased relative length of the gut (probably associated with their herbivorous habits), a posterior body sucker, and decreased body length.

Chapter Summary

This chapter introduced you to the lophotrochozoan phylum Nemertea, a group of invertebrates often overlooked or ignored in studies of marine diversity. However, ribbon worms are a major group of marine predators and scavengers, with 1,300 described species, and are one of the few animal phyla to have colonized freshwater and terrestrial environments. Nemerteans include what is considered by most the longest animal ever recorded (30 meters), although many species are small or even microscopic. Of all the animal phyla, nemerteans are unique in presenting a compact body and protonephridial excretory system, similar to that of flatworms, while possessing coeloms, as evidenced by their rhynchocoel and their closed circulatory system. The rhynchodeal apparatus is a unique characteristic of nemerteans, used for capturing prey. They can also be beautifully colored, can maintain commensal relationships with many other invertebrates, and can even display parental care. While clearly possessing spiral cleavage, their late developmental modes are varied, as are the ecological niches they inhabit.

CHAPTER 15

Phylum Annelida

The Segmented (and Some Unsegmented) Worms

This chapter treats of the segmented worms, or Annelida (Greek, *anellus*, "ringed"), which comprise about 20,000 described species. Annelids include the familiar earthworms and leeches, as well as various marine "sand worms," "tube worms," and an array of worms with other descriptors (Figures 15.1, 15.2, and 15.3). Some are tiny animals of the meiofauna; others, such as certain Southern Hemisphere earthworms and some marine species, can exceed 3 m in length.

Annelids have successfully occupied virtually all habitats where sufficient water is available. They are particularly ubiquitous in the sea but also abound in fresh water, and many occupy damp terrestrial environments. There are also parasitic, mutualistic, and commensal species. Their success is no doubt due in part to the evolutionary plasticity of their segmented bodies and use of a wide variety of life histories and feeding strategies. Most annelids are characterized by having a head followed by a segmented body in which most internal and external parts are repeated with each segment, a condition referred to as **serial homology**. This term refers to body structures with the same genetic and developmental origins that arise repeatedly during the ontogeny of an organism. In annelids this repetition of homologous body structures results in **metamerism**—body segmentation that arises by way of **teloblastic development** (the proliferation of paired, segmental mesodermal bands from teloblast cells at a posterior growth zone in the embryo). There are some dramatic exceptions to this for several annelid groups that have lost their metameric tendencies or transformed from having an obviously segmented body (e.g., Thalassematidae and Sipuncula). Annelids are triploblastic coelomate

This chapter, except for the Sipuncula, was revised by Greg Rouse.

BOX 15A Characteristics of the Phylum Annelida

1. Bilaterally symmetrical, vermiform, protostomes; terrestrial, freshwater, and marine
2. Segmented (segmentation absent in some groups, e.g., Sipuncula, Thalassematidae); segments arising by teloblastic growth
3. Development typically protostomous, with holoblastic, spiral, schizocoelous embryogeny
4. Digestive tract complete, usually with regional specialization (secondarily lost in some groups)
5. With a closed circulatory system (secondarily lost in some groups) and respiratory pigments that may include hemoglobin, chlorocruorin, and hemerythrin
6. Most adults possessing metanephridia or, less commonly, protonephridia
7. Nervous system well developed, with a dorsal cerebral ganglion, circumenteric connectives, and ventral ganglionated nerve cord(s)
8. Typically with lateral, segmentally arranged epidermal chaetae (absent in some, e.g., Sipuncula)
9. In most, head composed of presegmental prostomium and peristomium (often with body segments fused to it; peristomium may be reduced), not observed in nonsegmented groups
10. Gonochoristic or hermaphroditic; development indirect or direct; often with trochophore larva

worms with a complete gut (with few exceptions), a closed circulatory system (again with some exceptions), a well-developed nervous system, and excretory structures in the form of protonephridia or, more commonly, metanephridia (Box 15A). Marine annelids typically produce trochophore larvae, a feature shared with several other protostome taxa (e.g., Mollusca, Nemertea, Entoprocta). The story of annelid diversity and success is one of variation on this basic theme.

Taxonomic History and Classification

As mentioned in earlier chapters, the roots of modern animal classification can be traced to Linnaeus (1758), who placed all invertebrates except insects in the taxon Vermes. In 1802, Lamarck established the taxon Annelida; he had a reasonably good idea of their unity and of their differences from other groups of worms. He and many other workers recognized the affinity among most annelids, but Hirudinea (leeches and allies) were often erroneously allied with trematode platyhelminths.

Recent phylogenetic studies have shown that several groups previously regarded as separate phyla are actually annelids. These include Echiura (now the family Thalassematidae), Sipuncula, Orthonectida, and a group comprising the former phyla Pogonophora and Vestimentifera (now together comprising the family Siboglinidae). Although now known to be highly modified annelids, these groups are so distinct that they are given detailed treatment at the end of this chapter. The overall classification within Annelida is also currently undergoing significant revision and has yet to stabilize. Phylogenomic and other molecular phylogenetic analyses have shown that taxonomic groupings based on morphology are often invalid. Annelida was traditionally divided into three classes. Polychaeta was the largest and most diverse group, the other two being Oligochaeta (earthworms and their kin) and Hirudinea (leeches and their relatives). It is now clear that the closest relative of Hirudinea is the freshwater group Lumbriculidae, a taxon that was inside the Oligochaeta, and these two former classes (Hirudinoidea and Oligochaeta) are now referred to as Clitellata, a taxon that dates back to 1919. Furthermore, Clitellata has been shown to have arisen deep within the older formulation of Polychaeta, making the former "Polychaeta" synonymous with "Annelida." As a result of these recent studies, many annelid researchers have redefined "Polychaeta" as a clade of annelids that includes only the two major groups Errantia and Sedentaria (Figure 15.43A). Clitellata, Siboglinidae, and Thalassematidae are all part of Sedentaria and thus well within the newly designated clade Polychaeta.

SYNOPSES OF MAJOR GROUPS

As noted above, the taxonomy for Annelida has yet to fully stabilize, but our understanding of relationships within this phylum has undergone momentous changes in the last two decades. For a current assessment of the overall relationships among the major annelid groups, see Figure 15.43A, which is based on a synthesis of the phylogenomic studies of Weigert et al. (2014), Andrade et al. (2015), and Martín-Durán et al. (2021). No Linnaean ranks are used in the following classification, although those names ending with *-idae* have traditionally carried the rank of family.

OWENIIDA This clade is the sister group to all other Annelida. It has been given the misleading name of Paleoannelida, but the name Oweniida has priority and is less misleading.

> OWENIIDAE Fewer than 50 species (Figures 15.1A and 15.12B). Generally small-bodied (some reaching 10 cm), tube-dwelling annelids with numerous fine parapodial hooks. The prostomium may be lobed or folded into a ciliated crown (e.g., *Owenia*). The group is best known for its unusual and beautiful "mitraria" larvae (Figure 15.20H,I).
>
> MAGELONIDAE Around 70 species, all in the genus *Magelona* (Figure 15.2A). Relatively similar in appearance, with shovel-shaped anterior ends and a pair of papillated palps. Thin, cylindrical worms, less than 1 mm wide, but reaching 15 cm in length. Live as burrowers in sands and muds; do not seem to form permanent tubes, though they do line their burrows with mucus.

FIGURE 15.1 Representative annelids spanning the phylogenetic breadth of the group. (A) *Owenia* sp. (Oweniidae). (B) *Spiochaetopterus* sp. (Chaetopteridae). (C) *Protobonellia* sp. (Thalassematidae). (D) *Phascolion* sp. (Sipuncula). (E) *Arcovestia ivanovi* (Siboglinidae). (F) *Lumbricus terrestris* (Clitellata, Crassiclitellata). (G) *Boccardia proboscidea* (Spionidae). (H) *Harmothoe* sp. (Aphroditiformia, Polynoidae). (I) *Dorvillea* sp. (Eunicida, Dorvilleidae).

CHAETOPTERIDAE Around 70 species, placed mostly in the genera *Chaetopterus*, *Mesochaetopterus*, *Phyllochaetopterus*, or *Spiochaetopterus* (Figures 15.1B and 15.10C–E). Adults range in size from less than 1 cm to more than 40 cm, though there are fewer than 60 segments in most taxa. Body distinctly heteronomous, divided into 2 or 3 functional regions with varying parapodia. Chaetopterids live in straight or U-shaped tubes, and most are mucous-net filter feeders, eating plankton and detritus pumped through the tube in water currents they generate. The group is best known for the extraordinary filter-feeding mechanism employed by *Chaetopterus*, which is also renowned for the blue luminescence that it produces.

AMPHINOMIDA Includes Amphinomidae and Euphrosinidae; over 200 species (Figure 15.2B). The more motile forms, amphinomids, are often quite large (e.g., *Chloeia, Eurythoe, Hermodice*) and commonly referred to as fire worms. This name comes from a feature unique to Amphinomida, namely brittle calcareous chaetae that break off when touched and can be intensely irritating in the skin. Amphinomids are more common in shallow warm seas, whereas the more sessile Euphrosinidae (e.g., *Euphrosine*) are found in deeper, colder waters.

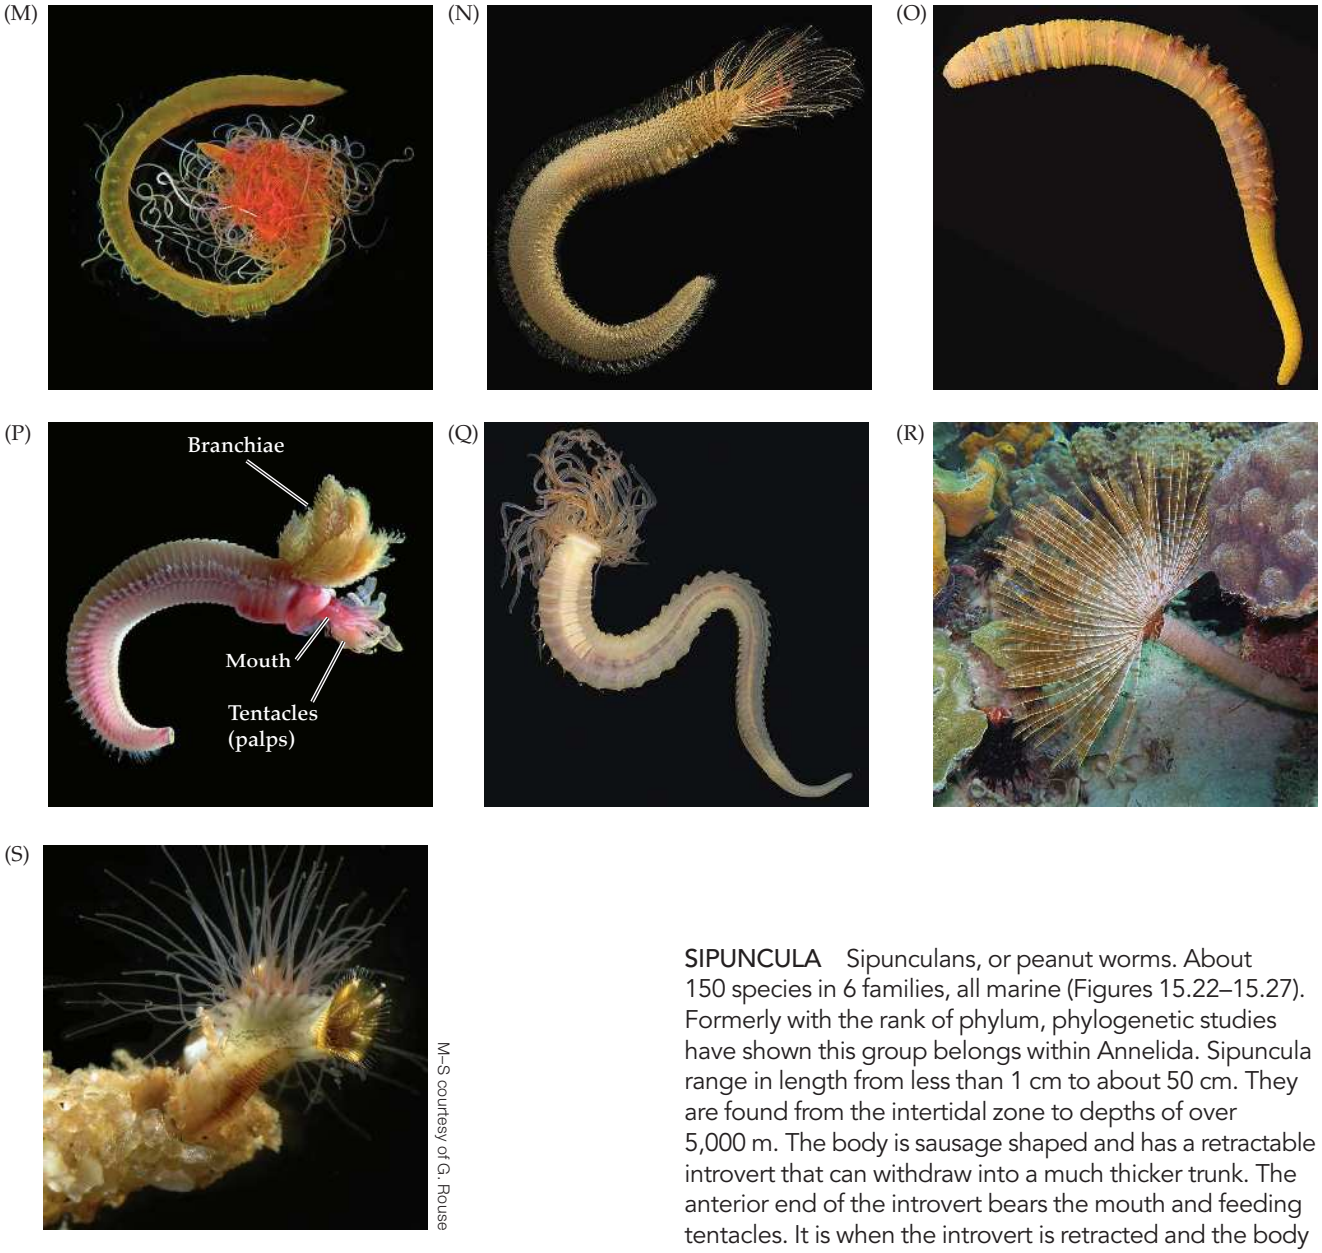

FIGURE 15.2 Further examples of annelid diversity. (A) *Magelona pitelkai* (Magelonidae). (B) *Hermodice carunculata* (Amphinomida). (C) *Saccocirrus* sp. (Protodrilida, Saccocirridae). (D) *Chrysopetalum* sp. (Chrysopetalidae). (E) *Platynereis dumerilii* (Nereididae). (F) The pelagic *Lopadorrhynchus* sp. (Lopadorrhynchidae). (G) *Trypanosyllis californiensis* (Syllidae). (H) *Lumbrineris* sp. (Lumbrineridae). (I) *Diopatra cuprea* (Onuphidae). (J) *Scoloplos armiger* (Orbiniidae). (K) *Thoracophelia mucronata* (Opheliidae). (L) *Capitella* sp. (Capitellidae). (M) *Cirriformia* sp. (Cirratulidae). (N) *Pherusa* sp. (Flabelligeridae). (O) *Abarenicola pacifica* (Arenicolidae). (P) *Paralvinella fijiensis* (Alvinellidae). (Q) *Amphitrite kerguelensis* (Terebellidae). (R) *Sabellastarte magnifica* (Sabellidae). (S) *Neosabellaria cementarium* (Sabellariidae).

SIPUNCULA Sipunculans, or peanut worms. About 150 species in 6 families, all marine (Figures 15.22–15.27). Formerly with the rank of phylum, phylogenetic studies have shown this group belongs within Annelida. Sipuncula range in length from less than 1 cm to about 50 cm. They are found from the intertidal zone to depths of over 5,000 m. The body is sausage shaped and has a retractable introvert that can withdraw into a much thicker trunk. The anterior end of the introvert bears the mouth and feeding tentacles. It is when the introvert is retracted and the body is turgid that some species resemble a peanut (e.g., *Phascolosoma*). Sipuncula lack a closed circulatory system and segmentation but have a spacious coelom. The gut is U-shaped and coiled, with the anus located dorsally on the body near the introvert-trunk junction. The body surface is usually beset with minute bumps, warts, tubercles, or spines. For a detailed classification of this taxon, see the Sipuncula section of this chapter.

ERRANTIA This is an old taxonomic grouping that has again found favor. It contains more than a quarter of all described annelid species diversity, in three major groups: Protodriliformia, Eunicida, Phyllodocida (the latter two comprising a sister group called Aciculata).

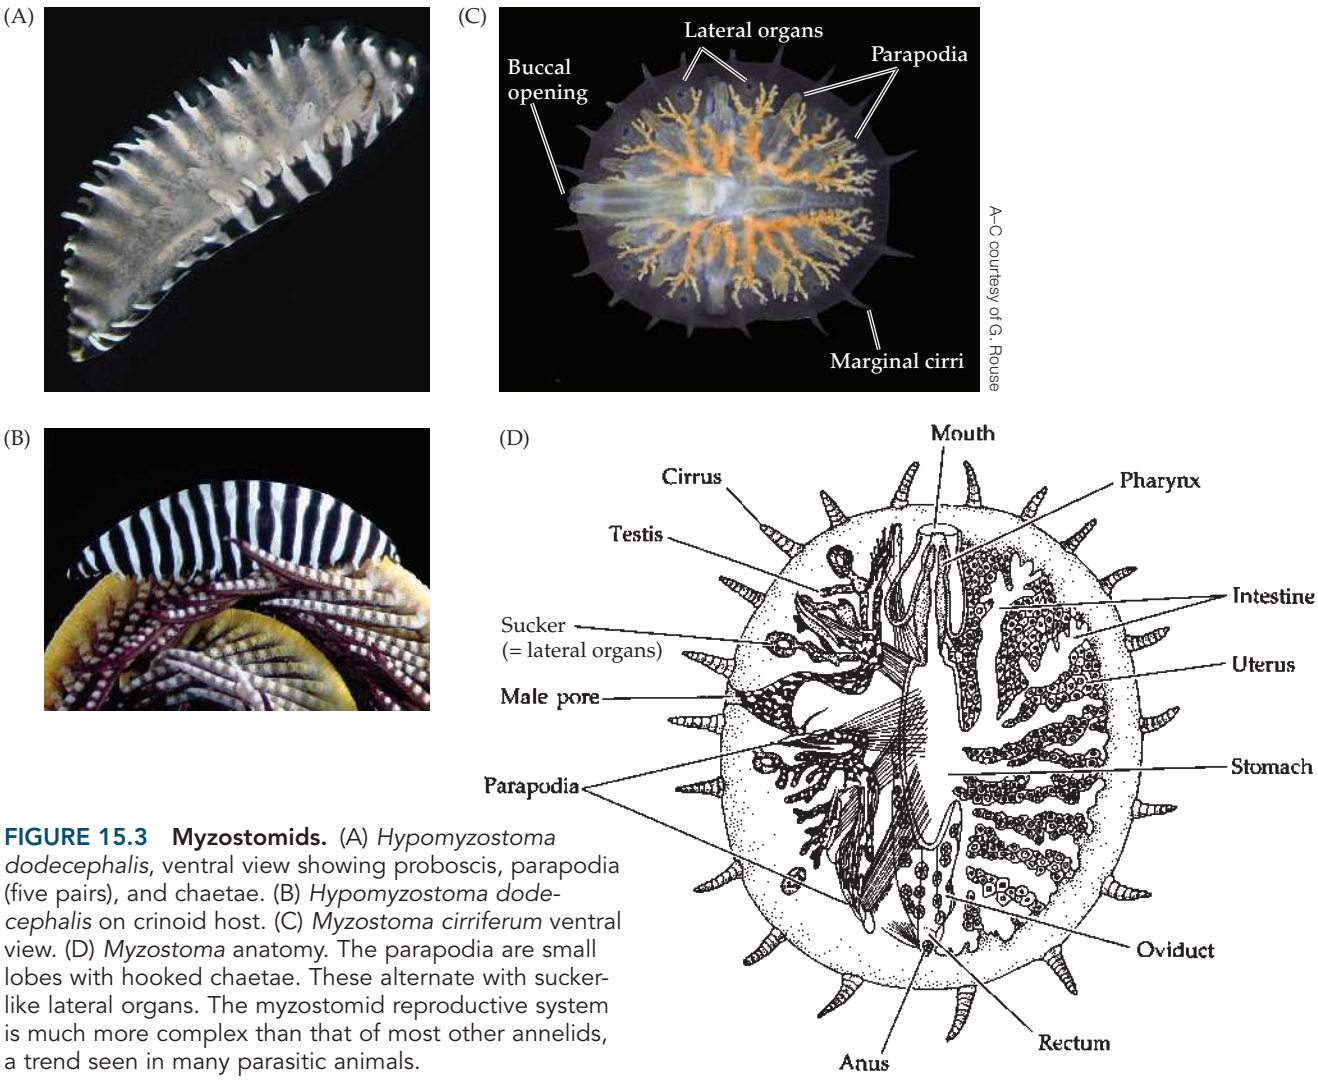

FIGURE 15.3 Myzostomids. (A) *Hypomyzostoma dodecephalis*, ventral view showing proboscis, parapodia (five pairs), and chaetae. (B) *Hypomyzostoma dodecephalis* on crinoid host. (C) *Myzostoma cirriferum* ventral view. (D) *Myzostoma* anatomy. The parapodia are small lobes with hooked chaetae. These alternate with sucker-like lateral organs. The myzostomid reproductive system is much more complex than that of most other annelids, a trend seen in many parasitic animals.

PROTODRILIFORMIA

PROTODRILIDA Over 60 species, mainly living interstitially in sediments (Figure 15.2C). Includes Protodrilidae, Protodriloididae, and Saccocirridae, best known for being members of the now defunct taxon Archiannelida. Taxa such as *Protodrilus* and *Saccocirrus* are found in medium to coarse sediments in shallow waters. Adult Protodrilida range in length from 2 to 30 mm and can have up to 200 segments. Protodrilidae lack chaetae, though these are found in Protodriloididae and Saccocirridae. All have a pair of palps emerging from the prostomium that form highly mobile sensory structures.

POLYGORDIIDAE Nicknamed "knot worms," they are generally found in coarse, well-sorted sediments and resemble very large nematodes as they writhe around. Lacking chaetae and obvious external segmentation, they were once thought to represent the ancestral annelid state. One accepted genus, *Polygordius*.

EUNICIDA Over 1,000 species that have a ventral muscularized pharynx with complex jaws that include elements such as ventral mandibles and dorsal maxillae. Their parapodia are supported by rodlike chaetae called aciculae and often bear compound chaetae. They generally have 3 antennae and a pair of sensory palps on the head. Eunicida include some of the smallest and largest known annelids. Currently with 7 family-ranked taxa (4 of which are described here).

DORVILLEIDAE Over 200 species (Figures 15.1I and 15.8F). Includes some of the smallest annelids (*Neotenotrocha*), while others may reach several centimeters and have many segments (e.g., *Dorvillea*). The head often has 3 antennae, and there can be a pair of palps that may either resemble or differ from the shape of the antennae. *Ophryotrocha* is a well-known "model annelid" as it is easily kept in culture on spinach or similar foods. Dorvilleids are also very commonly found in extreme habitats such as hydrothermal vents, methane seeps, and whale falls, where they are bacteriovores.

for more ebook/ testbank/ solution manuals requests (mail 960126734@qq.com)

EUNICIDAE Over 450 species (Figure 15.17H). A group that contains arguably the largest of annelids, some exceeding 3 m in length, with only a megascolecid earthworm species coming near this size. Usually with 3 antennae and a pair of palps that resemble antennae. Motile, though also living in burrows or temporary tubes in mucous or parchmentlike tubes. Carnivores, omnivores, or herbivores. Famous examples include palolo worms and the Bobbitt worms. (e.g., *Eunice*, *Marphysa*, *Palola*).

LUMBRINERIDAE Over 300 species (Figure 15.2H). Thin and elongate and, except for *Lysarete* and *Kuwaita*, lacking head appendages. Most crawl about in algal mats and holdfasts, and small cracks in hard substrata; some burrow in sand or mud. Carnivores, scavengers, detritivores, and deposit feeders. Other genera include *Lumbrineris*, *Lumbrinerides*, and *Ninoe*.

OENONIDAE Over 100 species. Elongate, with small parapodia; lacking head appendages, or with 3 small antennae. Resembling Lumbrineridae, though their jaws and chaetae differ. Often found in soft substrata where they burrow aided by secretion of copious amounts of mucus. Predatory carnivores: many have an endoparasitic juvenile stage living inside other annelids. (e.g., *Arabella*, *Drilonereis*).

ONUPHIDAE Over 330 species (Figure 15.2I). Closest relatives are Eunicidae, though onuphids generally have prominent gills on anterior segments. Most live in tubes, but others roam through sediments. Most tube dwellers are sessile (e.g. *Diopatra*), while others carry their tubes with them. Generally, scavengers or predators. Interesting forms include quill worms (*Hyalinoecia*) and the Australian beach worms (*Australonuphis*, etc.).

HISTRIOBDELLIDAE The "Charlie Chaplin worm" are tiny members of Eunicida that live as commensals on a variety of Crustacea. There are currently 13 nominal species placed in this family, including *Histriobdella, Steineridrilus*, and *Stratiodrilus*, with most of them known from rivers of South America. They lack chaetae but share other features with Eunicida.

PHYLLODOCIDA With more than 4,500 species, is distinguished by its members having an axial muscular proboscis (often armed with 2 or more jaws). They tend to show fusion of some anterior segments with the head, often only identifiable by the retention of anterior enlarged cirri, and the head usually has 2 or 3 antennae and a pair of sensory palps. Like Eunicida, their parapodia are also often supported by aciculae and bear compound chaetae. Currently with around 20 family-ranked taxa; the more species-rich ones are introduced here.

APHRODITIFORMIA Scale worms comprise a diverse group of over 1,500 species in 7 family-ranked taxa (Figures 15.1H, 15.5E, and 15.11A,B): Acoetidae, Aphroditidae, Eulepethidae, Polynoidae (contains most species), Iphionidae, and Sigalionidae. Aphroditiformia also includes the scaleless scale worms of the former family Pisionidae. Most are relatively short and somewhat flattened dorsoventrally; one highly unusual Antarctic species, *Eulagisca gigantea*, reaches a length of nearly 30 cm and a width of about 15 cm. Most also have relatively few segments at adulthood, some sigalionids being exceptions. Most of the dorsal surface is normally covered by transformed flattened cirri (called elytra, or scales), hence the common name. The eversible pharynx has one pair of jaws that close dorsoventrally somewhat like a parrot's beak. Most scale worms are motile but usually cryptic (under stones, etc.). Many are predators while others are bacteriovores. Many scale worms are commensals, living on the bodies or in the dwellings of other animals. Other genera include *Arctonoe*, *Gorgoniapolynoe*, *Halosydna*, *Harmothoe*, *Hesperonoe*, *Macellicephala*, and *Polynoa*.

CHRYSOPETALIDAE Over 100 species (Figure 15.2D). The name (Latin for "golden petals") refers to the shape and color of the golden, flattened notochaetae (called paleae) that cover the dorsal surface in many species (e.g., *Chrysopetalum*). These worms are of small to moderate size, with adults varying in length from 1 to 50 mm, and with as few as 10 to over 300 segments. Those with the dorsum covered by flattened paleae tend to be yellowish-brown to golden, sometimes with transverse stripes. One clade, Calamyzinae, contains parasitic forms that live in bivalve molluscs (these were formerly in their own family, Nautiliniellidae, as they show little resemblance to other chrysopetalids, e.g., *Shinkai*). Other genera include *Ichthyotomus* (Figure 15.11C).

GLYCERIDAE Over 90 species (Figures 15.5B, 15.8D, and 15.12C). Cylindrical, tapered, homonomous segmentation, usually red or pink, reaching 30 cm in length. Enormous eversible pharynx that can be retracted into one-third of the body length, armed with 4 hooklike jaws used in prey capture; each jaw has a venom gland. The pharynx is also used in burrowing. Most are infaunal burrowers in soft substrata. (e.g., *Glycera*, *Glycerella*, *Hemipodus*)

HESIONIDAE Over 175 species (Figure 15.11D). Generally beautiful worms, adults measuring from a few millimeters in length to more than 10 cm. Subtidal, especially on rocky and mixed bottoms, and increasingly known from hydrothermal vents and methane seeps. A famous hesionid is the ice worm, *Sirsoe methanicola,* which lives on methane hydrates in the Gulf of Mexico. Many Hesionidae have striking pigmentation patterns, and some are commensals, particularly with echinoderms. The number of segments in adults may be fixed at 21 (e.g., *Hesione*, *Leocrates*) or varying up to about 50–60. Other genera include *Hesiolyra*.

NEPHTYIDAE Over 150 species (Figure 15.5C). Usually long and slender, with well-developed

parapodia but simple heads. They can be very abundant in shallow-water sediments, and there are often several different taxa in a single sediment sample. While they are easily identified to this family level, species identification is difficult. Adults range from a few millimeters to 30–40 cm and up to 150 segments. Eversible jawed pharynx used in prey capture and burrowing. (e.g., *Aglaophamus*, *Micronephthys*, *Nephtys*)

NEREIDIDAE Over 700 species (Figures 15.2E, 15.8A–C, and 15.13A). Among the best-known marine annelids and widely used in teaching, in laboratories, and as fishing bait. Most nereidids are found in shallow waters, though some are found at hydrothermal vents. Small to very large (over 100 cm) with homonomous segments. Mostly errant predators or scavengers with well-developed eyes and parapodia. Immediately recognized by their pair of large, curved pharyngeal jaws (e.g., *Cheilonereis*, *Dendronereis*, *Neanthes*, *Nereis*, *Platynereis*). One group, Namanereidinae, is semiterrestrial or lives in fresh water. (e.g., *Lycastella*, *Namanereis*).

PHYLLODOCIDAE Over 500 species (Figures 15.5F, 15.8E, and 15.16D). Thin, often elongate (over 50 cm) bodies of up to 700 homonomous segments; commonly active epibenthic predators on solid substrata; a few burrow in mud (e.g., *Eteone*, *Eulalia*, *Notophyllum*, *Phyllodoce*). One clade, Alciopini, comprise holopelagic forms, in which the body is transparent except for pigment spots and a large pair of lensed eyes. Other genera include *Alciopa*, *Alciopina*, *Torrea*, *Vanadis*.

SPHAERODORIDAE Over 140 species. Easily recognized by conspicuous tubercles and/or papillae all over the body, generally arranged in transverse rows. Adults range from a few millimeters to several centimeters. Bodies can be short and grublike with up to about 30 segments (e.g., *Sphaerodoridium, Sphaerodoropsis*) or elongate and slender with a larger number of segments. Other genera include *Ephesiella*.

SYLLIDAE Over 1,000 species (Figures 15.2G, and 15.17C,D,G). Mostly small, homonomous worms found on various substrata. Best known for their diversity in reproductive biology, including various forms of epitoky. Adult sizes from 1 to 150 mm; with only a few segments or with many segments. Syllids show some of the most striking coloration patterns among annelids. Mainly predators on small invertebrates. The pharynx has a distinct barrel-shaped region that may be armed with a single tooth or a ring of small teeth for grasping prey. (e.g., *Autolytus*, *Brania*, *Myrianida*, *Odontosyllis*, *Ramisyllis*, *Syllis*, *Typosyllis*, *Trypanosyllis*)

PELAGIC PHYLLODOCIDA A polyphyletic grouping of about 150 pelagic species. In addition to Alciopini, several other groups of Phyllodocida have independently evolved into holopelagic forms, though the number of evolutionary events has yet to be fully resolved. Holopelagic forms are included in the families Lopadorrhynchidae (Figure 15.2F), Pontodoridae, Tomopteridae, Typhloscolecidae. Most are likely to be predators. Tomopterids are spectacular forms with transparent flattened bodies, finlike parapodia, and only a few chaetae.

MYZOSTOMIDA 156 species (Figure 15.3). During the twentieth century, these animals were treated as annelids with a rank of family or order, or even as a separate class. Some workers suggested that Myzostomida are more closely related to Platyhelminthes than to any annelids. However, the pendulum swung back in favor of myzostomids being annelids, starting with a molecular analysis by Bleidorn et al. (2007). Recent phylogenomic analyses have not been able to stabilize the phylogenetic position of the group, and while they clearly appear to be annelids, their closest relative is still not known, though there are morphological similarities with the Errantia. Myzostomids include several groups of flattened, oval, or elongate forms, always with 5 chaetae-bearing segments. They are mainly ectosymbionts, endosymbionts, or parasites of crinoid echinoderms, though a few are parasitic on Anthozoa. (e.g., *Hypomyzostoma* and *Myzostoma*).

SEDENTARIA Another previously defunct taxonomic group resurrected in the 2010s and containing over 13,000 species. It comprises a series of major groups, though the relationships among them are not fully resolved. The former phyla Echiura and Pogonophora (and Vestimentifera) are placed here, as well as a variety of tube-dwelling and burrowing forms. Clitellata are also nested in Sedentaria.

ORBINIIDAE Over 230 species (Figures 15.2J and 15.16G). Prostomium can be rounded or pointed, without appendages. Adults from 3 to 300 mm long and large forms can have several hundred segments: usually with an anterior "muscular" thoracic region and a more fragile abdomen. Usually with complex parapodia and a wide range of chaetae. Generally burrowing forms, they are usually found in the sediments of shallow bays and estuaries (e.g., *Orbinia*, *Scoloplos*) but also have been recorded from hydrothermal vents and methane seeps. (e.g., *Methanoaricia, Proscoloplos*)

CIRRATULIDA

ACROCIRRIDAE Around 50 species. Often found intertidally, under rocks or in shallow sediments and muds. The head is simple with a rounded prostomium and a pair of grooved peristomial palps used for feeding. Each of the first 4 segments bears a pair of simple unbranched branchiae, which are easily lost. Adults reach 5 to 150 mm and have from as few as 10 segments to more than 200. Live acrocirrids tend to be yellowish to greenish-brown in color (e.g., *Acrocirrus*, *Macrochaeta*). An extraordinary new group of holopelagic Acrocirridae was recently described in which the anterior branchiae have transformed into bioluminescent structures that glow when shed, presumably to distract predators. (e.g., *Swima*)

for more ebook/ testbank/ solution manuals requests (email 960126734@qq.com)

CIRRATULIDAE Over 350 species (Figures 15.2M and 15.17B). Elongate, with relatively homonomous segmentation, with up to 350 segments, often each with a pair of threadlike branchial filaments (e.g., *Cirratulus*, *Cirriformia*). In others there may be only 4 pairs of branchiae anteriorly (e.g., *Dodecaceria*), or none in smaller forms (e.g., *Ctenodrilus*). Cirratulids are mostly shallow-water burrowers lying just beneath the surface of the sediment, from where they extend their branchiae into the overlying water. Most are selective deposit feeders, extracting organic detritus from surface sediments, using grooved palps that may be a simple pair (e.g., *Chaetozone*, *Dodecaceria*) or transformed into 2 clusters. Other genera include *Timarete*.

FLABELLIGERIDAE Over 200 species (Figure 15.2N). Sometimes called bristle-cage worms. With papillae covering the body, papillae often sticky, hence some have a sediment coating. Others have a thick, transparent gelatinous sheath, allowing the body contents and green circulatory system to be seen. The head, which has a pair of grooved palps and presumably some achaetous anterior segments bearing branchiae, is often retractable into the following anterior segments that bear a "cage" of protective chaetae. Mostly benthic, from the intertidal under stones to deep-sea muds, though there are two holopelagic groups, *Poeobius* and *Flota*, that were in their own families until recently. Adults are 5 mm to more than 10 cm in length. Other genera include *Brada*, *Pherusa*.

SPIONIDA

SPIONIDAE Over 600 species (Figures 15.1G and 15.9F). Body thin, elongate, homonomously segmented. The head is simple with a pair of grooved peristomial palps. Most burrow or form delicate sand or mud tubes. A few bore into calcareous substrata, including rocks and mollusc shells; most use the grooved peristomial palps to selectively extract food from the sediment surface. (e.g., *Boccardia*, *Polydora*, *Scolelepis*, *Spio*, *Spiophanes*)

SABELLARIIDAE Over 130 species (Figures 15.2S and 15.7H,I). Sabellariidae are easily distinguished from most other annelids by having an operculum that is developed from anterior segments and a robust tube built from coarse sand grains. The operculum comprises two fleshy lobes that are fused (e.g., *Sabellaria*), or free (e.g., *Lygdamis*), and it includes 1–3 rows of large golden or black stout chaetae (paleae). Generally found in intertidal to slightly subtidal areas, though deep-water forms are known. Sabellariids can form extensive biogenic reefs and can reach densities of up to 6,000 individuals/m^2 (e.g., *Phragmatopoma*, *Sabellaria*), while others are solitary.

SABELLIDA

SABELLIDAE Over 550 species (Figures 15.2R, 15.7A, and 15.16E). Commonly called fan worms or feather-duster worms. Sabellids live in sediment and mucous tubes and are common at all depths. The body is heteronomous, divided into a thorax and an abdomen, and can be 3 to 300 mm long. The thorax bears long dorsal "capillary" or hooded chaetae and ventral hooks, while the abdomen shows the inverse (chaetal inversion). The prostomium is a crown of branched, feathery palps (radioles) that projects from the tube and functions in gas exchange and ciliary suspension feeding (e.g., *Bispira*, *Eudistylia*, *Myxicola*, *Sabella*, *Schizobranchia*) and may bear simple eyes (e.g., *Demonax*) or compound eyes (e.g., *Megalomma*). Some species bore into calcareous substrates (e.g., *Pseudopotamilla*). Sabellidae also once included Fabriciidae, all small-bodied feather-duster worms, but these have been shown to be more closely related to Serpulidae and were placed in their own family. Other genera include *Acromegalomma*, *Amphiglena, Neosabellaria, Sabellastarte*.

SERPULIDAE Over 560 species (Figures 15.7E,F,J and 15.20A–C). Like sabellids, except the secreted tube is calcareous and usually attached to rocks. The body is heteronomous, divided into thorax and abdomen, ranging in size from 3 to 200 mm. Anterior end bears radiolar crown as in sabellids; many species have one radiole transformed into an operculum that plugs the end of the tube when the worm withdraws (e.g., *Hydroides*, *Serpula*, *Spirobranchus*), though many lack this (e.g., *Filograna, Protula*). The most well-known serpulid group is *Spirobranchus*, the Christmas tree worms, which bore into coral substrates and have colorful spiral radiolar crowns (Figure 15.7J). One speciose clade, Spirorbinae, contains small-bodied forms that secrete coiled calcareous tubes. Other genera include *Circeis*, *Ditrupa*, *Paralaeospira*, *Spirorbis*.

FABRICIIDAE Over 80 species. Fabriciidae were for many years considered part of Sabellidae, and they share similarities such as the radiolar crown and dwelling in a mucus/sediment tube. These characters alone are taxonomically misleading, and the closest relative of Sabellidae is Serpulidae. Unlike Sabellidae, Fabriciidae are consistently small bodied as adults, the smallest of which is *Fabriciola minuta*, which has an adult length of only 0.85 mm. When alive, fabriciids are usually translucent but can have patches of pigment on the crown and body. They often abandon their tubes when disturbed, and they may have eyes behind the crown and in the pygidium. All are intratubular brooders with crawl-away larvae and so can reach very high population densities.

SIBOGLINIDAE Over 200 species (Figures 15.1E, 15.32, and 15.33). Previously classified as the phyla Pogonophora and Vestimentifera. Morphological and molecular analyses now recognize this group as a clade within Annelida; the original family name, Siboglinidae, has since been generally adopted. Siboglinidae all appear to live via symbiotic bacteria in their bodies

and are generally found at greater than 1,000 m depth, even down to nearly 10,000 m, though exceptionally they are found in depths of less than 100 m. Though most are known from deep-sea muds (e.g., *Siboglinum*), mud volcanoes, or sunken plant material (e.g., *Sclerolinum*), vestimentiferan siboglinids (e.g., *Riftia*) are spectacular members of hydrothermal vent communities or methane seeps (e.g., *Lamellibrachia*). Siboglinidae vary greatly in size, with adults of some *Siboglinum* reaching 5 cm in length (and only 0.1 mm in width), while *Riftia pachyptila* are more than 150 cm in length and live in tubes more 2.5 m long. The most recently discovered group of Siboglinidae is the genus *Osedax*, a group that devours the bones of marine vertebrates by dissolving through them with tissue that resembles plant roots. Other genera include *Arcovestia, Lamellisabella, Polybrachia*.

MALDANOMORPHA

ARENICOLIDAE Over 25 species (Figures 15.2O and 15.5H). Arenicolids or lugworms have simple heads and a thick, fleshy, heteronomous body divided into two or three distinguishable regions; the pharynx is unarmed but eversible and aids burrowing and feeding. Most arenicolids live in J-shaped burrows in intertidal and subtidal sands and muds, where they are direct deposit feeders. (e.g., *Abarenicola*, *Arenicola*)

MALDANIDAE Over 250 species (Figure 15.7C,D). Known as bamboo worms because of the long cylindrical segments with ridgelike parapodia that resemble stalks of bamboo. Like arenicolids, the head has no appendages; maldanids are 0.3 cm to more than 20 cm in length. They usually have 20–30 segments and the body does not taper posteriorly as in most other annelids. (e.g., *Axiothella*, *Clymenella*)

TEREBELLIFORMIA

ALVINELLIDAE An unusual hydrothermal vent group from the Pacific and Indian Oceans, the Pompeii worms (2 genera and 11 species: *Alvinella*, *Paralvinella*). Adult alvinellids can be up to 15 cm long (Figures 15.2P and 15.11D).

AMPHARETIDAE Over 260 species. Ampharetids are tubicolous and easily distinguished from the similar Terebellidae in that their multiple grooved palps, usually called tentacles, can be retracted into the mouth. Generally, 4 pairs of branchiae. Relatively uncommon in intertidal and shallow waters; in recent years, most new taxa have been described from deeper sediments. The body consists of 2 distinct regions in addition to the head, a thoracic region that generally has biramous parapodia and an abdomen that has neuropodia only. (e.g., *Ampharete, Amphicteis*). Used to include Melinnidae, which is now a separate family. Adult Ampharetidae are 0.5–6 cm long.

PECTINARIIDAE Over 70 species (Figures 15.7G and 15.9G). The ice-cream-cone worms. Body short and conical with stout golden chaetae projecting from the head. Also, easily recognizable from their elegant cone-shaped tubes, constructed from sand, small shells, or other small particles, open at both ends. Body length 1 to 10 cm, with no more than 20 segments bearing chaetae. Multiple grooved palps ("tentacles") used to feed on detritus extracted from sediment. (e.g., *Pectinaria, Petta*)

TEREBELLIDAE Over 620 species (Figures 15.2Q and 15.9B–E). Tube dwelling, though many are burrowers or "creepers" and some are even capable of swimming. The grooved palps are often seen extending out over the sediment in shallow marine waters. When disturbed, the tentacles, often brightly colored, are retracted back toward the worm, though they are not retracted into the mouth. Usually, three pairs of branchiae. The body usually consists of 2 distinct regions in addition to the head: a thoracic region that generally has biramous parapodia, and a long tapering abdomen that has neuropodia only. (e.g., *Amphitrite*, *Pista*, *Polycirrus*, *Terebella*, *Thelepus*)

CAPITELLIFORMIA

OPHELIIDAE Over 170 species (Figure 15.2K). With homonomous segmentation, usually less than 3 cm long, with up to 60 segments. Body shape varies from short and thick to elongate and somewhat tapered. Most opheliids burrow in soft substrata, but some can swim by undulatory body movements. The eversible pharynx is unarmed. Most are direct deposit feeders. (e.g., *Armandia*, *Euzonus*, *Ophelia*, *Polyophthalmus, Thoracophelia*)

CAPITELLIDAE Over 200 species (Figure 15.2L). Easily recognized by the division of the body into an anterior region with capillary chaetae only and a posterior region with long-handled hooks. The body is a simple cylindrical shape, resembling Clitellata. The head has no appendages and is a simple conical structure in most. Body less than 1 cm to more than 20 cm in length; usually bright red. Extensions of the body wall, often erroneously called "branchiae" (erroneous, since capitellids lack a circulatory system), are present in abdominal segments of some taxa. Some, such as *Capitella,* are well known as pollution indicators since their numbers explode in nutrient-rich conditions that exclude many other annelid species. Other genera include *Dasybranchus*, *Notomastus*.

THALASSEMATIDAE (FORMERLY ECHIURA) Around 160 species (Figures 15.1C and 15.28–15.30). Spoon worms, anchor worms. Unusual annelids in that they have a muscular extensible preoral proboscis at the anterior end of an apparently unsegmented trunk. The proboscis cannot be withdrawn into the mouth, but it can be extended for several meters in some species. The trunk ranges from 1 to 40 cm in length and bears a single pair of chaetae anteriorly, or both anteriorly and with rings of chaetae posteriorly. Thalassematidae were generally considered annelids, but W. W. Newby proposed a separate phylum, Echiura, based on a detailed embryological study of

for more ebook/ testbank/ solution manuals requests (mail 960126734@qq.com)

Urechis caupo. His proposal was generally accepted until molecular evidence showed that they are, in fact, annelids. Subsequent morphological studies supported that conclusion, and recent molecular analyses have shown the group to be closely related to Capitellidae. Thalassematids appear to be unsegmented, but their nervous system proceeds from anterior to posterior during embryogenesis, suggesting the occurrence of a posterior growth zone (teloblasty). Genera include *Bonellia, Echiurus, Ikeda, Listriolobus, Metabonellia, Onchnesoma, Protobonellia, Prometor, Thalassema, Urechis*.

CLITELLATA Over 8,500 species. Earthworms, leeches, and related forms. Without parapodia; chaetae usually greatly reduced or absent. Hermaphroditic, with complex reproductive systems. A distinct ring, the clitellum, functions in cocoon formation; development is direct. Cephalic sensory structures reduced; body externally homonomous except for clitellum. Mostly terrestrial or freshwater annelids, although there are also many marine species.

CAPILLOVENTRIDAE 5 species. The morphology and arrangement of their chaetae resemble those of some errantiate annelids, but the presence of a clitellum and other features reveals they are clitellates. Interestingly, both morphological and molecular evidence suggests they are the sister group to all other clitellates and lends support to the hypothesis that Clitellata has an aquatic origin. Two of the species are marine, 2 live in fresh water, and 1 in brackish water. A single genus, *Capilloventer*.

NAIDIDAE (FORMERLY KNOWN AS TUBIFICIDAE) Around 700 species. Range in length from a few millimeters to several centimeters. The best known of the freshwater clitellates, though some live in marine or brackish water. Some build tubes, others are burrowers. Usually, the body is homonomous throughout with a simple head, though several species bear an elongate prostomial proboscis; some have branchiae. Many reproduce asexually, but most have gonads at some stage of development. Some species are very common in areas of high pollution. Some small, gutless species that rely on symbiotic bacteria for nutrition are known from tropical regions (e.g., *Inanidrilus*, *Olavius*). Other genera include *Branchiodrilus*, *Branchiura*, *Clitellio*, *Dero*, *Limnodrilus*, *Ripistes*, *Slavina*, *Stylaria*, and *Tubifex*.

CRASSICLITELLATA Earthworms and their allies (Figures 15.1F, 15.12F, 15.15F, and 15.18). Over 5,500 valid species that are mainly terrestrial, but some taxa (e.g., Biwadrilidae and Almidae) live in aquatic or semiaquatic environments. The most species-rich families are Megascolecidae (e.g., *Amynthas*, *Pheretima*), Lumbricidae (e.g., *Eisenia*, *Lumbricus*), and Glossoscolecidae. Crassiclitellata include the common terrestrial earthworms, including *Lumbricus terrestris*, which has been spread to soils across the world from its native Europe. Crassiclitellates are relatively large, with well-developed and complex reproductive systems. They are deposit feeders, living in soil, feeding on live and dead organic matter. The largest of all clitellates belong to Megascolecidae, for example the giant Gippsland earthworm, *Megascolides australis* (an endangered species native to Australia), can stretch to about 3 m in length, though their normal length is said to be around 1 m long and 2 cm in diameter. Invasion of nonnative earthworms can profoundly alter native soil ecosystems. Such invasions are particularly problematic in regions of North America that were historically devoid of native earthworms prior to European settlement. Earthworm invasions can accelerate litter loss and reduce soil horizon thickness, alter nutrient pools, increase soil microbial biomass and activities, shift understory plant community composition and diversity, and decrease native soil microbes, fungi, and invertebrates. Among the many invasive earthworms in North America are the Asian jumping earthworms (*Amynthas agrestis* and *A. tokioensis*), notable for their rapid snakelike movements and jumping behavior when disturbed. Reaching 15 cm in length, these worms can reduce soil surface litter by up to 95%.

ENCHYTRAEDIDAE 700 species. Found mainly in soil but also in a wide range of freshwater and marine/brackish water habitats. Marine enchytraeids are common in intertidal sands, but they are also known from deep-sea sediments. Those of the genus *Mesenchytraeus* are known as ice worms, as they thrive in glacial ice.

LUMBRICULIDAE Over 150 species (Figure 15.18H). Worms of moderate size, found in marshes, streams, and lakes. The group shows a great deal of endemism, mainly in Siberia (notably Lake Baikal) and the western parts of North America. This is the sister group of Hirudinea. (e.g., *Alma*, *Lamprodilus*, *Phagodrilus*, *Rhynchelmis*, *Stylodrilus*, *Styloscolex*, *Trichodrilus*)

HIRUDINEA Leeches and their relatives (Figures 15.34–15.40). Body with fixed number of segments, each with superficial annuli; chaetae generally absent; heteronomous, with clitellum and a posterior and usually an anterior sucker; most live in freshwater or marine habitats, a few are semiterrestrial; ectoparasitic, predaceous, or scavenging. There are 3 major clades within Hirudinea.

ACANTHOBDELLIDA Two species, *Acanthobdella peledina* and *A. livanowi*, both from Northern Hemisphere freshwater lakes (Figure 15.34A). Part of the animal's life is spent as an ectoparasite on freshwater fishes, especially salmonids and thymallids, and presumably the rest of the time is spent in vegetation. Body with 30 segments, reaching 3 cm in length; with posterior sucker only in *A. peledina*; chaetae on anterior segments; coelom partially reduced but obvious and with intersegmental septa.

BRANCHIOBDELLIDA Around 150 species (Figure 15.34B). Usually less than 1 cm long; ectocommensal or ectoparasitic on freshwater crayfish;

body with 15 segments; with anterior and posterior suckers; chaetae absent; coelom partially reduced but spacious throughout most of the body. A single family, Branchiobdellidae. (e.g., *Branchiobdella*, *Cambarincola*, *Stephanodrilus*)

HIRUDINIDA Over 700 species (Figures 15.34C, 15.37, and 15.38). The "true" leeches. Around 100 species are marine, 90 are terrestrial, and the remainder freshwater. Many are ectoparasitic bloodsuckers, others are free-living predators or scavengers; some parasitic forms serve as vectors for pathogenic protozoa, nematodes, and cestodes. Body always with 34 segments; with anterior and posterior suckers; no chaetae; coelom reduced to a complex series of channels (lacunae). About 12 families, in 2 main groups. Rhynchobdellida (proboscis leeches) is a paraphyletic group of several families that contains the marine species as well as many freshwater forms (e.g., *Glossiphonia*, *Johanssonia*, *Piscicola*). Arhynchobdellida is a clade that lacks a proboscis, although many have jaws; all are either freshwater or terrestrial. (e.g., *Erpobdella*, *Haemopsis*, *Hirudo*, *Macrobdella*).

DIURODRILIDAE These tiny animals reach only 500 µm in length as adults in the case of *Diurodrilus* and about 1 mm for *Apharyngtus*. They are exclusively marine, tidal to subtidal meiofaunal sand dwellers. They lack chaetae and obvious segmentation. Their position as part of Annelida was debated, but they now appear to be part of this group, though with an uncertain position in Sedentaria.

DINOPHILIFORMIA This name applies to the clade composed of Dinophilidae and *Lobatocerebrum*, two groups of tiny annelids that also lack chaetae. *Lobatocerebrum* has only recently been accepted as an annelid group. Dinophilidae can be strikingly colorful, and *Dimorphodrilus* shows remarkable sexual size dimorphism, with minute males that mate with their sisters after emerging from their brood cocoon.

The Annelid Body Plan

The typical annelid body is composed of four regions: a presegmental region derived from the larval episphere, the prototroch region around the mouth, the serially repeated body segments, and the posterior pygidium. The episphere (see the section on Reproduction and Development) becomes the presegmental **prostomium** in the adult, and the prototroch and buccal region give rise to the **peristomium**, the region surrounding the mouth (Figures 15.1F, 15.2L, and 15.8). The body segmentation of annelids is referred to as metamerism. The extreme posterior end of the body is the **pygidium,** and it bears the anus and often some cirri. As with the prostomium, the pygidium is nonsegmental and may well contain remnants of the larval body. From this basic scheme, the tremendous diversity of body forms seen in annelids is built. Externally visible metamerism and a greatly elongated cylindrical body typify most annelids. They are triploblastic, have a through (complete) gut, and have a spacious coelom. Exceptions concerning obvious metamerism include Sipuncula, Thalassematidae (formerly Echiura), Dinophiliformia, and Diurodrilidae, where this has been lost. In other groups, like Hirudinea and Myzostomida, the coelom is reduced. The gut (lost in some clitellates and in all Siboglinidae) is separated from the body wall by the coelom, except in those where the body cavity has been secondarily reduced.

The simplest annelid head is composed of a prostomium and a peristomium. The segmentation of the main body is typically visible externally as rings, or annuli, and is reflected internally by the serial arrangement of coelomic compartments separated from one another by intersegmental septa (Figure 15.4). This basic arrangement has been modified to various degrees among annelids, particularly by reduction in the size of the coelom or by loss of septa; the latter modification leads to fewer but larger internal compartments. The bodies of many annelids are **homonomous**, bearing segments that are very much alike. Many others, particularly tubicolous forms, have groups of segments specialized for different functions and are thus **heteronomous** (as in many Chaetopteridae). Specialization of segment groups (i.e., **heteronomy**) has contributed greatly to morphological diversification among annelids.

Our current view of annelid phylogeny (Figure 15.43) hypothesizes Oweniida, Chaetopteridae, and Amphinomida + Sipuncula forming a grade of three basal groups leading to the Polychaeta. These basal groups encompass a wide variety of body forms, and so inferring the structure of the ancestral annelid is challenging. A relatively homonomous body may be plesiomorphic since it is seen in Oweniida, some Chaetopteridae, and Amphinomida, though taxa such as Sipuncula and most Chaetopteridae may have dramatically different body forms.

Body Forms

Most annelids are marine, living in habitats ranging from the intertidal zone to extreme depths, although about a third of all annelid species live on land or in fresh water. But a good number inhabit brackish or fresh water, and the majority of Clitellata (thousands of species) live on land. Annelids range in length from less than 0.5 mm as adults for some interstitial species, to over 3 m for some giant eunicids and megascolecid clitellates (earthworms). The myriad variations in body form among annelids can best be described relative to the basic annelid regions of a head, segmented trunk, and pygidium. Note, though, that some groups such as Thalassematidae, Hirudinea, Siboglinidae, and

for more ebook/ testbank/ solution manuals requests (email 960126734@qq.com)

Sipuncula are so transformed from this condition, each in its own interesting way, that they are treated as special sections near the end of this chapter. However, in general, the annelid head is composed of the prostomium and peristomium, which take various forms, and may also have one or more body segments fused with it, in which cases cirri and lateral chaetae may be present (Figures 15.8, 15.12A, and 15.15). The prostomium and peristomium often bear appendages in the form of antennae and/or palps, or they may be naked, as in many infaunal burrowers such as the clitellates. The nature of these head appendages varies greatly and often reveals clues as to the worms' habits. The trunk may be homonomous or variably heteronomous, and each segment often bears a pair of unjointed appendages, called parapodia, and bundles of chaetae (Figures 15.4C and 15.5).

Chaetae are a distinctive feature of annelids, although they are also found in some Brachiopoda (and perhaps some other phyla). They come in a huge range of shapes and sizes, each is derived from the microvillar border of an invaginated epidermal cell, and they are essentially bundles of parallel longitudinal canals, the walls of which are the sclerotized chitin (Figure 15.5). Chaetae have been lost in several annelid groups, most notably in Sipuncula and Hirudinea.

Parapodia, when present, are generally biramous, with a dorsal **notopodium** and a ventral **neuropodium**, each lobe with its own cluster of chaetae (Figures 15.4C and 15.5). However, annelids have evolved a huge diversity of parapodia that serve a variety of functions (locomotion, gas exchange, protection, anchorage, creation of water currents). In heteronomous annelids, the morphology of the parapodia may vary greatly in different body regions. Often, for example, parapodia in one region are modified as gills, in another region as locomotory structures, and elsewhere to assist in food gathering. In some cases, particularly in burrowing forms, as well as Sipuncula, Thalassematidae,

(E) A chaeta and its associated musculature. (A after P. A. Meglitsch. 1972. *Invertebrate Zoology*. Oxford University Press, London.)

Diurodrilidae, *Polygordius*, and Clitellata, parapodia have been lost altogether.

Most annelids are gonochoristic and proliferate the gametes from the peritoneum into the coelom, where they develop. Many annelids have broadcast spawning and produce free-swimming larvae, but there is a great variety of life history strategies in this phylum, with a wide range of kinds of parental care also present. Notably, many annelids are hermaphrodites, including all members of Clitellata, which typically exchange sperm and produce brooded or encapsulated embryos that develop directly to juveniles.

Body Wall and Coelomic Arrangement

The annelid body is covered by a thin cuticle, which is composed of scleroprotein and mucopolysaccharide fibers deposited by epidermal cellular microvilli. The epidermis is a columnar epithelium that is often ciliated on certain parts of the body. Beneath the epidermis lies a layer of connective tissue, circular muscles (sometimes absent), and thick longitudinal muscles, the latter often arranged as four bands (Figure 15.4C). The circular muscles do not form a continuous sheath but are interrupted at least at the positions of the parapodia. The inner lining of the body wall is the peritoneum, which surrounds the coelomic spaces and lines the surfaces of internal organs. The coelom of annelids with homonomous bodies is generally arranged as laterally paired (i.e., right and left) spaces, serially (segmentally) arranged within the trunk. Dorsal and ventral mesenteries separate the members of each pair of coeloms, and muscular intersegmental septa isolate each pair from the next along the length of the body. In several annelid lineages, the intersegmental septa have been secondarily lost or are perforated, so in these animals the coelomic fluid and its contents, such as gametes, are continuous among segments. This is of course the case for Thalassematidae and Sipuncula, where there are no segments.

In addition to the main body wall and septal muscles, other muscles function to retract protrusible or eversible body parts (e.g., branchiae, pharynx) and to operate the parapodia (Figure 15.4C). Each parapodium is an evagination of the body wall and contains a variety of muscles. Movable parapodia are operated primarily by sets of diagonal (oblique) muscles, which have their origin near the ventral body midline. These muscles branch and insert at various points inside the parapodium. In the clades Aciculata and Amphinomida, and some Orbiniidae, the large parapodia may contain stout internal

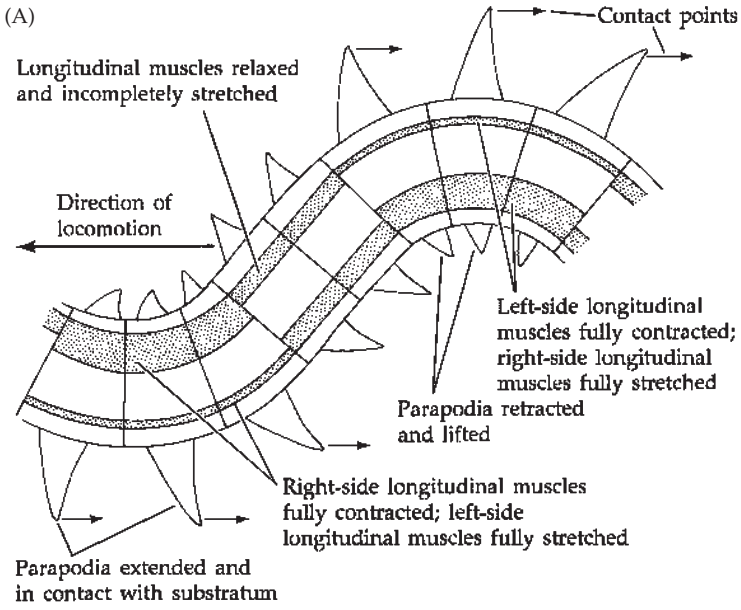
(D) The parapodium of a eunicid with its modified notopodium; note the dorsal filamentous gill. (E) The parapodium of a polynoid (a scale worm) has the dorsal cirrus modified as a scale, or elytron. (F) The parapodium of a phyllodocid; the noto- and neuropodia are modified as gill blades. (G) The reduced parapodium of a tube-dwelling sabellid. (H) The parapodium of an arenicolid. (I–Q) Chaetae from various annelids. The classification of chaetal types rivals that of sponge spicules in complexity and terminology. A few general types are distinguished here as simple chaetae (I–M), compound chaetae (N–O), hooks (P), and uncini (Q). (A–H after P. A. Meglitsch, 1972. *Invertebrate Zoology*. Oxford University Press, London.)

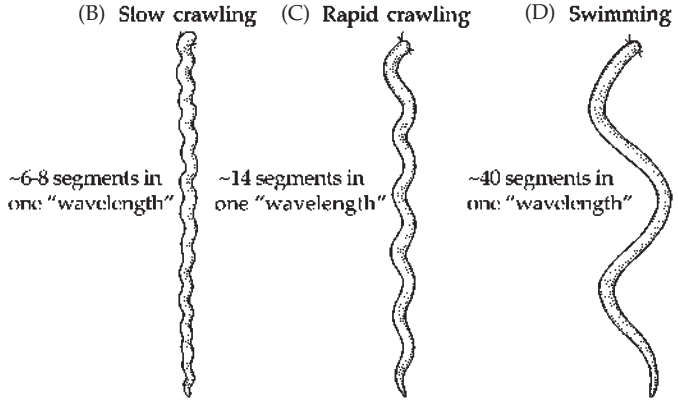
chaetae called **aciculae** (Figure 15.5), on which some muscles insert and operate. In general, chaetae are also maneuvered by muscles and can usually be retracted and extended (quite unlike the setae of arthropods).

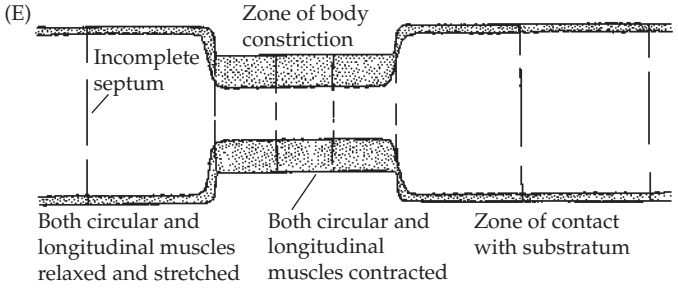
Support and Locomotion

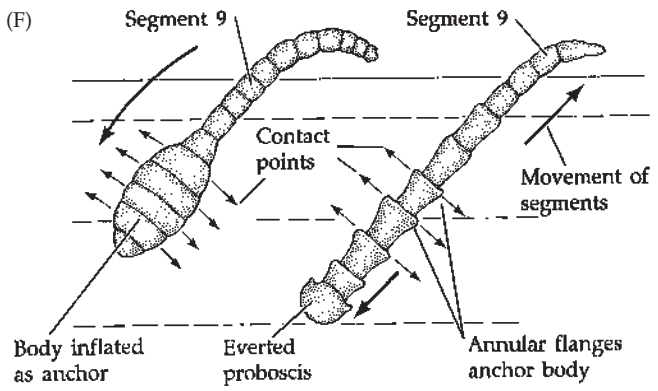
Annelids provide a great example of the employment of coelomic spaces as a hydrostatic skeleton for body support. Coupled with the well-developed musculature, the metameric body, and the parapodia, this hydrostatic quality provides the basis for understanding locomotion in these worms. The genera *Nereis* and *Platynereis* (Phyllodocida, Nereididae) are errant, homonomous annelids that show a variety of locomotory patterns that are worth describing (Figures 15.2E and 15.6A–D). In such annelids the intersegmental septa are functionally complete, and thus the coelomic spaces in each segment can be effectively isolated hydraulically from each other. Modifications on this fundamental arrangement are discussed later.

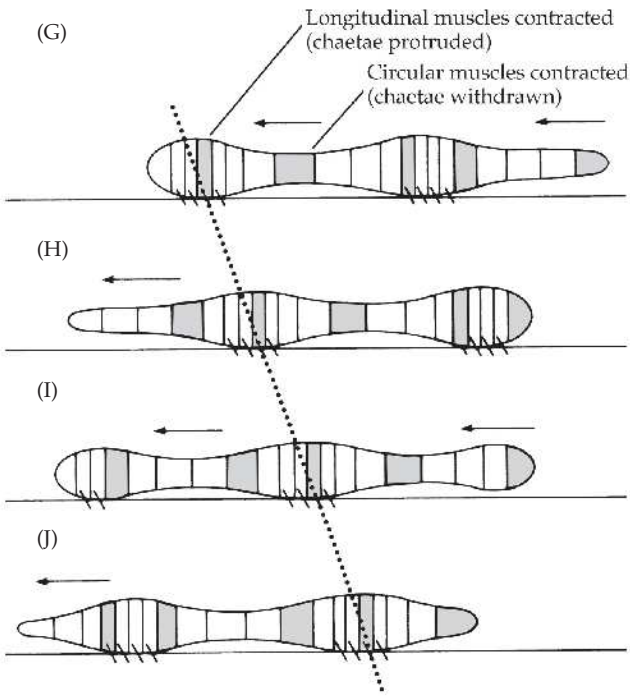
In addition to burrowing *Nereis* can engage in three basic epibenthic locomotory patterns: slow crawling, rapid crawling, and swimming (Figure 15.6A–D). All these methods of movement depend primarily on the bands of longitudinal muscles, especially the larger











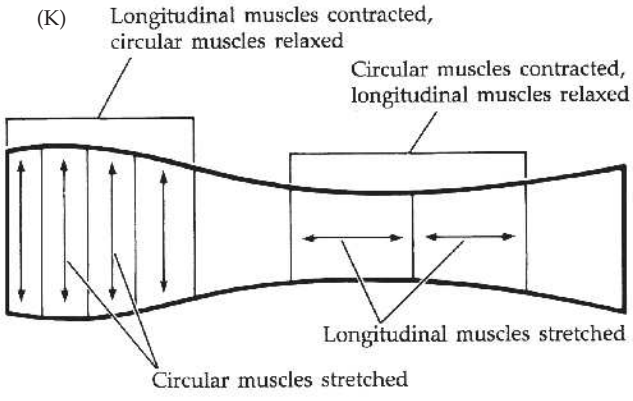


FIGURE 15.6 Patterns of locomotion in annelids. (A) Dorsal view of several segments of *Nereis* during crawling. Note the states of contraction of longitudinal muscles (stippled), the body curvature, and the retraction and extension of parapodia. (B–D) *Nereis* crawling and swimming. Note the changes in metachronal wavelength and amplitude. (E) Midsagittal section through an annelid. The perforated intersegmental septa allow peristaltic body contractions to cause volumetric changes in segments. (F) Burrowing movements in *Arenicola*. (G–J) An earthworm moving to the left. Every fourth segment is darkened for reference. The dotted line passes through a posteriorly moving point of contact with the substratum. (K) Several segments of an earthworm (sagittal section). Since each segment is a functionally isolated compartment, shortening and elongation accompany the contraction of longitudinal and circular muscles, respectively, while each segment essentially maintains a constant volume.

for more ebook/ testbank/ solution manuals requests (mail 960126734@qq.com)

dorsolateral bands, and on the parapodial muscles. The circular muscles are relatively thin and serve primarily to maintain adequate hydrostatic pressure within the coelomic compartments. Each method of locomotion in *Nereis* (and similar forms) involves the antagonistic action of the longitudinal muscles on opposite sides of the body in each segment.

During movement, the longitudinal muscles on one side of any given segment alternately contract and relax (and are stretched) in opposing synchrony with the action of the muscles on the other side of the segment. Thus, the body is thrown into undulations that move in metachronal waves from posterior to anterior. Variations in the length and amplitude of these waves combine with parapodial movements to produce the different patterns of locomotion. The parapodia and their chaetae are extended maximally in a power stroke as they pass along the crest of each metachronal wave. Conversely, the parapodia and chaetae retract in the wave troughs during the recovery stroke. Thus, the parapodia on opposite sides of any given segment are exactly out of phase with one another.

When *Nereis* is crawling slowly, the body is thrown into a high number of metachronal undulations of short wavelength and low amplitude (Figure 15.6B). The extended parapodial chaetae on the wave crests are pushed against the substratum and serve as pivot points as the parapodia engage in the power stroke. As each parapodium moves past the crest, it is retracted and lifted from the substratum as it is brought forward during its recovery stroke. The main pushing force in this sort of movement is provided by the oblique parapodial muscles (Figure 15.4C). During rapid crawling, much of the driving force is provided by the longitudinal body-wall muscles in association with the longer wavelength and greater amplitude of the body undulations (Figure 15.6C), which accentuate the power strokes of the parapodia.

Nereis can also leave the substratum to swim (Figure 15.6D). In swimming, the metachronal wavelength and amplitude are even greater than they are in rapid crawling. When watching a nereidid swim, however, one gets the impression that the "harder it tries," the less progress it makes, and there is some truth to this. The problem is that, even though the parapodia act as paddles pushing the animal forward on their power strokes, the large metachronal waves continue to move from posterior to anterior and create a water current in that same direction; this current tends to push the animal into reverse. The result is that *Nereis* can lift itself off the substratum, but it then largely thrashes about in the water. This behavior is used primarily as a short-term mechanism to escape benthic predators rather than to get from one place to another. There are, however, some annelid groups, such as Alciopini (Phyllodocidae) and *Tomopteris* (Tomopteridae), whose members live their whole lives as pelagic swimming animals.

With these basic patterns and mechanisms in mind, we consider a few other methods of locomotion in annelids. *Nephtys* (Nephtyidae) superficially resembles *Nereis*, but its methods of movement are significantly different. Although *Nephtys* is less efficient than *Nereis* at slow walking, it is a much better swimmer, and it is also capable of effective burrowing in soft substrata. The large, fleshy parapodia serve as paddles, and when swimming, *Nephtys* does not produce long, deep metachronal waves. Rather, the faster it swims, the shorter and shallower the waves become, thus eliminating much of the counterproductive force described for *Nereis*. When initiating burrowing, *Nephtys* swims head first into the substratum, anchors the body by extending the chaetae laterally from the buried segments, and then extends the proboscis deeper into the sand. A swimming motion is then employed to burrow deeper into the substratum.

In contrast to the above descriptions, scale worms (Polynoidae) have capitalized on the use of their muscular parapodia as efficient walking devices. The body undulates little if at all, and there is a corresponding reduction in the size of the longitudinal muscle bands and their importance in locomotion. These worms depend almost entirely on the action of the parapodia for walking, and most adult polynoids cannot swim, except for very short bursts.

Nereis is also a burrower and studies on *N. virens* showed that they can extend their burrows in muddy sediments by using a mechanically efficient fracturing style of locomotion called "crack propagation." This is an efficient use of energy as the worm forces its way through the mud, and it involves everting the pharynx to apply dorsoventral forces to burrow walls that are amplified at the burrow tip making a crack in a forward direction. The worm then anchors itself by expanding the body laterally and pushing its narrow head into the crack, whereupon it repeats the process. Other annelid groups such as cirratulids, glycerids, and orbiniids are also known to use this form of burrowing. Burrowing in sand presents different challenges than burrowing in mud, since sand doesn't "crack" but instead needs to be fluidized. Sand burrowing has been described for *Arenicola* (Arenicolidae), which, like many burrowers, has lost most of the intersegmental septa. Some burrowers have septa that are perforated. This means that segments are not of constant volume; in other words, a loss of coelomic fluid from one body region causes a corresponding gain in another. *Arenicola* also has reduced parapodia. The chaetae, or simply the surface of the expanded portions of the body, serve as anchor points, while the burrow wall provides an antagonistic force resisting the hydraulic pressure. *Arenicola* burrows in sand by first embedding and anchoring the anterior body region in the substratum. The anchoring is accomplished by contracting the circular muscles of the posterior portion of the body, thus forcing coelomic fluid anteriorly and causing the first

few segments to swell. Then the posterior longitudinal muscles contract, thereby pulling the back of the worm forward. To continue the burrowing, a second phase of activity is undertaken. As the anterior circular muscles contract and the longitudinal bands relax, the posterior edges of each involved segment are protruded as anchor points to prevent backward movement; the proboscis is thrust forward, deepening the burrow. Then the proboscis is retracted, the front end of the body is engorged with fluid, and the entire process is repeated (Figure 15.6F).

Clitellates such as crassiclitellates (earthworms) face the problem of burrowing in soils, which may not crack or fluidize like marine sediments. It is argued that they solve this by eating their way through compacted soils or pushing sediment aside in looser soils. In some cases, they line the burrows with mucus to stop the burrows from collapsing. Movement in most clitellates involves the alternately contracting circular and longitudinal muscles within each segment, and this is seen in many other annelids with complete body septa. The shape of a segment changes from long and thin to short and thick with the respective muscle actions (Figure 15.6G–J). These shape changes move anteriorly along the body in a peristaltic wave generated by a sequence of impulses from the ventral nerve cord and associated motor neurons. So, at any moment during locomotion, the body of the worm appears as alternating thick and thin regions. Without some method of anchoring the body surface, this action would not produce any motion. The chaetae provide this anchorage as they protrude like barbs from the thicker portions of the body. When the longitudinal muscles relax and the circular muscles contract, the body diameter decreases, and the chaetae are turned to point posteriorly and lie close to the body. As shown in Figure 15.6G–K, as the anterior end of the body is extended by circular-muscle contraction, the chaetae prevent backsliding, the head is pressed into the substratum, and the worm advances. The anterior end then swells by contraction of the longitudinal muscles, and the rest of the body is pulled along.

Most tube-dwelling annelids (Figure 15.7) are heteronomous and many, such as Terebelliformia, have rather soft bodies and relatively weak muscles. The parapodia are reduced, so the chaetae are used to position and anchor the animal in its tube. Movement within the tube is usually accomplished by slow peristaltic action of the body or by chaetae movements. When the anterior end is extended for feeding, it may be quickly withdrawn by special retractor muscles while the unexposed portion of the body is anchored in the tube. Annelid tubes provide protection as well as support for these soft-bodied worms and keep the animal oriented properly in relation to the substratum. Some annelids build tubes composed entirely of their own secretions. Most notable among these tube builders are the serpulids, which construct their tubes of calcium carbonate secreted by a pair of large glands near a fold of the peristomium called the collar. The crystals of calcium carbonate are added to an organic matrix; the mixture is molded to the top of the tube by the collar fold and held in place until it hardens.

FIGURE 15.7 Tube-dwelling annelids. (A) *Eudistylia vancouveri* (Sabellidae in and out of its tube). (B) The ventral base of the radiolar crown of a sabellid. Note the addition of a mucus-sand mixture to the lip of the tube. (C) The bamboo worm, *Axiothella rubrocincta* (Maldanidae), oriented head down in its sand tube. (D) Bamboo worm *Clymenella* (Maldanidae) out of tube. (E) A cluster of serpulid tubes formed of calcium carbonate and cemented to the substratum. (F) *Ditrupa arietina* (Serpulidae) in its calcareous tube. (G) The particulate tube of the ice-cream-cone worm, *Pectinaria* (Pectinariidae), and animals out of their tubes. (H) A colony of *Phragmatopoma californica* (Sabellariidae). (I) Specimen of *Phragmatopoma californica* (Sabellariidae) removed from its tube. (J) *Spirobranchus giganteus* (Serpulidae), with algae-encrusted operculum.

Sabellids, close relatives of serpulids, produce parchmentlike or membranous tubes of organic secretions molded by the collar. Some, such as *Sabella*, mix mucous secretions with size-selected particles extracted from feeding currents, then lay down the tube with this material (Figures 15.7A,B and 15.10A,B). Numerous other annelid groups form similar tubes of sediment particles collected in various ways and cemented together with mucus. Some of the most beautiful are made by pectinariids, the ice-cream-cone worms, where the ornate tube is only one particle thick (Figure 15.7G).

A few annelids can excavate burrows by boring into calcareous substrata, such as rocks, coral skeletons, or mollusc shells (e.g., certain members of the families Cirratulidae, Eunicidae, Spionidae, Sabellidae). In extreme situations, the activity of the annelids may have deleterious effects on the "host." For example, a boring sabellid, *Terebrasabella*, which lives in abalone shells, can cause fatalities by making them deform their shells. Species of *Polydora* (Spionidae) often excavate galleries in various calcareous substrata (e.g., shells) and have been responsible for killing oysters in commercially harvested areas of Europe, Australia, and North America (Figure 15.9F).

Feeding and Digestion

Feeding The great diversity of form and function among annelids has allowed them to exploit nearly all marine food resources, in one way or another, and to be critical ecosystem components of most terrestrial soils. For convenience we have categorized annelids as raptorial, deposit, and suspension feeders (see Chapter 3). However, there are several feeding methods and dietary preferences within each of these basic designations. Following a discussion of selected examples of these feeding types, we mention a few of the symbiotic annelids.

The most familiar raptorial annelids are hunting predators belonging to the clade Errantia (e.g., many phyllodocids, syllids, nereidids, and eunicids, all part of Aciculata). These animals tend toward homonomy and are capable of rapid movement across the substratum. For the most part they feed on small invertebrates. When prey is located by chemical or mechanical means, the worm everts its pharynx by quick contractions of the body wall muscles in the anterior segments, increasing the hydrostatic pressure in the coelomic spaces and causing the eversion. As a result of the design of the pharynx, the jaws (if present) gape at the anterior-most end when the pharynx is everted (Figure 15.8). Once the prey is positioned within the jaws, the coelomic pressure is released, the jaws collapse on the prey, and the proboscis and captured victim are pulled into the

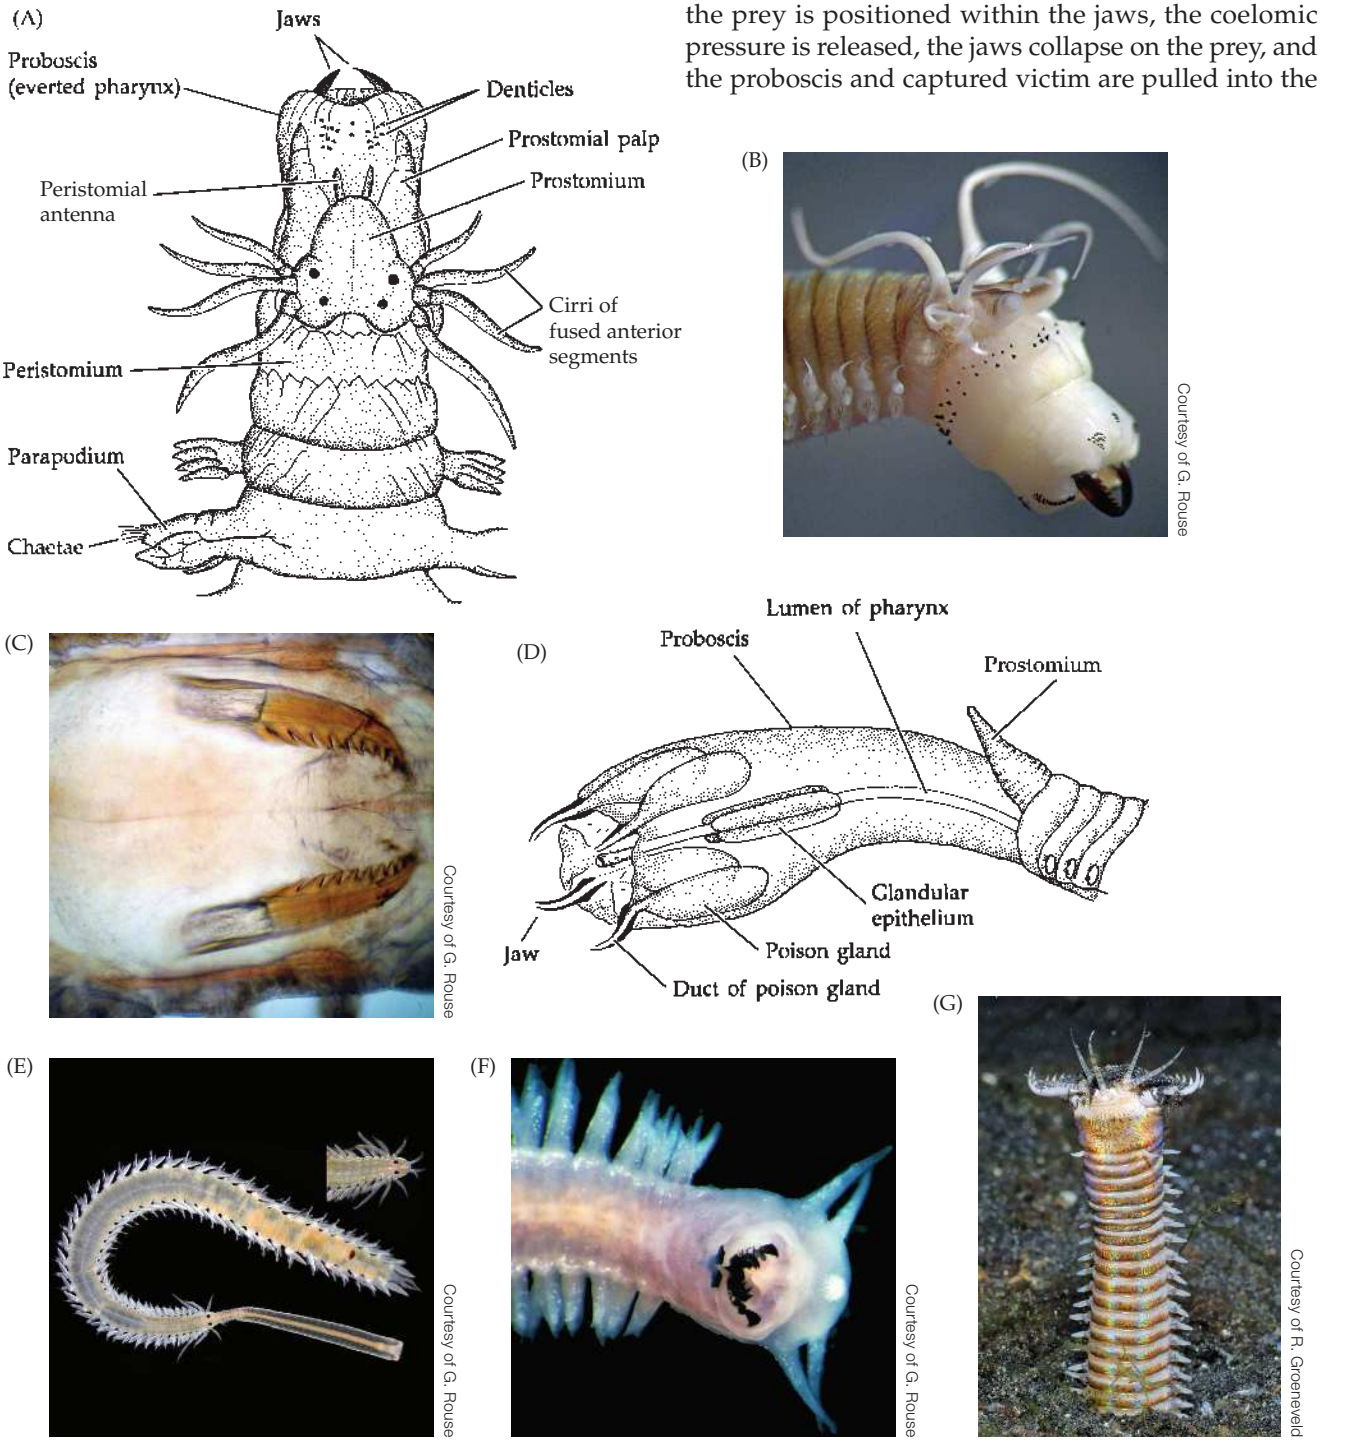

FIGURE 15.8 The eversible pharyngeal jaws of annelids. (A) *Nereis* (Nereididae) with jaws everted. (B) *Perinereis* (Nereididae) with jaws everted. (C) Nereidid with jaws retracted inside body. (D) *Glycera* (Glyceridae) with jaws everted. (E) *Eumida* (Phyllodocidae) with proboscis (lacking jaws but with numerous papillae) withdrawn and everted. (F) *Ophryotrocha* (Dorvilleidae). Complex jaws being everted. (G) The giant (1–3 m) tropical sand striker worm, *Eunice aphroditois*, with its head extended from the sediment at night. The jaws are locked open while it awaits a passing victim, typically a fish. When the antennae or palps detect the prey, the jaws snap shut and it draws the victim into its burrow.

body by large retractor muscles. Many of these raptorial feeders can also ingest plant material and detritus. Some scavenge, feeding on almost any dead organic material they encounter. Raptorial feeding also occurs in some freshwater clitellates such as Lumbriculidae (e.g., *Phagodrilus*), which capture prey (often other clitellates!) with their muscular pharynx.

Some predatory annelids do not actively hunt. Many scale worms (Polynoidae) sit and wait for passing prey, then ambush it by sucking it into their mouth or grasping it with their pharyngeal jaws. In addition, not all raptorial annelids are surface dwellers. Some live in tubes (*Diopatra*) or in complex branched burrows (*Glycera*). Such annelids detect the presence of potential prey outside their tubes or burrows by sensing chemicals or vibrations and extend their everted proboscis to capture the prey. Some leave their residence to hunt for short periods of time, or they emerge from their burrows and wait for a fish to swim into range (e.g., *Eunice aphroditois* [Figure 15.8G], a famous worm known as the "sand striker"). Poison glands, associated with the jaws, occur in some genera (e.g., *Glycera*; Figure 15.8D).

Several groups of annelids are deposit feeders that are relatively unselective, simply ingesting the substratum and digesting the organic matter contained therein (e.g., members of Arenicolidae, Opheliidae, Maldanidae, and many clitellates). Lugworms, such as *Arenicola*, excavate an L-shaped burrow; the worm irrigates the burrow with water drawn into the open end by peristaltic movements of its body (Figure 15.9A). The water percolates upward through the overlying sediment and tends to liquefy the sand at the blind end of the L, near the worm's mouth. This sand is ingested by the muscular action of a bulbous proboscis. The water brought into the burrow also adds suspended organic material to the sand at the feeding site. The worm periodically moves to the open end of its tunnel and defecates the ingested sand outside the burrow in characteristic surface castings. Some maldanids live in straight vertical burrows, head down, and ingest the sand at the bottom (Figure 15.7C). They periodically move upward (backward) to defecate on the surface. A number of other direct deposit feeders (e.g., some opheliids) do not live in constructed burrows but simply move through the substratum ingesting sediments as they go. In high concentrations, populations of these annelids can pass thousands of tons of sediments through their guts each year—which has a significant impact on the nature of the deposits in which they live. Most terrestrial and many aquatic clitellates are, at least in part, direct deposit feeders. Earthworms burrow through the soil, ingesting the substratum as they move. As the soil is passed along the digestive tract, the organic material is digested and absorbed from the gut. The inorganic, indigestible material passes out the anus. Earthworms are said to "work" the soil in this manner, loosening and aerating it. Many of these terrestrial burrowers, including the common earthworm *Lumbricus*, are more selective and retrieve organic material from the surface. These worms can burrow to the surface of the soil and there use their suckerlike mouth to obtain relatively large pieces of food (e.g., partially decomposed leaves), which they carry back underground for ingestion.

Selective deposit feeders are defined by their ability to effectively sort the organic material from the sediment prior to ingestion (e.g., many species of Terebellidae, Spionidae, and Pectinariidae). However, the methods used to sort food differ among these groups. Most terebellids (e.g., *Amphitrite*, *Pista*, *Terebella*) establish themselves in shallow burrows or permanent tubes (Figure 15.9B–E). The feeding tentacles are grooved prostomial palps that are extended over the substratum. These are extended by ciliary crawling and can be retracted by muscles. Once extended, their epithelium secretes a mucous coat to which organic material, sorted from the sediment, adheres. The tentacle edges curl up to form a longitudinal groove along which food and mucus are carried by cilia to the mouth. Tube-dwelling spionids engage in a similar method of feeding. In these animals, the feeding structures are more muscular and derived from the peristomial palps (Figure 15.9F). They are swept through the water or brushed through the surface sediments, extracting food and moving it to the mouth.

Pectinaria, the ice-cream-cone worms, live in a tube constructed of sand grains and shell fragments. The tube is open at both ends. The animal orients itself head down, with the posterior end of the tube projecting to the sediment surface (Figure 15.9G). Head appendages partially sort the sediment, and a relatively high percentage of organic matter is ingested. Several other annelids employ these and other methods of selective deposit feeding.

Various forms of suspension feeding are accomplished by many tube-dwelling annelids (e.g., members of Serpulidae and Sabellidae) and by some that live in relatively permanent burrows (e.g., Chaetopteridae). The feeding structures of *Sabella* and many related types are a crown of branching prostomial palps called **radioles**. Some of these worms generate their own feeding currents, whereas others "fish" their tentacles in moving water. As food-laden water passes over the tentacles, the water is driven by cilia upward between the pinnules (branches) of the radioles (Figure 15.10A,B). Eddies form on the medial side (inside) of the tentacular crown and between the pinnules, slowing the flow of water, decreasing its carrying capacity, and thus facilitating extraction of suspended particles. The particles are carried, with mucus, along a series of small ciliary tracts on the pinnules to a groove along the main axis of each radiole. This groove is widest at its opening and decreases in width in a stepwise fashion to a narrow slot deep in the groove. By this means, particles are mechanically sorted into three size categories as they are carried into the groove. Typically, the smallest particles are carried to the mouth and ingested, the largest particles are rejected, and the medium-sized ones are stored for use in tube building. FIGURE 15.10 Two strategies of suspension feeding in annelids. (A,B) Suspension feeding by a sabellid. (A) Tentacular crown extended from tube and water currents (arrows) passing between tentacles. (B) A portion of a tentacle (radiole) in section. Various ciliary tracts remove particulate matter and direct it to the longitudinal groove on the radiole axis. Here, sorting by size occurs. Most of the largest particles are rejected, the smallest ones are ingested, and the medium-sized particles are used in tube building. (C) *Chaetopterus* (Chaetopteridae) in its U-shaped burrow. The ventral view shows details of the worm's anterior end. A water current (arrows) is produced through the burrow by fan-shaped parapodia. Food is removed as the water passes through a secreted mucous bag. The bag is eventually passed to the mouth and ingested, food and all. See text for additional details. (D) The two ends of the U-shaped tube of a *Chaetopterus* emerging from the sediment. (E) *Chaetopterus* (Chaetopteridae) removed from its tube.

Ripistes parasita, long chaetae located on the anterior segments are waved about in the water, and small detrital particles adhere to them; food material is then ingested by wiping the chaetae across the mouth.

Some members of Chaetopteridae, such as *Chaetopterus*, are among the most heteronomous of all annelids, and the body is distinctly regionally specialized (Figures 15.1B and 15.10C–E). *Chaetopterus* filters water for food. These animals reside in U-shaped burrows through which they move water, extracting suspended materials. Each body region plays a particular role in this feeding process. Segments 14–16 bear greatly enlarged notopodial fans that serve as paddles to create the water current through the burrow. A mucous bag, produced by secretions from segment 12, is held as shown in Figure 15.10C, so that water flows into the open end of the bag and through its mucous wall. Particles as small as 1 μm in diameter are captured by this structure, and there is some evidence that even protein molecules are held in the mucous net (probably by ionic charge attraction rather than mechanical filtering). During active feeding, the bag is rolled into a ball, passed to the mouth by a ciliary tract, and ingested every 15–30 minutes or so; then a new bag is produced.

Symbiotic relationships with other animals occur among several groups of annelids. There are some interesting cases that reflect, again, the adaptive diversity of these worms. Many symbiotic annelids are hardly modified from their free-living counterparts and do not show the drastic adaptive characteristics often associated with this sort of life. For many, the relationship with their host is a loose one, the annelid often using the host merely as a protective refuge. We have already mentioned annelids, otherwise quite like their free-living relatives, that burrow into the shells of other invertebrates. Among the most commonly found commensal annelids are polynoid scale worms, especially members of the genera *Arctonoe*, *Halosydna,* and *Macellicephala,* which live on the bodies of various molluscs, echinoderms, and cnidarians (Figure 15.11A,B). A polynoid has even been

discovered living as a commensal in the mantle cavity of giant deep-sea mussels residing near thermal vents on the East Pacific Rise. One scale worm, *Hesperonoe adventor*, inhabits the burrows of the Pacific innkeeper worm, *Urechis caupo* (Thalassematidae) (Figure 15.28G). One group of annelids, Myzostomida, is nearly always symbiotic with echinoderms, chiefly crinoids, but also asteroids and ophiuroids. Myzostomids show a variety of adult body shapes and lifestyles, with most described species living freely on the exterior of their hosts as adults, while others live in galls, cysts, or in the host's mouth, digestive system, coelom, or even the gonads. Myzostomid lifestyles range from stealing incoming food from the host's food grooves to consuming the host's tissue directly (Figure 15.3).

There are many examples of these rather informal associations: certain syllids that live and feed on hydroids, a nereidid (*Nereis fucata*) that resides in the shells of hermit crabs, and so on. Most of these animals do not feed upon their hosts but prey upon tiny organisms that happen into their immediate environment. Others consume detritus or scraps from their host's meals. Several other odd associations are known among the annelids. Most oenonids live part of their lives as parasites in the bodies of thalassematids and other annelids. Again, these endosymbionts show little structural modification associated with their lifestyles, other than a tendency for small body size and reduction in the pharyngeal jaws. An example of a fully parasitic annelid is *Ichthyotomus sanguinarius* (Chrysopetalidae). These small (1 cm long) worms attach to eels by a pair of stylets or jaws. The stylets are arranged so that when their associated muscles contract, the stylets fit together like the closed blades of scissors. The stylets are thrust into the host, and when the muscles relax, they open and anchor the parasite to the fish (Figure 15.11C,E). The Pacific hydrocoral *Stylaster californicus* typically harbors colonies of the spionid *Polydora alloporis*, whose paired burrow openings are often mistaken for the hydrozoan's polyp cups.

A most unusual symbiotic relationship exists between the strange ampharetid Pompeii worm *Alvinella pompejana* (Figure 15.11D) and a variety of marine chemoautotrophic sulfur bacteria. *Alvinella* (the genus named after the deep-sea submersible *Alvin*) is a notable member of deep hydrothermal vent communities of the East Pacific Rise. It lives closer to the hot water extrusions than any other animal in the vent community, often near perforated structures called "snowballs" or "beehives" formed by the thermal plumes. Temperatures inside the tubes of *Alvinella* can reach an astonishing 80°C. The bodies of Pompeii worms are covered with unique vent bacteria. The worms are somehow protected from the hot temperatures, and they feed on these symbiotic bacteria. A hesionid worm, *Hesiolyra bergi*, is often found living in the tubes of *Alvinella pompejana* and may also be eating the bacteria or possibly preying on the worm itself.

Over 80 species of gutless marine clitellates, all in the family Naididae, have been described in shallow coral-sand habitats and in anaerobic, sulfide-rich subsurface sediments. These worms typically harbor a range of coexisting subcuticular symbiotic bacteria (up to five species), whose precise role in the host's nutritional regimen is not yet fully understood. The endosymbiotic bacteria are clearly important to the worms; they are passed to the fertilized eggs during oviposition from storage areas next to the female's gonopore.

Digestion The gut of annelids is constructed on a basic plan of foregut, midgut, and hindgut; some examples are shown in Figure 15.12. The foregut is a stomodeum and includes the buccal capsule or tube, the pharynx, and at least the anterior portion of the esophagus. It is lined with cuticle, and the teeth or jaws, when present, are derived from scleroproteins produced along this lining. The jaws are often hardened with calcium carbonate or metal compounds. When present, the eversible portion of this foregut (the proboscis) is derived from the buccal tube or the pharynx. Various glands are often associated with the foregut, including poison glands (glycerids), esophageal glands (nereidids and others), and mucus-producing glands in several groups. In earthworms the posterior esophagus often bears enlarged regions forming a crop, where food is stored, and one or more muscular gizzards lined with cuticle and used to mechanically grind ingested material. The esophagus of many clitellates also has thickened portions of the wall in which are located lamellar evaginations lined with glandular tissue (Figure 15.12G). These **calciferous glands** remove calcium from ingested material. The excess calcium is precipitated by the glands as calcite and then released back into the gut lumen. Calcite is not absorbed by the intestinal wall and so passes out of the body via the anus. In addition, the calciferous glands apparently regulate the level of calcium ions and carbonate ions in the blood and coelomic fluids, thereby buffering the pH of those fluids.

The endodermally derived midgut generally includes the posterior portion of the esophagus and a long, straight intestine, the anterior end of which may be modified as a storage area, or stomach. The midgut may be relatively smooth, or its surface area may be increased by folds, coils, or many large evaginations (or ceca). The midgut is often histologically differentiated along its length. Typically, the anterior midgut (stomach or anterior intestine) contains secretory cells that produce digestive enzymes. The secretory midgut grades to a more posterior absorptive region. In many terrestrial clitellate species, the surface area of the intestine is enlarged by a middorsal groove called the **typhlosole**. Associated with the midgut of many clitellates, and some other annelids as well, are masses of pigmented cells called **chloragogen cells**. These modified peritoneal cells contain greenish, yellowish, or brownish globules

that impart the characteristic coloration to this **chloragogenous tissue**. This tissue lies within the coelom but is pressed tightly against the visceral peritoneum of the intestinal wall and typhlosole. Chloragogenous tissue serves as a site of intermediary metabolism (e.g., synthesis and storage of glycogen and lipids, deamination of proteins). It also plays a major role in excretion.

Toward the posterior end of the gut, there may be additional secretory cells that produce mucus. This mucus is added to the undigested material during the formation of fecal pellets. Food is moved along the midgut by cilia and by peristaltic action of gut muscles, usually comprising both circular and longitudinal layers. A short rectum connects the midgut to the anus, located on the pygidium. A variety of digestive enzymes are known from different species. Predators tend to produce proteases, while herbivores largely produce carbohydrases. Some omnivorous forms (e.g., *Nereis virens*) produce a mixture of proteases, carbohydrases, lipases, and even cellulase. Digestion is predominantly extracellular in the midgut lumen, although intracellular digestion is known in some groups (e.g., *Arenicola*). Some annelids harbor symbiotic bacteria in their guts that aid in the breakdown of cellulose and perhaps other compounds.

Circulation and Gas Exchange

Given the relatively large size of many annelids, the compartmentalization of their coelomic chambers, and the fact that only certain portions of their gut absorb digested food products, it is essential that a circulatory mechanism be present for internal transport and distribution of nutrients. Furthermore, many annelids have their gas exchange structures limited to certain body regions. Hence, they depend on the circulatory system for internal transport of gases.

It is easiest to understand the circulatory system of annelids by considering it in concert with their gas exchange structures, which are remarkably varied. In many annelids that lack appendages, the entire body surface functions in gas exchange (e.g., lumbrinerids, oenonids). Some of the active epibenthic forms utilize highly vascularized portions of the parapodia as gills. Special gas exchange structures, or branchiae, are found in the form of trunk filaments (cirratulids, orbiniids), anterior gills (ampharetids, terebellids), and tentacular, or branchial, crowns on the head (sabellids, serpulids, and siboglinids). Since the blood generally carries respiratory pigments, the anatomy of the circulatory system has evolved along with the structure and location of these gas exchange structures.

We again begin our examination with a homonomous annelid, such as *Nereis*, in which the parapodia are more or less like one another and the notopodia function as gills. The major blood vessels include a middorsal longitudinal vessel, which carries blood anteriorly, and a midventral vessel, which carries blood posteriorly. Exchange of blood between these vessels occurs through posterior and anterior vascular networks and serially arranged segmental vessels (Figure 15.13A). Anterior vessel networks are especially well developed around the muscular pharynx and the region of the cerebral ganglion.

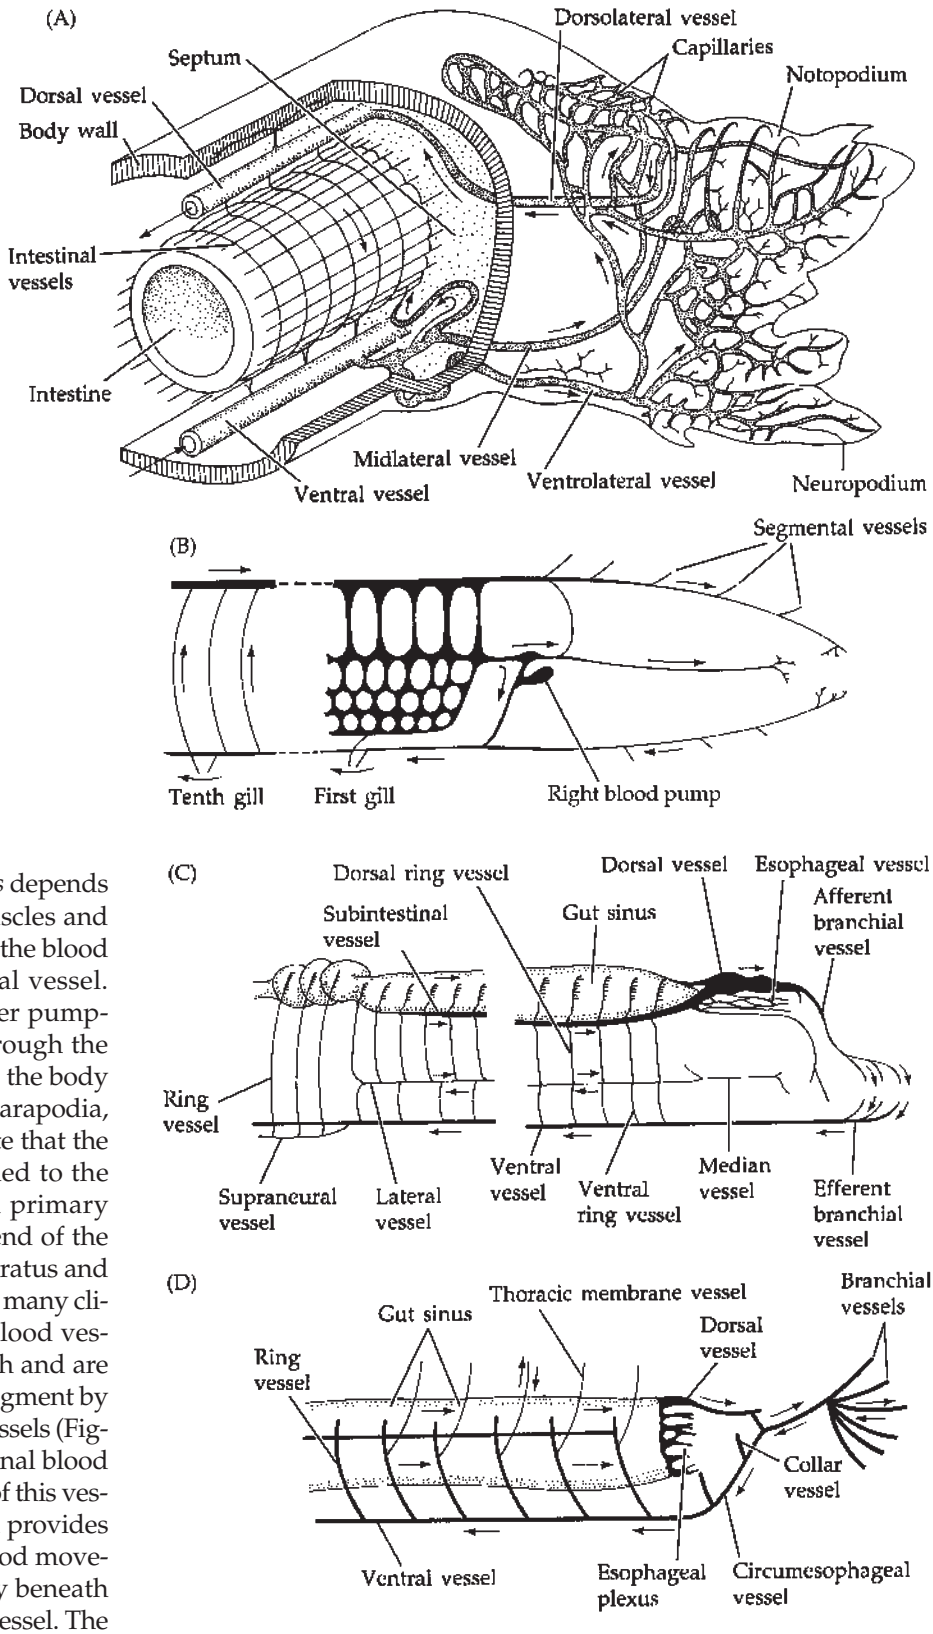

FIGURE 15.13 Annelid circulatory and gas exchange systems. Variations from the basic plan include additional vessels, sinuses associated with the foregut, and branchial vessels serving anterior gills. (A) A segment and parapodium (cutaway view) of a nereid. Note the major blood vessels and blood flow pattern (arrows). Blood flows anteriorly in the dorsal vessel and posteriorly in the ventral vessel. In such annelids the flattened parapodia serve as gills. (B–F) Circulatory patterns in an arenicolid (B), a terebellid (C), a serpulid (D), and *Lumbricus* (Clitellata). (E) Anterior blood vessels (lateral view) and (F) the circulatory pattern in one segment (cross section). (E After C. A. Edwards and J. R. Lofty. 1972. *Biology of Earthworms*. Chapman and Hall, London. https://link.springer.com/chapter/10.1007/978-1-4899-6912-5_1)

The movement of blood in *Nereis* depends on the action of the body wall muscles and on intrinsic muscles in the walls of the blood vessels, especially the large dorsal vessel. There are no special hearts or other pumping organs. The blood passing through the various segmental vessels supplies the body wall muscles, gut, nephridia, and parapodia, as illustrated in Figure 15.13A. Note that the oxygenated blood is being returned to the dorsal vessel, thus maintaining a primary supply of oxygen to the anterior end of the animal, including the feeding apparatus and cerebral ganglion. In *Lumbricus* and many clitellates, three main longitudinal blood vessels extend most of the body length and are connected to one another in each segment by additional segmentally arranged vessels (Figure 15.13E,F). The largest longitudinal blood vessel is the dorsal vessel; the wall of this vessel is quite thick and muscular and provides much of the pumping force for blood movement. Suspended in the mesentery beneath the gut is the longitudinal ventral vessel. The third longitudinal vessel lies ventral to the nerve cord and is called the subneural vessel. Exchanges between the longitudinal vessels occur in each segment through various routes supplying the body wall, gut, and nephridia (Figure 15.13F). Most of the exchanges between the blood and the tissues take place through capillary beds supplied by afferent and efferent vessels. Blood flows posteriorly in ventral and subneural vessels and anteriorly in the dorsal vessel; exchange between the dorsal and ventral vessels occurs in each segment, as shown in Figure 15.13E.

There are many variations on the basic circulatory schemes just outlined, and we mention only a few variations to illustrate the diversity within annelids. Drastic differences are present even among annelids of generally similar body forms. Among the homonomous forms, for example, the circulatory system may be reduced (e.g., Phyllodocidae) or lost (e.g., Capitellidae, Glyceridae, and Sipuncula). In some cases, reduction is probably associated with small size. This hypothesis, however, cannot be applied to capitellids and glycerids, many of which are large and quite active. In these worms and some others, the circulatory system is greatly reduced and has become fused with remnants of the coelom. The coeloms of glycerids and capitellids contain red blood cells (with hemoglobin). Since glycerids have incomplete septa, the coelomic fluid can pass among segments, moved by body activities and ciliary tracts on the peritoneum. In their burrowing lifestyle, enlarged parapodial gills or delicate anterior gills would be disadvantageous, so the general body surface has probably taken over the function of gas exchange, and the coelom the function of circulation. A similar phenomenon may have occurred in Sipuncula.

Compared with *Nereis* or *Lumbricus*, many annelids display additional blood vessels, modification of vessels, differences in blood flow patterns, and formation of large sinuses. As might be predicted, some striking differences are seen among certain heteronomous annelids with reduced parapodia and anteriorly located branchiae (e.g., terebellids, sabellids, and serpulids). In many of these worms, in the region of the stomach and anterior intestine, the dorsal vessel is replaced by a voluminous blood space called the gut sinus (Figure 15.13C,D). Usually, the dorsal vessel continues anteriorly from this sinus, and it often forms a ring connecting with the main ventral vessel. In the sabellids and serpulids, a single, blind-ended vessel extends into each branchial tentacle. Blood flows in and out of these branchial vessels that, in some forms (e.g., serpulids), are equipped with valves that prevent backflow into the dorsal vessel. This two-way flow of blood within single vessels is quite different from the capillary exchange system in most closed vascular systems. A few clitellates possess extensions of the body wall that increase the surface area and function as simple gills (e.g., *Branchiura*, *Dero*), but most exchange gases across the general body surface.

Specialized pumping structures have evolved in several annelid groups. They are especially well developed in certain tube-dwelling forms where they compensate for the reduced effect of general body movements on circulation. These structures, sometimes called hearts, are often little more than an enlarged and muscularized portion of one of the usual vessels; the dorsal muscular vessel of chaetopterids is such a structure. Terebellids possess a "pumping station" at the base of the gills that functions to maintain blood pressure and flow within the branchial vessels (Figure 15.13B). A variety of similar structures are known among other annelids, including the 5 pairs of aortic arches of earthworms.

Most annelids contain respiratory pigments within their circulatory fluid, which is generally acellular. Those without any such pigment include some very small forms and various syllids, phyllodocids, polynoids,

aphroditids, *Chaetopterus*, and a few others. When a pigment is present, it is usually some type of hemoglobin, although chlorocruorin is common in some taxa (e.g., certain flabelligerids, sabellids, and serpulids), and hemerythrin occurs in magelonids. Magelonidae are also interesting in that their blood contains cells (corpuscles). Some annelids have more than one type of pigment; for example, the blood of some serpulids contains both hemoglobin and chlorocruorin.

Annelid respiratory pigments may occur in the blood itself, the coelomic fluid, or both. With a few exceptions, blood pigments occur in solution and coelomic pigments are contained within corpuscles. The latter situation is generally associated with reduction or loss of the circulatory system (as in glycerids). The incorporation of coelomic pigments, usually hemoglobin, into cells is probably a mechanism to prevent the serious osmotic effects that would result from large numbers of free dissolved molecules in the body fluid. Corpuscular coelomic hemoglobins tend to be of much smaller molecular sizes than those dissolved in the blood plasma. The significance of this difference is not clear, but in the case of arenicolids it could be related to oxygen challenges, as these worms often burrow in low-oxygen sediments.

The types of respiratory pigments and their disposition within the body of annelids are related at least in part to lifestyles. As discussed in Chapter 3, different pigments—even different forms of the same pigment—have different oxygen loading and unloading characteristics. The nature of the pigments in a particular worm reflects its ability to store oxygen and then release it during periods of environmental oxygen depletion. Species in several intertidal burrowing annelid groups take up and store oxygen during high tides and dissociate the stored oxygen during low tides. This sort of physiological cycle ameliorates the potential stress of oxygen depletion in the body during low tide periods. In some species, one form of hemoglobin is used for normal conditions, and another form stores oxygen and releases it during periods of stress. Some annelids (e.g., *Euzonus*) can convert to anaerobic metabolic pathways during extended periods of anoxic conditions. Many terrestrial clitellates are capable of sufficient gas exchange only when exposed to air; they will drown if submerged. (Remember, air contains far more oxygen than water.) We have all seen earthworms crawling about the surface following a heavy rain. One species of earthworm (*Alma emini*) has evolved a remarkable adaptation that allows it to survive the rainy season in its East African habitat. When rains cause its burrow to flood, the worm moves to the surface of the soil and forms a temporary opening. The worm then projects its posterior end out through the opening and rolls the sides of the body wall into a pair of folds, forming an open chamber that serves as a kind of "lung." The highly vascularized posterior epithelium enhances the exchange of gases. Several aquatic clitellates can tolerate periods of low availability of oxygen and even anoxic conditions for short periods of time. This includes the sludge worms such as *Tubifex*, members of Naididae that live in very enriched, low-oxygen environments such as sewage.

Excretion and Osmoregulation

In Chapter 3 we discussed nephridial organs in invertebrates. Thus far, we have seen various types of protonephridia, especially among the acoelomate and certain blastocoelomate Metazoa. In annelids, metanephridia are typically found in adults, and these structures commonly pass through a protonephridial stage during their development. Most annelids possess some type of metanephridia, often serially arranged as one pair per segment, with the pore in the segment posterior to the nephrostome. However, variations on this theme are many, and protonephridia are found in some adult annelids. The success of an animal with segmentally arranged isolated coelomic compartments depends on the physical and physiological maintenance of those separate segments. The removal of metabolic wastes (predominantly ammonia) and the regulation of osmotic and ionic balance must occur in each functionally isolated coelomic chamber. (See also the discussion and figures pertaining to excretion and osmoregulation in Chapter 3). While it was once assumed that annelids had separately derived excretory (nephridial) and gonoduct (coelomoduct) systems, the evidence now suggests that while the ducts exiting the body are for the most part nephridial, they may also function in the spawning of gametes.

Protonephridia are found in certain adult annelids mostly in groups within Phyllodocida, and these appear to be metanephridia that have altered their development such that the funnel opening to the coelom connects to a nephridioduct (Figure 15.14A) that also leads to some flame cells. However, most annelids possess paired metanephridia, each metanephridium opening to the coelom via a ciliated nephrostome. In a few annelids (e.g., capitellids), both metanephridia and separate coelomoducts occur, but in most there are metanephridia only. In certain annelid groups with incomplete or missing septa, the number of nephridia is reduced. In some, such as Terebelliformia, anterior nephridia are excretory only, whereas in the posterior region of the body, where the gametes are formed, nephridia are used for spawning and presumably also excretion. The extreme case of this is found in groups such as acrocirrids, cirratulids, serpulids, siboglinids, and sabellids where there is a single anterior pair of large excretory metanephridia. In sabellids and serpulids these lead to a single fused nephridioduct and common pore behind the head (Figure 15.14C). A typical clitellate nephridium is composed of a preseptal nephrostome (either open to the coelom or secondarily

for more ebook/ testbank/ solution manuals requests (email 960126734@qq.com)

closed as a bulb), a short canal that penetrates the septum, and a postsegmental nephridioduct that is variably coiled and sometimes dilated as a bladder (Figure 15.14D). The nephridiopores are usually located ventrolaterally on body segments.

As described in Chapter 3, the open nephrostomes of metanephridia nonselectively pick up coelomic fluids. This action is followed by resorption of materials from the nephridium back into the body, either directly into the surrounding coelomic fluid, or into the blood in cases where extensive nephridial blood vessels are present (e.g., in some nereidids and in aphroditids). In either case the composition of the urine is quite different from that of the body fluids; the difference indicates a significant amount of physiological selectivity along the length of the nephridium.

Osmoregulation presents little problem for subtidal marine annelids living in relatively constant osmotic conditions. Intertidal and estuarine forms, however, must be able to withstand periods of stress associated with fluctuations in environmental salinities. Many species are osmoconformers (e.g., *Arenicola*), allowing the tonicity of their body fluids to fluctuate with changes in the environmental salinity. Most annelid osmoconformers have relatively simple metanephridia, with comparatively short nephridioducts and correspondingly weaker resorptive and regulatory capacities. Some also have relatively thin body-wall musculature, and the

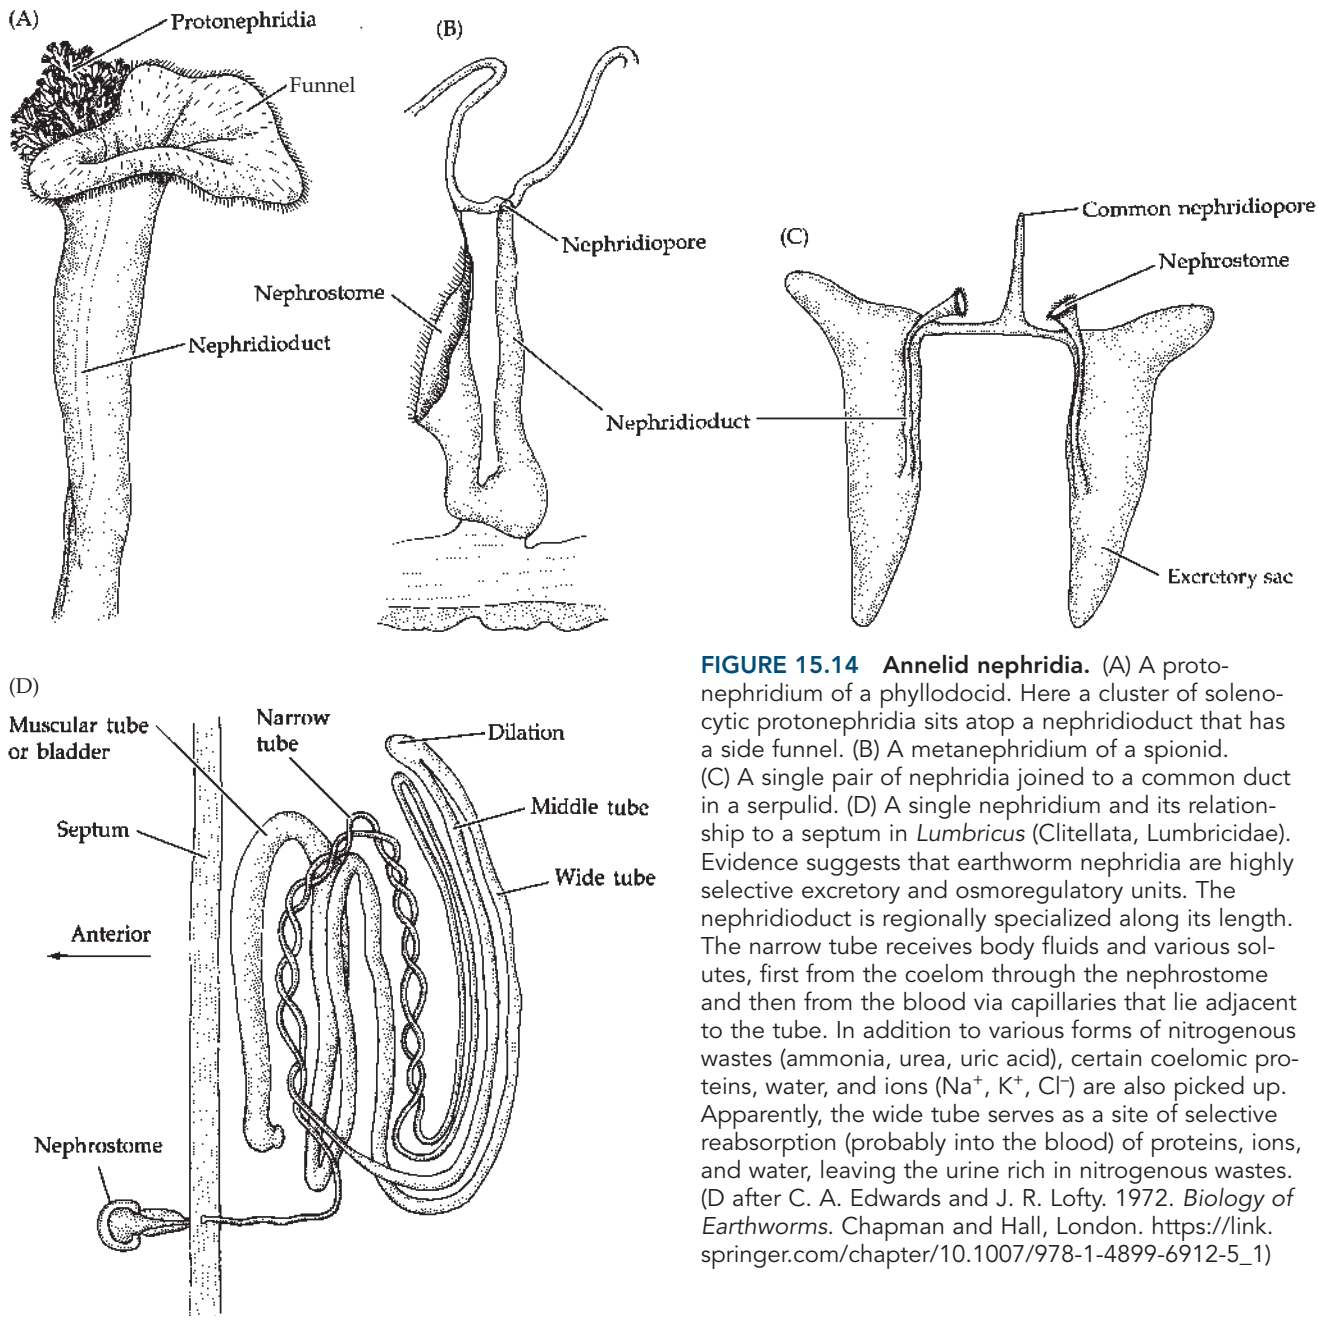

FIGURE 15.14 Annelid nephridia. (A) A protonephridium of a phyllodocid. Here a cluster of solenocytic protonephridia sits atop a nephridioduct that has a side funnel. (B) A metanephridium of a spionid. (C) A single pair of nephridia joined to a common duct in a serpulid. (D) A single nephridium and its relationship to a septum in *Lumbricus* (Clitellata, Lumbricidae). Evidence suggests that earthworm nephridia are highly selective excretory and osmoregulatory units. The nephridioduct is regionally specialized along its length. The narrow tube receives body fluids and various solutes, first from the coelom through the nephrostome and then from the blood via capillaries that lie adjacent to the tube. In addition to various forms of nitrogenous wastes (ammonia, urea, uric acid), certain coelomic proteins, water, and ions (Na^+, K^+, Cl^-) are also picked up. Apparently, the wide tube serves as a site of selective reabsorption (probably into the blood) of proteins, ions, and water, leaving the urine rich in nitrogenous wastes. (D after C. A. Edwards and J. R. Lofty. 1972. *Biology of Earthworms*. Chapman and Hall, London. https://link.springer.com/chapter/10.1007/978-1-4899-6912-5_1)

body swells when in a hypotonic medium. It is likely that burrowers and tube dwellers face less osmotic stress than epibenthic forms, because the water in their tubes may be less subject to ionic variation than the overlying water. Osmoregulators, such as several estuarine nereidids, often have thicker body walls that tend to resist changes in shape and volume. When water enters the body from hypotonic surroundings, the increased hydrostatic pressure generated within the coelom works against that osmotic gradient. In addition, regulators can maintain (within limits) a constant internal fluid tonicity because of the greater selective capabilities of their more complex nephridia.

Ionic and osmotic regulation are major challenges for annelids in freshwater and terrestrial habitats, and few evolutionary lineages have solved these problems, the main example being the Clitellata. The moist, permeable surface necessary for gas exchange, and the severe osmotic gradients across the body wall, present potentially serious problems associated with water loss in terrestrial forms and with water gain in freshwater forms. Both situations threaten the loss of precious diffusible salts. Passive diffusion of water and salts also occurs across the gut wall. The major organs of water and salt balance in freshwater annelids are, of course, the nephridia. Excess water is excreted, and salts are retained by selective and active resorption along the nephridioduct. The problem in terrestrial species is more serious. Surprisingly, earthworms are not absolute osmoregulators; rather, they lose and gain water according to the amount of water in their environment. Various species can tolerate a loss of 20% to 75% of their body water and still recover. Under normal conditions, water conservation by earthworms is probably accomplished in several ways. The production of urea allows the excretion of a relatively hypertonic urine compared with that of a strictly ammonotelic animal. There may also be active uptake of water and salts from food across the gut wall. Certainly, there are behavioral adaptations for remaining in relatively moist environments, in addition to the physiological adaptations that allow these animals to tolerate temporary partial dehydration of their bodies.

Aquatic clitellates are ammonotelic, but most terrestrial forms are at least partially ureotelic. These wastes are transported to the nephridia via the circulatory system and by diffusion through the coelomic fluid. Uptake of materials into the nephridial lumen is partly nonselective from the coelom (in those worms with open nephrostomes) and partly selective across the walls of the nephridioduct from the afferent nephridial blood vessels. A significant amount of selective resorption occurs into the efferent blood flow along the distal portion of the nephridioduct, facilitating efficient excretion as well as ionic and osmoregulation.

Nervous System and Sense Organs

The central nervous system in annelids (as in protostomes in general) includes a dorsal cerebral ganglion, paired circumenteric connectives, and one or more ventral longitudinal nerve cords. The most common ventral nerve cord condition seen in annelids consists of two closely allied cords with segmental ganglia (a **rope ladder nerve cord**; Figure 15.15). This lies inside the body, away from the epidermis (i.e., it is subepidermal). However, a series of annelid groups show a ventral nerve cord that, while somewhat rope-ladder-like, lies within the epidermis (i.e., it is intraepidermal). The occurrence of intraepidermal paired ventral nerve cords in taxa such as Oweniida and Chaetopteridae, as well as Errantia, suggests this might be the plesiomorphic condition for Annelida. The classical rope ladder cord has arguably evolved several times from the intraepidermal nerve cord condition.

The cerebral ganglion of annelids is usually bilobed and lies within the prostomium. One or two pairs of circumenteric connectives extend from the cerebral ganglion around the foregut and unite ventrally in the subenteric ganglion. Commonly, a pair of longitudinal nerve cords arises from the subenteric ganglion and extends the length of the body. Ganglia are arranged along these nerve cords, one pair in each segment, and are connected by transverse commissures. Lateral nerves extend from each ganglion to the body wall, and each bears a so-called **pedal ganglion**. This double nerve cord arrangement is common in certain groups of annelids, including sabellids and serpulids, though these are derived annelids. Other taxa, such as amphinomids, have four longitudinal ventral nerve cords, a medial pair and a lateral pair, the latter connecting the pedal ganglia. Similar, but perhaps nonhomologous, lateral longitudinal cords appear in some other annelid taxa that are relatively derived. In many other annelids there has been fusion of the medial nerve cords to form a single midventral longitudinal cord. The degree of fusion varies among taxa, and some retain separate nerve tracts within the single cord.

The cerebral ganglion is often specialized into three regions, typically called the forebrain, midbrain, and hindbrain. Generally, the forebrain innervates the prostomial palps, the midbrain the eyes and prostomial antennae or tentacles, and the hindbrain the chemosensory nuchal organs (Figure 15.15A,D,E). The circumenteric connectives arise from the fore- and midbrain. The midbrain also gives rise to a complex of motor stomatogastric nerves associated with the foregut, especially with the operation of the proboscis or pharynx. The circumenteric connectives often bear ganglia from which nerves extend to the peristomial cirri, or else these appendages are innervated by nerves from the subenteric ganglion. The subenteric ganglion appears

Meglitsch. 1972. *Invertebrate Zoology*. Oxford University Press, London.)

to exhibit excitatory control over the ventral nerve cord(s) and segmental ganglia.

The nerves that arise from the segmental ganglia innervate the body wall musculature and parapodia (via the pedal ganglia) and the digestive tract. The ventral nerve cord and sometimes the lateral nerves of most annelids contain some extremely long neurons, or giant fibers, of large diameter; these neurons facilitate rapid, "straight-through" impulse conduction, bypassing the ganglia (Figure 15.15B). Giant fibers are apparently lacking in some annelids (e.g., syllids) but are well developed in tube dwellers, such as sabellids and serpulids, permitting rapid contraction of the body and retraction into the tube. The central nervous system of clitellates consists of the usual annelid components: a supraenteric cerebral ganglion joined to a ganglionated ventral nerve cord by circumenteric connectives and a subenteric ganglion (Figure 15.15). With the reduction in head size, especially of the prostomium, the cerebral ganglion occupies a more posterior position than in the other annelids, often lying as far back as the third body segment. The paired ventral nerve cords are almost always fused as a single tract in clitellates, and it usually contains some giant fibers, especially in leeches.

Annelids show an impressive array of sensory receptors. As would be expected, the kinds of sense organs present and the degree of their development vary greatly among annelids with different lifestyles. Certainly, the requirements for sorts of sensory information are not the same for a tube-dwelling sabellid as they are for an errant predatory nereidid or a burrowing arenicolid.

In general, annelids are highly touch sensitive. Crawlers, tube dwellers, and burrowers depend on tactile reception for interaction with their immediate surroundings (locomotion, anchorage within their tube, and so on). Touch receptors are distributed over much of the body surface but are concentrated in such areas as the head appendages and parts of the parapodia. The chaetae are also typically associated with sensory neurons and serve as touch receptors. Some burrowers and tube dwellers have such a strong positive response to contact with the walls of their burrow or tube that the response dominates all other receptor input. Some of these annelids will remain in their burrow or tube regardless of other stimuli that would normally produce a negative response.

Most annelids possess photoreceptors, although these structures are lacking in many burrowers (Figure 15.16). The best-developed annelid eyes occur in pairs on the dorsal surface of the prostomium. In some there is a single pair of eyes (e.g., most phyllodocids); in many there are two or more pairs (e.g., nereidids, polynoids, hesionids, many syllids). These prostomial eyes are direct pigment cups. They may be simple depressions in the body surface lined with retinular cells, or they may be quite complex, with a distinct refractive body or lens (Figure 15.16A–C). In nearly all cases, the eye units are covered by a modified section of the cuticle that functions as a cornea. The eyes of most annelids are capable of transmitting information on light direction and intensity, but in certain pelagic forms (e.g., alciopin phyllodocids) the eyes are huge and possess true lenses capable of accommodation and perhaps image perception (Figure 15.16C,D).

In addition to, or instead of, the prostomial eyes, some annelids bear photoreceptors on other parts of the body. A few species bear simple eyespots along the length of the body (e.g., *Polyophthalmus*). Pygidial eyespots occur in newly settled sabellariids and on some adult fabriciids (e.g., *Fabricia*) and sabellids (small ones such as *Amphiglena*). Interestingly, in these cases the animals crawl backward. Many sabellids and serpulids possess simple ocelli, or even compound eyes remarkably like those of arthropods, on the branchial crown tentacles, and they react to sudden decreases in light intensity by retracting into their tubes (Figure 15.16E). This "shadow response" helps these sedentary worms avoid predators and can easily be demonstrated by passing one's hand to cast a shadow over a live worm.

Nearly all annelids are sensitive to dissolved chemicals in their environment. Most of the chemoreceptors are specialized cells that bear a receptor process extending through the cuticle. Sensory nerve fibers extend from the base of each receptor cell. Such simple chemoreceptors are often scattered over much of the worm's body, but they tend to be concentrated on the head and

(E) *Acromegalomma* (Sabellidae) has compound eyes like, but convergently evolved to, those seen in arthropods. This pair of compound eyes allows the worm to detect potential predators and safely withdraw into the tube. (F) Nuchal organs of *Notomastus* (Capitellidae). (G) SEM of *Proscoloplos* (Orbiniidae) showing nuchal organs on the prostomium.

its appendages. Some annelids also possess ciliated pits or slits called **nuchal organs,** which are presumed to be chemosensory (Figure 15.16F,G). These structures are typically paired and lie posteriorly on the dorsal surface of the prostomium. In some forms (e.g., certain nereidids) the nuchal organs are simple depressions, whereas in others (e.g., opheliids) they are rather complex eversible structures equipped with special retractor muscles. In members of Amphinomidae, the nuchal organs are elaborate outgrowths of an extension of the prostomium called the **caruncle**.

Statocysts are common in some burrowing and tube-dwelling annelids (e.g., certain terebellids, arenicolids, and sabellids). A few forms possess several pairs of statocysts, but most have just a single pair, located near the head. These statocysts may be closed or open to the exterior, and the statolith may be a secreted structure or formed of extrinsic material,

such as sand grains. It has been demonstrated experimentally that the statocysts of some annelids do serve as georeceptors and help maintain proper orientation when the bearer is burrowing or tube building.

Several other structures of presumed sensory function occur in some annelids. These structures are often in the form of ciliated ridges or grooves occurring on various parts of the body and associated with sensory neurons. A variety of names have been applied to these structures, but in most cases their functions remain unclear. Annelids also possess organs or tissues of neurosecretory or endocrine functions. Most of the secretions appear to be associated with the regulation of reproductive activities, as discussed in the Reproduction and Development section.

Reproduction and Development

Regeneration and asexual reproduction Annelids show various degrees of regenerative capabilities. Nearly all of them are capable of regenerating lost appendages such as palps, tentacles, cirri, and parapodia. Most of them can also regenerate posterior body segments if the trunk is severed. There are numerous exceptional cases of the regenerative powers of annelids. While regeneration of the posterior end is common, most cannot regenerate lost heads. However, sabellids, syllids, and some others can regrow the anterior end. The most dramatic regenerative powers among the annelids occur, oddly, in a few forms with highly specialized and heteronomous bodies. In *Chaetopterus*, for example, the anterior end will regenerate a normal posterior end if the regenerating part (the anterior end) includes not more than 14 segments; if the animal is cut behind the fourteenth segment, regeneration does not occur. Furthermore, any single segment from among the first 14 can regenerate anteriorly and posteriorly to produce a complete worm (Figure 15.17A). An even more dramatic example of regenerative power is known among certain species of *Dodecaceria*, which can fragment their bodies into individual segments, each of which can regenerate a complete individual! A similar situation is seen in another cirratulid, *Ctenodrilus*, where segments transform into a series of heads that then proliferate further segments behind, resulting in a chain of individuals that eventually separates. A chain of six is shown in Figure 15.17B. Such clonal reproduction has been maintained by *Ctenodrilus* in culture for decades without any instances of sexual reproduction.

Regeneration appears to be controlled by neuroendocrine secretions released by the central nervous system at sites of regrowth. It is initiated by severing the elements of the nervous system. Initiation has been demonstrated experimentally by cutting the ventral nerve cord while leaving the body intact; the result is the formation of an extra part at the site of cutting (e.g., two "tails"). The actual mechanism of regeneration has been studied in a variety of annelids, and although the results are not entirely consistent, a general scenario can be outlined. Normal growth and addition of segments (in young worms) take place immediately anterior to the pygidium, in a region known as the growth zone. However, this growth zone is obviously not involved in regeneration. Rather, when the trunk is severed, the cut region heals over and then a patch of generative tissue, or blastema, forms. The blastema comprises an inner mass of cells, originating from nearby tissues that were derived originally from mesoderm, and an outer covering of cells from ectodermally derived tissues such as the epidermis. Somewhat like a growth zone analogue, these two cell masses proliferate new body parts according to their tissue origins. This process is coupled with the growth of the gut, which contributes parts of endodermal origin.

In addition, research has shown that relatively undifferentiated cells from mesenchyme-like layers of the body migrate to injured areas and contribute, to various (and uncertain) degrees, to the regenerative process. These so-called neoblast cells are ectomesodermal in origin and arise embryonically from presumptive ectoderm. During regeneration, they apparently contribute to tissues and structures normally associated with true mesoderm, and perhaps other germ layers as well. The implication here is that the germ layer of the precursor of a regenerated part may not correspond to the normal origin of that part. For example, regenerated coelomic spaces may be lined with tissue derived originally from ectoderm rather than from mesoderm.

Several annelid groups use their regenerative powers for asexual reproduction. A few reproduce asexually by multiple fragmentation. We have discussed the ability of *Dodecaceria* to regenerate complete individuals from isolated segments; this phenomenon occurs spontaneously and naturally in these animals as a highly effective reproductive strategy. Spontaneous transverse fragmentation of the body into two or several groups of segments also occurs in certain syllids, chaetopterids, cirratulids, and sabellids (Figure 15.17B). The point (or points) at which the body fragment is typically species specific and can be anticipated by an ingrowth of the epidermis that produces a partition across the body called a **macroseptum**. Asexual reproduction results in a variety of regeneration patterns, including chains of individuals, budlike outgrowths, or direct growth to new individuals from isolated fragments. Asexual reproduction in annelids may be under the same sort of neurosecretory control as that postulated for nonreproductive regeneration.

Sexual reproduction The majority of annelids are gonochoristic. Hermaphroditism is known in some sabellids, serpulids, certain freshwater nereidids, and isolated cases in other clades, but it is notably found across all Clitellata. The gametes arise by

The more mature epitoke (posterior) is full of eggs and has enlarged eyes. (H) The epitokous palolo worm, *Palola viridis* (Eunicidae). (A,C after P. A. Meglitsch. 1972. *Invertebrate Zoology*. Oxford University Press, London.)

proliferation of cells from the peritoneum, these being released into the coelom as gametogonia or primary gametocytes. Formation of gametes may occur throughout the body or only in particular regions of the trunk. Within a reproductive segment, the production of gametes may occur all over the coelomic lining or only on specific areas.

The gametes generally mature within the coelom and are released to the outside by mechanisms such as metanephridia or a simple rupture of the parent body wall. Many species release eggs and sperm into the water, where external fertilization is followed by indirect development with planktotrophic trochophore larvae. Others display mixed life history patterns. In these latter forms, fertilization is internal, followed by brooding or by the production of floating or attached egg capsules. In most instances the embryos are released as free-swimming lecithotrophic trochophores. Some species brood their embryos on the body surface or in their tubes.

Many of the free-spawning annelids have evolved methods that ensure relatively high rates of fertilization. One of these methods is the fascinating phenomenon of **epitoky**, characteristic of many syllids, nereidids, and eunicids (Figure 15.17D–H). This phenomenon involves the production of a sexually reproductive worm called an **epitokous individual**. Epitokous forms may arise from nonreproductive (**atokous**) animals by a transformation of an individual worm, as in nereidids, or by the asexual production of new epitokous individuals, as in many syllids. In nereidids, the whole body may transform into a sexual **epitokous** individual called a heteronereid. In these heteronereids the posterior body segments are swollen and filled with gametes and the associated parapodia become enlarged and natatory, while the head develops large eyes and the gut atrophies (Figure 15.17E,F). In syllids, where the epitokous worm is clonally produced, the epitokes are formed as single clones, in a linear series (Figure 15.17G), or even as clusters of outgrowths from certain body regions (Figure 15.17C,D).

In any event, the epitokes are gamete-carrying bodies capable of swimming from the bottom upward into the water column, where the gametes are released. Epitoky is controlled by neurosecretory/hormonal activity, and the upward migration of the epitokes is precisely timed to synchronize spawning within a population. The reproductive swarming of epitokes is linked with lunar periodicity. This activity not only ensures successful fertilization but establishes the developing embryos in a planktonic habitat suitable for the larvae. Perhaps the most famous of the epitokous worms are eunicids in the genus *Palola*, commonly known as palolo worms based on the Samoan name for them. Native Polynesian islanders have long been known to predict the swarming (typically to the day and hour) and collect the ripe epitokes, which are the released posterior ends of the worms' bodies, under a full moon to feast on them (Figure 15.17H).

Clitellates are hermaphroditic, and the various parts of the reproductive apparatus are restricted to certain anterior segments (Figure 15.18). The arrangement of the reproductive system facilitates mutual cross-fertilization followed by encapsulation and deposition of the zygotes. The male system includes one or two pairs of testes located in one or two specific body segments. Sperm are released from the testes into the coelomic spaces, where they mature or are picked up by storage sacs (seminal vesicles) derived from pouches of the septal peritoneum (Figures 15.12G and 15.18B). There may be a single seminal vesicle or as many as three pairs in some earthworms. When mature, the sperm are released from the seminal vesicles, picked up by ciliated seminal (sperm) funnels, and carried by sperm ducts to paired gonopores. The female reproductive system consists of a single pair of ovaries located posterior to the male system (Figures 15.12G and 15.18B). Again, the ova are released into the adjacent coelomic space and sometimes stored until mature in shallow pouches in the septal wall; these pouches are called ovisacs. Next to each ovisac is a ciliated funnel that carries the mature ova to an oviduct and eventually to the female gonopore. Most clitellates also possess one or two or more pairs of blind sacs called spermathecae (seminal receptacles) that open to the outside via separate pores (Figure 15.18A,B).

Of major importance to the overall reproductive strategy of clitellates is the unique region of glandular tissue called the **clitellum** (Latin for "saddle") (Figure 15.18A,C–G,I), a principal anatomical feature giving rise to the name Clitellata. The clitellum has the appearance of a thick sleeve that partially or completely encircles the worm's body. It is formed of secretory cells within the epidermis of several segments. The exact position of the clitellum and the number of segments involved are consistent within any given species. In freshwater forms the clitellum is located around the position of the gonopores, but in most earthworms it is posterior to the gonopores. There are three types of gland cells within the clitellum, each secreting a different substance important to reproduction: mucus that aids in copulation, the material forming the outer casing of the egg capsule (or cocoon), and albumin deposited with the zygotes inside the cocoon.

During copulation in most clitellates, the mating worms align themselves facing in opposite directions (Figure 15.18C,D,I), and mucous secretions from the clitellum hold them in this copulatory posture. Many clitellates position themselves so that the male gonopores of one are aligned with the spermathecal openings of the other. In such cases, special copulatory chaetae near the male pores or eversible penislike structures aid in

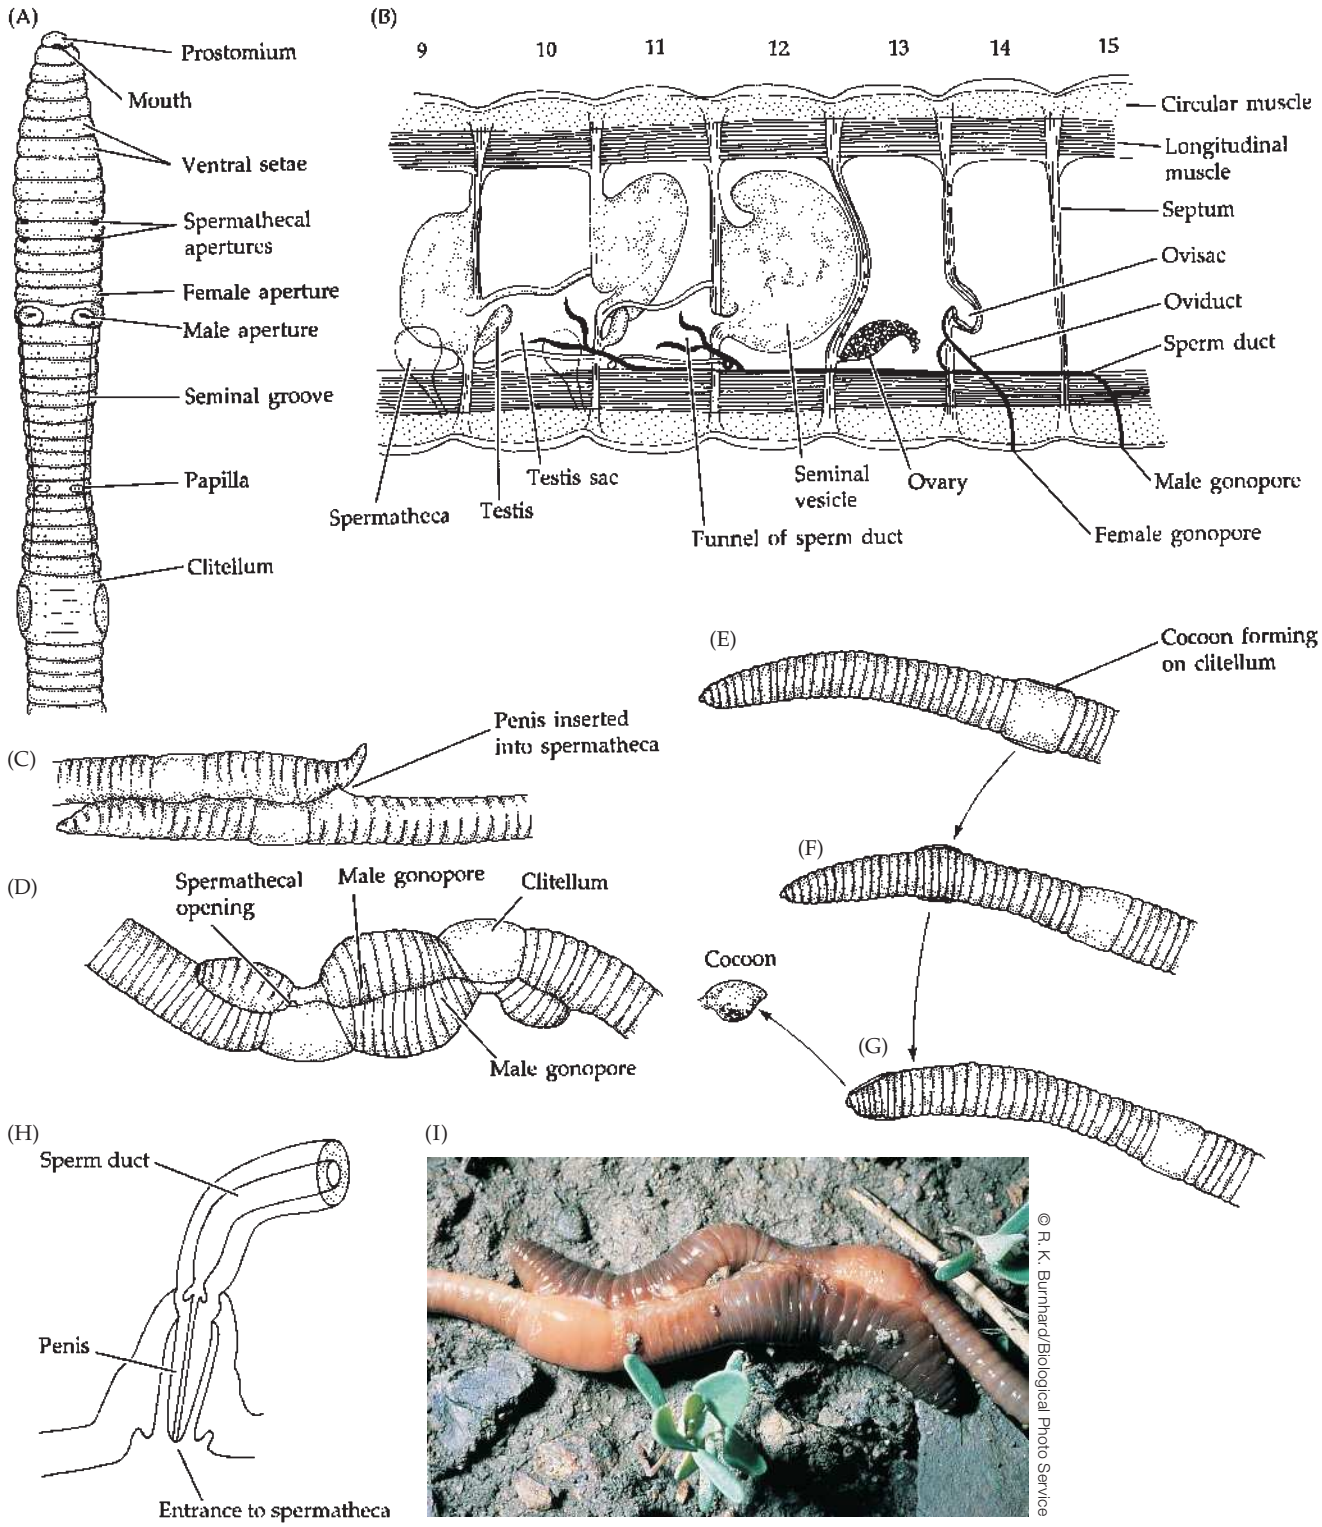

FIGURE 15.18 The reproductive system of *Lumbricus* (Clitellata) and mating in earthworms. (A) External structures associated with reproduction of *Lumbricus* (ventral view). (B) Segments 9–15 of *Lumbricus* (composite lateral view). (C,D) Copulating earthworms. (C) *Pheretima* (Crassiclitellata, Megascolecidae) transfers sperm directly from the male pore, through a penis, into the mate's spermatheca. (D) *Eisenia* uses indirect sperm transfer. As in *Lumbricus*, the sperm leave the male pores and travel along paired seminal grooves to the spermathecal openings of the mate. (E–G) An earthworm forming and releasing a cocoon. As the cocoon slides over the worm, it receives ova and sperm. (H) Engaged copulatory apparatus of *Rhynchelmis*, a lumbriculid with direct sperm transfer. (I) Copulating earthworms (*Lumbricus*). (A,B,D–G after C. A. Edwards and J. R. Lofty. 1972. *Biology of Earthworms*. Chapman and Hall, London. https://link.springer.com/chapter/10.1007/978-1-4899-6912-5_3)

anchoring the mates together (Figure 15.18H). Some earthworms (Crassiclitellata) are not so accurate with their mating, and their copulatory position does not bring the male pores against the spermathecal openings. Instead, they develop external sperm grooves along which the male gametes must travel prior to entering the spermathecal pores. These grooves are formed temporarily by muscle contraction and are covered by a sheet of mucus. Underlying muscles cause the grooves to undulate, and the sperm are transported along the body to their destination. Following the mutual exchange of sperm to the seminal receptacles of each mate, the worms separate, each functioning as an inseminated female.

From several hours to a few days following copulation between clitellate annelids, a sheet of mucus is produced around the clitellum and all the anterior segments. Then the clitellum produces the cocoon itself in the form of a leathery, proteinaceous sleeve. The cocoons of terrestrial species are especially tough and resistant to adverse conditions. Albumin is secreted between the cocoon and the clitellar surface. The amount of albumin deposited with the cocoon is much greater in terrestrial species than in aquatic forms. Thus formed, the cocoon and underlying albumin sheath are moved toward the anterior end of the worm by muscular waves and backward motion of the body. As it moves along the body, the cocoon first receives eggs from the female gonopores, and then sperm previously received from the mate and stored in the seminal receptacles. Fertilization occurs within the albumin matrix inside the cocoon (though not in leeches). The open ends of the cocoon contract and seal as they pass off the anterior end of the body (Figure 15.18E–G). The closed cocoons are deposited in benthic debris by aquatic clitellates. Terrestrial forms deposit their cocoons in the soil at various depths, depending on the moisture content of the substratum.

Development Early annelid development exemplifies a classic protostomous, spiralian pattern (Figures 15.19, 15.20, and 15.21). The eggs are telolecithal with small to moderate quantities of yolk. Those with a period of encapsulation or brooding prior to larval release generally contain more yolk than those that free-spawn.

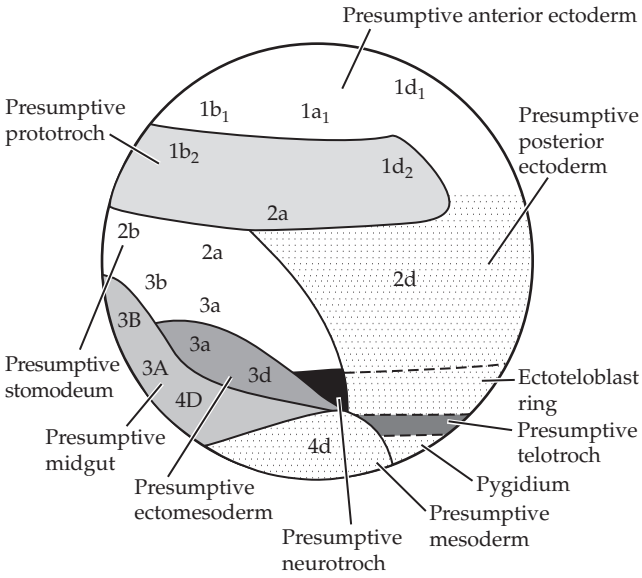

FIGURE 15.19 Fate map of a *Scoloplos* (Orbiniidae) blastula (viewed from the left side).

In any case, cleavage is holoblastic and clearly spiral. A coeloblastula or, in the cases of more yolky eggs, a stereoblastula develops and undergoes gastrulation by invagination, epiboly, or a combination of these two events. Gastrulation results in the internalization of the presumptive endoderm (the 4A, 4B, 4C, 4D and the 4a, 4b, 4c cells) and presumptive mesoderm (4d micromere). The derivatives of the first three micromere quartets give rise to ectoderm and ectomesoderm, the latter producing various larval muscles between the body wall and the developing gut. As the endoderm hollows to produce the archenteron, a stomodeal invagination forms at the site of the blastopore and a proctodeal invagination produces the hindgut.

In most annelids, these early ontogenetic events result in a clearly recognizable trochophore larva characterized by a locomotory ciliary band just anterior to the region of the mouth (Figures 15.20 and 15.21). Trochophores are also seen in Mollusca and Nemertea (and possibly some other phyla). This ciliary band, the **prototroch**, arises from special cells, called trochoblasts,

FIGURE 15.20 Some annelid larvae—trochophores and beyond. (A–C) Opposed-band planktotrophic trochophores of serpulid polychaetes. of the first and second quartets of micromeres. Most trochophores also bear an apical ciliary tuft associated with an apical sense organ derived from a plate of thickened ectoderm at the anterior end. In addition, there is often a perianal ciliary band called the telotroch and/or a midventral band called the neurotroch. Some trochophores may also have a band called a metatroch. The mesentoblast divides to form a pair of cells called teloblasts, which in turn proliferate a pair of mesodermal bands, one on each side of the archenteron in the region of the hindgut, an area known as the growth zone (Figure 15.21B). Many trochophores bear larval sense organs such as ocelli, as well as a pair of larval protonephridia, and develop bundles of mobile chaetae that are known to serve as a defense against predators and to help retard sinking. Several annelid larvae are shown in Figure 15.20.

The larva grows and generally elongates by proliferation of tissue in the growth zone and may initially form several segments simultaneously (Figure 15.21C), while subsequent segments are produced by the anterior proliferation of mesoderm from the teloblast derivatives on either side of the gut. These packets of mesoderm hollow (the process known as schizocoely) and expand as paired coelomic spaces, which eventually obliterate the blastocoel. Thus, the production of serially arranged coelomic compartments and the formation of segments are one and the same; the anterior and posterior walls of adjacent coelomic compartments form the intersegmental septa. Proliferation of segments by this process is called **teloblastic growth**. Externally, additional ciliary bands are added at each segment. These metatrochal bands aid in locomotion as the animal increases in size. Such segmented larvae are sometimes called **polytroch larvae**.

The fates of the various larval regions are now apparent (Figures 15.19 and 15.21). The region anterior to the prototrochal ring (the **episphere**) becomes the prostomium, while the prototrochal area itself forms the peristomium. Note that these two parts are not involved in the proliferation of segments and are thus presegmental. However, in some annelids, one or more of the anterior trunk segments may be incorporated into the peristomium during growth. The segmental, metatrochal portion of the larva forms the trunk, and the growth zone and postsegmental pygidium remain as the corresponding adult body parts. The apical sense organ becomes the cerebral ganglion, which is eventually joined with the developing ventral nerve cord by the formation of circumenteric connectives. The body continues to elongate as more segments form, and the juvenile worm finally drops from the plankton and assumes the lifestyle of a young annelid. This whole affair was beautifully described in verse by the late Walter Garstang (1951), where he explained the development of *Phyllodoce* in the first part of his classic poem, "The Trochophores":

The trochophores are larval tops the Annelids
set spinning
With just a ciliated ring—at least in the beginning—
They feed, and feel an urgent need to grow more like
their mothers,
So sprout some segments on behind, first one,
and then the others.

for more ebook/ testbank/ solution manuals requests (mail 960126734@qq.com)

And since more weight demands more power,
each segment has to bring
Its contribution in an extra locomotive ring:
With these the larva swims with ease, and,
adding segments more,
Becomes a Polytrochula instead of Trochophore.
Then setose bundles sprout and grow,
and the sequel can't be hid:
The larva fails to pull its weight, and sinks—
an Annelid.

Clitellates produce telolecithal ova, but the amount of yolk varies greatly and inversely with the amount of albumin secreted into the cocoon. The eggs of freshwater forms often contain relatively large amounts of yolk but are encased with only a small quantity of albumin. Conversely, the eggs of terrestrial species tend to have little yolk but are supplied with large quantities of albumin on which the developing embryos depend for a source of nutrition. In any case, cleavage is holoblastic and unequal. And, although highly modified, evidence of the ancestral spiralian pattern is still apparent in cell placement and fates (e.g., an identifiable 4d mesentoblast homologue gives rise to the presumptive mesoderm). Development is direct, with no trace of a trochophore larval stage. However, the teloblastic production of coelomic spaces and segments is an obvious retained characteristic of the basic annelid developmental program. Development time varies from about one week to several months, depending on the species and environmental conditions. In climates where relatively severe conditions follow cocoon deposition, development time is usually long enough to ensure that the juveniles hatch in the spring. Under more stable conditions, development time is shorter, and reproduction is less seasonal.

Sipuncula: The Peanut Worms

In the past, the coelomate worm phyla Sipuncula and Echiura were often dismissed in short fashion as "minor" or "lesser" groups. However, thanks to recent molecular phylogenetic research, we now know that these two groups are remarkably modified spiralian clades embedded within the phylum Annelida. Sipunculans and echiurans (Thalassematidae) resemble one another in several respects, although they are not closely related, and they are often found in similar habitats. For these reasons, biologists who find interest in one of these groups often study both. Sipunculans are never as abundant or important ecologically as some other worms, especially the polychaetes and nematodes. Nonetheless, they display body plans that are different from any we have discussed so far and provide important lessons in functional morphology—and thus deserve special attention.

The clade Sipuncula (Greek *siphunculus*, "little tube") includes about 150 species in 16 genera and 6 families. Usually called "peanut worms," adult sipunculans show no evidence of segmentation or chaetae (two features viewed as characteristic of annelids). The body is sausage shaped and divisible into a retractable introvert and a thicker trunk (Figure 15.22). It is when the introvert is retracted and the body is turgid that some species resemble a peanut. The anterior end of the introvert bears the mouth and feeding tentacles. The tentacles are derived from the regions around the mouth (**peripheral tentacles**) and around the nuchal organ (**nuchal tentacles**); differences in tentacular arrangements are of taxonomic importance. The gut is characteristically U-shaped and highly coiled, and the anus is located dorsally on the body near the introvert-trunk junction. The body surface is usually beset with minute bumps, warts, tubercles, or spines. Sipunculans range in length from less than 1 cm to about 50 cm, but most are 3–10 cm long. With the exception of the coiled gut, the body plan of sipunculans has remained largely unchanged since the early Cambrian, as judged by two fossil species from the Maotianshan Shales of southwest China.

The coelom is well developed and unsegmented, forming a spacious body cavity. Metanephridia are present, with nephridiopores on the ventral body surface. There is no circulatory system, but the coelomic fluid includes cells containing a respiratory pigment. Most sipunculans are gonochoristic and reproduce by epidemic spawning. Development is typically spiral, usually indirect, and includes a free-swimming larva.

Sipunculans are benthic and exclusively marine. They are usually reclusive, either burrowing into sediments or living beneath stones or in algal holdfasts. In tropical waters sipunculans are common inhabitants of coral and littoral communities, where they often burrow into hard, calcareous substrata. Some inhabit abandoned gastropod shells, annelid tubes, and other such structures. They are found from the intertidal zone to depths of over 5,000 m, and some deep-burrowing species may play an important role in influencing the ecology and geochemistry of the Nordic Seas region. In Southeast Asia (e.g., Vietnam), large sand-burrowing species are occasionally consumed as human food, and others are used as fishing bait in Europe.

The sipunculan body plan is founded on the qualities of the spacious body coelom. Uninterrupted by transverse septa, the coelomic fluid provides an ample circulatory medium for these sedentary worms. The coelom and associated musculature function as a hydrostatic skeleton and as a hydraulic system for locomotion, circulation of coelomic fluid, and introvert extension.

The embryonic and adult characteristics of sipunculans place them solidly within the spiralian protostomes,

FIGURE 15.22 Representative sipunculans. (A) *Phascolosoma*, with the tip of the introvert turned inward. (B) *Sipunculus nudus*. (C) *Thysanocardia nigra*. (D) *Aspidosiphon cristatus*. and molecular data have provided strong evidence for their membership in the phylum Annelida, despite the lack of adult segmentation. One might view the absence of segmentation as a secondary loss of a partitioned coelom associated with the exploitation of a sedentary, burrowing lifestyle. The reduction in sensory receptors and simplification of the nervous system in general are explainable on this same basis. However, many other species of annelids have evolved burrowing lifestyles while retaining their basic segmentation.

Classification of Sipuncula

The first published illustrations of sipunculans were produced from woodcuts made in the mid-sixteenth century. Linnaeus included these animals in the twelfth edition of his *Systema Naturae* (1767) and placed them in the Vermes, along with so many other odds and ends. In the nineteenth century, Lamarck and Cuvier considered the sipunculans to be relatives of holothuroid echinoderms (sea cucumbers). No separate taxon was established for these worms until 1828, when Henri Marie Ducrotay de Blainville introduced the name Sipunculida and allied the group with certain parasitic helminths.

In 1847 Jean Louis Armand de Quatrefages created the taxon Gephyrea to include sipunculans, echiurans, and priapulans. The Greek root *gephyra* means "bridge," as Quatrefages regarded these animals as intermediate between annelids and echinoderms. The gephyrean concept was founded on superficial characteristics, but it persisted well into the twentieth century even though many authors attempted to raise the constituent groups to individual phylum status. Finally, Libbie Hyman (1959), recognizing the polyphyletic nature of the Gephyrea, elevated the sipunculans to a separate phylum rank. At that time, however, no classes, orders, or families were recognized, and the phylum was divided into only genera and species. The Herculean effort by Alexander Stephen and Stanley Edmonds (1972) and subsequent modifications by other workers (e.g., Mary Rice 1982) led to a classification comprising 4 families and 16 genera. Later, Edward Cutler and Peter Gibbs (1985) applied phylogenetic methods and produced a classification scheme of 2 classes, 4 orders, 6 families, and 17 genera, which has been used until recently. However, with the use of molecular phylogenetics, this classification was challenged, the phylum was subsumed within Annelida, and a new system, consisting of 6 families and 16 genera was proposed by Lemer and collaborators in 2015, a system that is in use today (Figure 15.23).

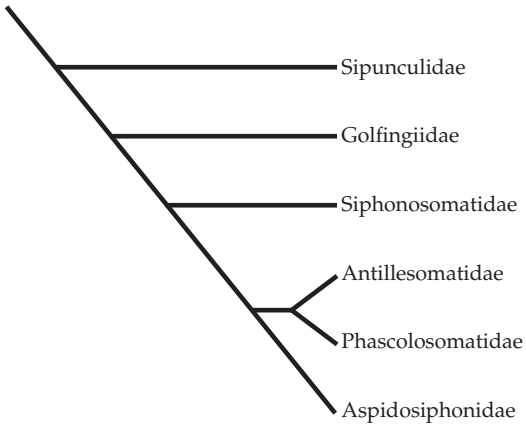

FIGURE 15.23 Phylogenetic relationships of the sipunculan families.

SIPUNCULA

FAMILY SIPUNCULIDAE Large sipunculans, trunk to 45 cm in length (Figure 15.22B,E and Figure 12.25A). Introvert shorter than the trunk, covered with prominent papillae arranged irregularly. Hooks absent. Circular and longitudinal muscle layers divided into distinct bands. Body wall with coelomic extensions in the form of parallel longitudinal canals extending through most of the trunk length, or short diagonal canals limited in length to the width of one circular muscle band. Two protractor muscles may be present. With paired metanephridia. Development proceeds through a planktotrophic pelagosphera larva. Two genera: *Sipunculus*, *Xenosiphon*.

FAMILY GOLFINGIIDAE Heterogeneous group of small to medium-sized sipunculans (trunk no longer than 20 cm) (Figure 15.22C,F,G and Figure 12.25B). Hooks may be deciduous, simple when present, not sharply curved and generally scattered, except in 3 species where hooks are arranged in rings. Body wall with a continuous muscle layer, except in *Phascolopsis*, where the longitudinal muscles are divided in anastomosing bands. With paired or single metanephridia. Seven genera: *Golfingia*, *Nephasoma*, *Onchnesoma*, *Phascolion*, *Phascolopsis*, *Themiste*, *Thysanocardia*.

FAMILY SIPHONOSOMATIDAE Large to medium-sized sipunculans (trunk to 50 cm in length). Introvert much shorter than trunk, with prominent conical papillae and/or hooks arranged in rings. Body wall with small, irregular saclike coelomic extensions. Circular and longitudinal muscle layers gathered into anastomosing, sometimes indistinct bands. With paired metanephridia. Two genera: *Siphonomecus*, *Siphonosoma*.

FAMILY ANTILLESOMATIDAE Medium-sized sipunculans (trunk to 8 cm). Distal part of the introvert smooth and white, proximal portion bears dark papillae and is marked off by a distinctive collar. Hooks absent in adults, but a few hooks present in small individuals (<1 cm). Oral disc consisting of nuchal organ enclosed by numerous tentacles, which vary in number according to size (from 30 to 200 in adults). Body wall with longitudinal muscle layer gathered into anastomosing bands. Contractile vessel with many villi. Four introvert retractor muscles with the lateral pair often extensively fused. With paired metanephridia. Without an anal shield. Single genus: *Antillesoma*.

FAMILY PHASCOLOSOMATIDAE Small to medium-sized sipunculans (trunk to 12 cm in length) (Figure 15.22A). Hooks recurved, usually with internal structures, and closely packed in regularly spaced rings (absent in *Apionsoma trichocephalus*). External trunk wall rough with obvious papillae. In *Apionsoma*, papillae are concentrated at the posterior end of the trunk. Internally, the longitudinal muscle is generally subdivided into anastomosing bands except in two subgenera—*Phascolosoma* (*Fisherana*) and *Apionsoma* (*Apionsoma*)—where this layer is thinner and continuous. Contractile vessel is

smooth but may be large with bulbous pouches or swelling in a few *Phascolosoma*. With paired metanephridia. Two genera: *Apionsoma*, *Phascolosoma*.

FAMILY ASPIDOSIPHONIDAE Generally small (to 30 mm) sipunculans with smooth trunk and 2 retractor muscles (Figure 15.22D). Introvert protruding at 45°–90° angle ventral to main axis of trunk. Muscle layers generally smooth and continuous, or with longitudinal muscle layer separated in anastomosing bundles. Trunk with anterior, and sometimes posterior, anal shields derived from thickened cuticle or calcareous deposits. With paired metanephridia. Two genera: *Aspidosiphon*, *Cloeosiphon*.

The Sipunculan Body Plan

Body Wall, Coelom, Circulation, and Gas Exchange

The sipunculan body surface is covered by a well-developed cuticle that varies from thin on the tentacles to quite thick and layered over much of the trunk (Figures 15.22 and 15.24). The cuticle often bears papillae, warts, or spines of various shapes. Beneath the cuticle lies the epidermis, the cells of which are cuboidal over most of the body but grade to columnar and ciliated on the tentacles. The epidermis contains a variety of unicellular and multicellular glands called epidermal organs, some of which project into the cuticle and produce some of the surface papillae or knobs. Some of these glands are associated with sensory nerve endings; others are responsible for producing the cuticle or for mucus secretion. In both larval and adult sipunculans, epidermal organs are externally encapsulated by a cuticle and internally delimited by regular epidermal cells. If pocketed deeply into the body ball, epidermal organs are also delimited by subepidermal musculature.

Beneath the epidermis, especially where it is raised, is a dermis composed of connective tissue fibers and loose cells. From one to four large introvert retractor muscles extend from the body wall into the introvert where they insert on the gut just behind the mouth (Figure 15.25A,B). All species so far studied go through developmental stages with four retractor muscles, which are eventually reduced to a lower number in the adult. Species with crawling larvae have more strongly developed body wall musculature than those with swimming larvae.

In Sipunculidae, which are mostly large and include some warm-water species, the dermis also houses a system of coelomic extensions or channels (Figure 15.24). These **coelomic channels** may extend entirely through the muscle layers and into the epidermal layer, and they have a gas transport function in some species. They are connected to the trunk coelom by pores. The muscles of the body wall include outer circular and inner longitudinal layers and sometimes a thin middle layer of diagonal fibers. The longitudinal muscles form a continuous sheet in many sipunculans, but in some genera these muscles

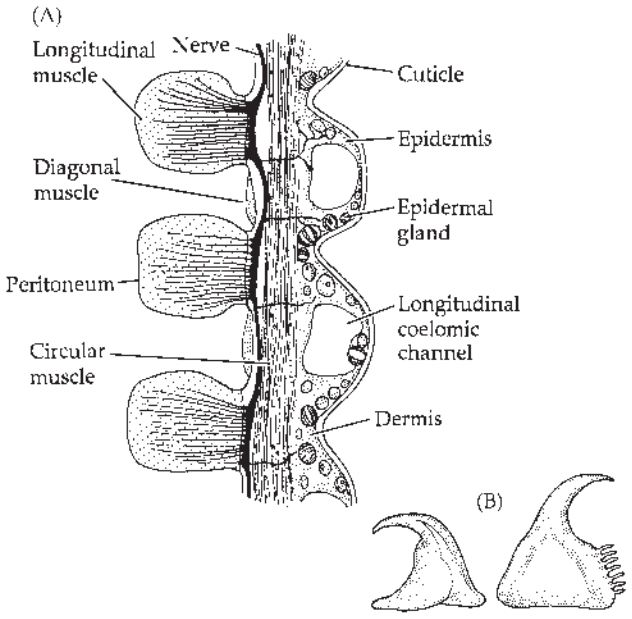

FIGURE 15.24 The sipunculan body wall. (A) The body wall of *Sipunculus nudus* (cross section). (B) Two types of cuticular hooks from sipunculans.

form distinct bundles or bands (e.g., *Phascolosoma*, *Phascolopsis*, *Siphonomecus*, *Siphonosoma*, *Sipunculus*, and *Xenosiphon*). This arrangement gives the internal surface of the body wall a ribbed appearance that is often visible through the animal's cuticle. While this character was once the basis for the family Sipunculidae, the family now has a more restricted definition, and it has been shown that this feature is homoplastic.

A peritoneum lines the body wall and the internal organs. The coelom is a continuous space, but peritoneal mesenteries form incomplete partitions supporting the organs. In addition to the main body coelom and the coelomic channels in the body wall, a separate fluid-filled "coelom" called the compensation system is associated with the tentacles. The hollow tentacles contain lined spaces that are continuous with one or two sacs (the **compensation sacs**) that lie next to the esophagus (Figure 15.25A,B). Upon eversion of the introvert, circular body muscles apply pressure on these sacs and force the contained fluid into the tentacles, causing their erection.

The fluid of the body cavity contains a variety of cells and other inclusions. There are both granular and agranular amebocytes of uncertain function, and red blood cells containing hemerythrin. Also contained in the coelomic fluid are unique and fascinating multicellular structures called **urns**, some of which are fixed to the peritoneum and some of which swim free in the fluid (Figure 15.25C,D). The urns accumulate waste materials and dead cells by trapping them with cilia and mucus.

Gas exchange apparently varies among species. It has been suggested that rock borers (e.g., *Phascolosoma*) and those that burrow in sediments of low oxygen content (e.g., *Themiste*) exchange gases largely across

the tentacles, which extend into the overlying water. Other burrowers with long introverts may use the body surface of both the tentacles and the introvert for gas exchange, whereas others, such as the large-bodied species of the genus *Sipunculus*, may use the entire body surface. The coelomic fluid in the body cavity and in body wall channels provides a circulatory medium, aided by diffusion and body movements. The erythrocytes that circulate in the coelomic fluid of sipunculans contain intracellular polymeric hemerythrin for storing and transporting oxygen.

Support and Locomotion

Sipunculans are sedentary creatures. The general body shape is maintained by the muscles of the body wall and the hydrostatic skeleton established by the large coelom. The body is essentially a fluid-filled bag of constant volume, so any constriction at one point is accompanied by an expansion at another. Burrowing in soft substrata is accomplished by peristalsis, driven by the circular and longitudinal muscles of the body wall and by the action of the introvert. Movement through algal holdfasts and

bottom rubble occurs in a similar manner. Some species with an anterior cuticular shield burrow into hard substrata and use the shield as a functional operculum to close the burrow entrance. Burrowing into hard substrata is probably accomplished by both mechanical and chemical means, the former using cuticular structures (such as spines and the posterior shield) as rasps, the latter facilitated by the secretions of epidermal glands.

The introvert is extended when the coelomic pressure is increased by contracting the circular muscles of the body wall. Withdrawal is accomplished by the retractor muscles, which pull from the mouth end, turning the introvert inward as the body wall muscles relax. When the introvert is fully extended, the tentacles are erected by increasing the pressure on the compensation sacs.

Sipunculans are highly tactile and strongly thigmotactic, requiring contact with their surroundings. Placed alone in a glass dish, they are rather inactive except for rolling the introvert in and out. However, if several sipunculans are placed together or with small stones or shell fragments, they soon respond by making contact with each other or surrounding objects.

Feeding and Digestion

There is surprisingly little information on the details of sipunculan feeding mechanisms. Indirect evidence from anatomy, gut contents, and general behavior suggests that these animals use different feeding methods in different habitats. Most of the sipunculans that can place their tentacles at a substratum-water interface are selective or nonselective detritivores (e.g., shallow burrowers, algal holdfast dwellers); they use the mucus and cilia on the tentacles to obtain food. Deeper burrowers in sand are direct deposit feeders. Some appear to be ciliary-mucus-suspension feeders, using the tentacles to extract organic material from the water. Sipunculans that burrow in calcareous substrata use spines or hooks on their introverts to retrieve organic detritus within reach and ingest the material by retracting the introvert. Limited data suggest that at least some sipunculans take up dissolved organic compounds directly across the body wall. Some workers have speculated that up to 10% of these animals' nutritional requirements may be met in this fashion.

Because the anus is located anteriorly on the dorsal side of the body, the digestive tract is basically U-shaped, although highly coiled (Figure 15.25A,B)—the coiled gut is unknown in any other annelid or invertebrate group. The mouth is terminal, located at the end of the introvert, and is wholly or partially surrounded by the peripheral tentacles (e.g., Sipunculidae) or lies near the nuchal tentacles (e.g., Phascolosomatidae). The mouth leads inward to a short, muscular stomodeal pharynx, which is followed by an esophagus that extends through the introvert and into the trunk. The midgut consists of a long intestine composed of descending and ascending portions coiled together, although this coiling is not observed in the Cambrian species. Studies comparing the expression patterns of regulatory "gut genes" of *Themiste* and other annelids (with uncoiled guts) revealed differences in persistence and extension of endodermal expression of *FoxA*, which could be related to the U-shaped gut and coiling. The gut is usually supported by a threadlike spindle muscle that extends from the body wall near the anus through the coils to the end of the trunk and by several fixing muscles connecting the gut to the body wall. The ascending intestine leads to a short proctodeal rectum, terminating in the anus.

The intestine is ciliated and bears a distinct groove along its length (Figure 15.25E). This ciliated groove leads ultimately to a small pouch or diverticulum (the rectal gland) off the rectum. The function of this groove and diverticulum is unknown. The lumen epithelium of the descending intestine contains a variety of gland cells that are presumably the sources of digestive enzymes.

Excretion and Osmoregulation

Most sipunculans possess one pair of elongate, saclike, tubular metanephridia with the coelomoducts becoming fused with the nephridia (a condition known as nephromixia; Figure 15.25A,B,F) located ventrolaterally at the anterior end of the trunk. Two genera (*Onchnesoma* and *Phascolion*) have but a single nephridium. Species in these genera tend to be asymmetrically coiled. The nephridiopores are located ventrally on the anterior region of the trunk. The nephrostome lies close to the body wall, near the pore, and leads to a large nephridial sac that extends posteriorly in the trunk.

Sipunculans are ammonotelic. Nitrogenous wastes accumulate in the coelomic fluid and are excreted via the nephridia. The urns also play a major excretory role by picking up particulate waste material in the coelom. The fate of wastes accumulated by urns is unknown, but at least some are probably transported to the nephridia. Urns originate as fixed epithelial cell complexes in the peritoneum, where they trap and remove particulate debris. They are also known to secrete mucus in response to pathogens in the coelomic fluid. Fixed urns regularly detach and become free-swimming in the coelomic fluid. Not only do urns effectively cleanse the coelomic fluid, but they also participate in a clotting process when a sipunculan is injured. Free urns can be seen by preparing a wet slide of fresh coelomic fluid. They are usually obvious, moving about like little bumper cars, trailing strands of mucus and bits of particulate matter.

Sipunculans are basically osmoconformers, and they are unknown from brackish and freshwater habitats. Under normal conditions, the coelomic fluid is nearly isotonic to the surrounding seawater. However, when sipunculans are placed in hypotonic or hypertonic environments, their body volume increases or decreases, respectively. Interestingly, the rates of volume change differ when the animal is exposed to these opposing

for more ebook/ testbank/ solution manuals requests (email 960126734@qq.com)

environments, suggesting that sipunculans are better at preventing water loss than at preventing water gain. This situation may be due to a differential permeability of the cuticle or, perhaps, to some active mechanism of the nephridia. In any case, sipunculans rarely face severe osmotic problems in their usual environments, and even in laboratory experiments they are able to recover nicely from most conditions of osmotic stress.

Nervous System and Sense Organs

The general structure of the sipunculan nervous system is similar in many respects to that in other annelids. A bilobed cerebral ganglion lies dorsally in the introvert, just behind the mouth. Circumenteric connectives extend from the cerebral ganglion to a ventral nerve cord running along the body wall through the introvert and trunk (Figures 15.25A,B and 15.26). The adult ventral nerve cord is single, and there is no evidence of segmental ganglia. In *Phascolosoma agassizii*, a double ventral nerve cord forms initially but later fuses into a single cord, and neurogenesis initially follows a segmental pattern similar to that of annelids. Starting out with paired FMRFamidergic and serotonergic axons, four pairs of associated serotonergic perikarya and interconnecting commissures form one after another in an anterior–posterior progression. In late-stage larvae, the two serotonergic axons of the ventral nerve cords fuse, the commissures disappear, and one additional pair of perikarya is formed. These cells (ten in total) migrate toward one another, eventually forming two clusters of five cells each. These neural-remodeling processes result in the single nonmetameric central nervous system of the adult sipunculan. This ontogenetic example suggests that the ancestral sipunculan condition may have been a double ventral nerve cord like that found in some primitive annelids. Lateral nerves arise from the nerve cord and extend to the body wall muscles and sensory receptors in the epidermis.

Sensory receptors are widespread in sipunculans, but many are poorly understood. Tactile receptor cells are scattered over the body within the epidermis, as would be expected, and are especially abundant on and around the tentacles. Chemosensory **nuchal organs** are located on the dorsal side of the introvert in many species (Figure 15.26B). Many possess a pair of pigment-cup ocelli on the dorsal surface of the cerebral ganglion, and some have a so-called cerebral organ, consisting of a ciliated pit projecting inward to the cerebral ganglion. The cerebral organ may be involved in chemoreception or perhaps neurosecretion, as is similar in structure to that seen in nemerteans.

Reproduction and Development

Sipunculans possess reasonable powers of regeneration. Most species are able to regrow lost parts of the tentacles and even the introvert, and some can

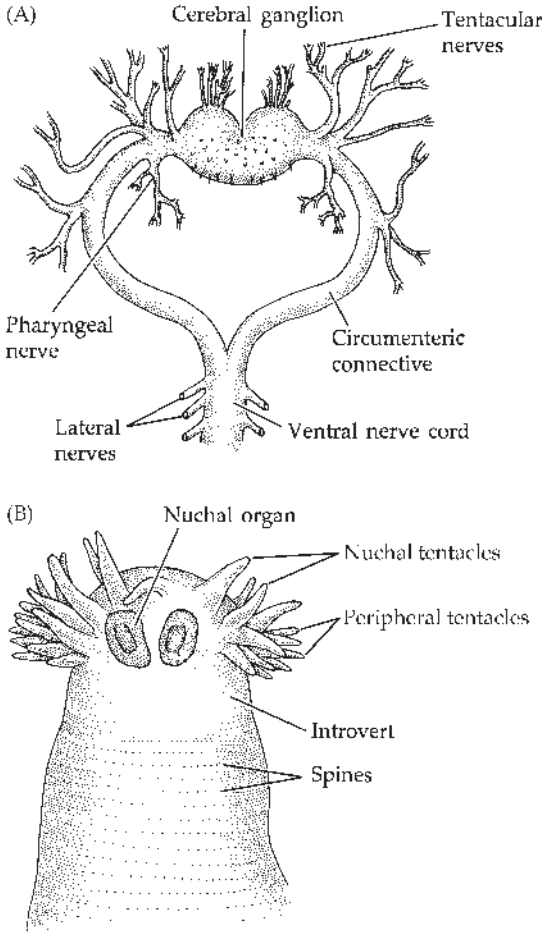

FIGURE 15.26 Sipunculan brains and nuchal organs. (A) Anterior portion of the central nervous system of *Golfingia*. (B) Anterior end of *Golfingia*. Note the nuchal organs.

regenerate portions of the trunk and the digestive tract. It was long believed that sipunculans could not reproduce asexually. However, in the 1970s it was discovered that at least some species do possess this capacity. The process takes place by transverse fission of the body, whereby the worm divides into a small posterior fragment and a larger anterior portion. Both portions then regrow the missing parts. Regeneration from the small posterior part is quite remarkable, since most of the trunk, anterior gut, retractor muscles, nephridia, introvert, and so on must be regrown.

Except for *Nephasoma minutum*, sipunculans are gonochoristic. (Facultative parthenogenesis has been reported in one species, *Themiste lageniformis*.) The gametes arise from the coelomic lining, often near the origins of the retractor muscles. Gametes are released into the coelom, where they mature. Ripe eggs and sperm are picked up selectively by the nephridia and stored in the sacs until released. The eggs are encased in a layered, porous covering. Males spawn first, probably in response to some environmental cue, and the presence of sperm in the water stimulates females to spawn.

Following external fertilization, the zygotes pass through typical spiralian development. In *Golfingia*

cleavage is spiral and holoblastic, but the relative sizes of micromeres and macromeres differ among species, depending on the amount of yolk in the egg. Although traditionally sipunculan embryos were described as having a "molluscan cross," which suggested a close relationship with the Mollusca, this character is now known to have been misinterpreted, and sipunculans are now considered to be an early but highly derived offshoot of Annelida.

The cell fates are the same as those in most typical spiralians. The first three quartets of micromeres become ectoderm and ectomesoderm; the 4d cell produces endomesoderm; and 4a, 4b, 4c, and 4Q form the endoderm. The mouth opens at the site of the blastopore, and the surrounding ectodermal cells grow inward as a stomodeum. The anus breaks through secondarily on the dorsal surface (Figure 15.27). The 4d mesoderm proliferates as two bands, as it does

in other annelids, but yields the major trunk coelom without segmentation.

Four different developmental sequences have been recognized among the sipunculans, including direct (e.g., *Nephasoma minutum*, *Phascolion cryptum*, *Themiste pyroides*) and indirect development. In direct development, the eggs are covered by an adhesive jelly and attached to the substratum after fertilization. The embryo develops directly to a vermiform individual that hatches as a minute juvenile sipunculan. The other three developmental patterns are indirect, involving various combinations of larval stages. In some species (e.g., *Phascolion strombus*), a free-living lecithotrophic trochophore larva develops and metamorphoses into a juvenile worm. The other two developmental patterns involve a second larval stage, the **pelagosphera larva**, that forms after a metamorphosis of the trochophore (Figure 15.27C). In some species, both the trochophore and the pelagosphera forms are lecithotrophic and relatively short-lived (e.g., some species of *Golfingia* and *Themiste*), while in others the pelagosphera larva is planktotrophic and may live for extended periods of time in the plankton (e.g., *Aspidosiphon parvulus*, *Sipunculus nudus*, members of the genus *Phascolosoma*).

The transformation of the trochophore to the pelagosphera larva involves a reduction or loss of the prototrochal ciliary band and the formation of a single metatrochal band for locomotion. The pelagosphera eventually elongates, settles, and becomes a juvenile sipunculan (Figure 15.27D).

Since the pelagosphera larva of some species are estimated to spend several months in the plankton and sipunculans display little morphological variation, a disproportionate number of species, when compared with any other marine worm groups, have been suggested to be cosmopolitan. However, detailed developmental and molecular analyses of several supposed cosmopolitan species have shown that cosmopolitanism cannot be the norm and that, instead, sipunculans have many cryptic or pseudocryptic species remaining to be properly described.

Thalassematidae: The Spoon Worms

Thalassematidae is a group of about 220 species of secondarily unsegmented annelids that, until recently, were regarded as their own phylum, Echiura. With their accepted placement as the sister group to Capitellidae within Annelida, it was recommended by Ryutaro Goto and colleagues in 2020 that the group be known by the first family-ranked taxon that was made for the group, Thalassematidae. The vermiform body is divided into an anterior, preoral proboscis and an enlarged trunk (Figure 15.28). The mouth is located at the anterior end of the trunk at the base of a proboscis groove, or gutter. The body surface may be smooth or somewhat warty, and it often bears chaetae (e.g., *Protobonellia*). The trunk may terminate in an anal lobe, which can contain glands, the secretions of which might be used during burrow construction. Most thalassematids are quite large. The trunk may be from a few to as many as 40 cm long, but the proboscis may reach lengths of 1–2 m (e.g., in *Ikeda*, Figure 15.29B). Some forms, such as the beautiful emerald green *Metabonellia*, show drastic sexual dimorphism, wherein "dwarf" males are less than 1 cm long (Figure 15.28E,F). *Bonellia,* and relatives such as *Metabonellia,* are also notable for females producing the compound bonellin, which appears to act as an antibiotic for the worm but also as a sex hormone to create dwarf males (see the Reproduction and Development section). Thalassematids are always benthic and marine, though a few species are known from brackish-water habitats. Most burrow in sand or mud or live in surface detritus or rubble. Some species typically inhabit rock galleries excavated by boring clams or other invertebrates. They are known from intertidal regions to a depth of 10,000 m.

Body Wall and Coelom

The body wall of thalassematids has an outer thin cuticle covering the epidermis, which is composed of a cuboidal epithelium and contains a variety of gland cells. Epidermal chaetae occur in some species at either the anterior trunk or the posterior trunk, or at both locations. Layers of circular, longitudinal, and oblique muscles form the bulk of the body wall, which is lined internally by the peritoneum. The epidermis is ciliated along the proboscis groove, or gutter. The coelomic cavity is spacious and occupies most of the trunk—it is interrupted only by partial mesenteries between the gut and the body wall. The coelomic fluid contains red blood cells, with hemoglobin in some species, and various types of amebocytes.

Support and Locomotion

The large trunk coelom provides a hydrostatic skeleton against which the body wall muscles operate. The nonseptate coelom allows peristaltic movements as the animal burrows or moves through various sediments, gravel, or rubble. The proboscis can shorten and lengthen, but it does not roll in and out as does the introvert of sipunculans. This characteristic and the more conventional posterior position of the anus allow one to easily distinguish the two groups.

Feeding and Digestion

Most thalassematids feed on epibenthic detritus. Typically, the animal lies with the trunk buried in the substratum, with the proboscis extended over the

sediment (Figure 15.28C,E,G,H and 15.29). Densely packed gland cells of the proboscis epithelium secrete mucus, to which organic detrital particles adhere. The mucous coating and the food are moved along a ventral proboscis groove, often called the gutter, by ciliary action into the mouth.

An interesting exception to the this feeding method occurs in *Urechis*, worms that live in U-shaped burrows in soft substrata (Figure 15.28G). They have a short proboscis, unlike those of more typical echiurans, and engage in mucous-net filter feeding. A ring of glands located near the proboscis-trunk junction produces a funnel-shaped mucous net, which is attached to the burrow wall by the proboscis. Water is drawn through the burrow and the sheet of mucus by peristaltic movements of the body, and suspended food particles as small as 1 μm are caught in the fine-meshed net. Periodically the animal grasps the food-laden net with its proboscis and ingests it. The whole process is somewhat like the feeding behavior of another annelid, *Chaetopterus*, as previously described.

The digestive tract is generally very long and coiled, leading from the mouth at the base of the proboscis to the posterior anus (Figure 15.30). The foregut may be regionally specialized as pharynx, esophagus, gizzard, and stomach, or it may be uniform along its length. The midgut usually bears a longitudinal ciliated groove, the **siphon**, which probably aids the movement of materials through the gut. It may also shunt excess water from the main midgut lumen, thereby concentrating food and facilitating digestion. The hindgut, or cloaca, varies in structure among

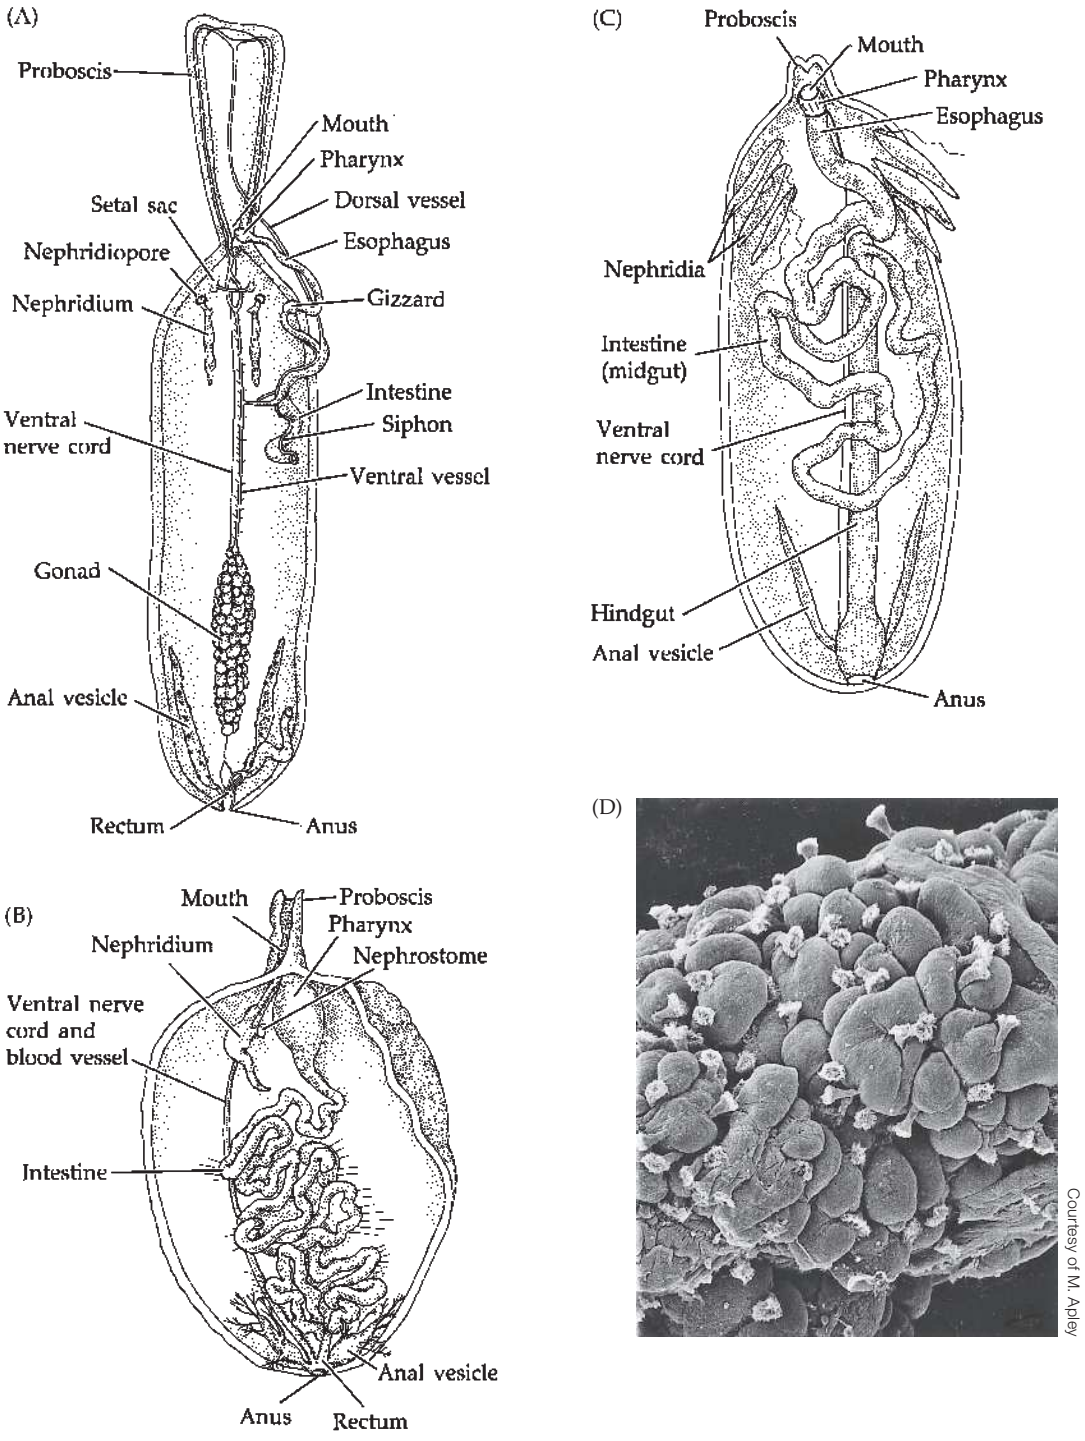

FIGURE 15.30 Internal anatomy of three thalassematids. (A) General internal anatomy, as seen in *Echiurus*. (B) A dissected *Bonellia viridis* female (proboscis cut off). Oxford University Press, London.)

different species. In most thalassematids, the cloaca bears a pair of large excretory diverticula called anal vesicles (see the Excretion and Osmoregulation section). In some species of *Urechis* the cloaca is enlarged and thin walled. In such cases water is pumped in and out of the hindgut for gas exchange. Not much is known about digestive physiology in thalassematids. The epithelium of the midgut is rich in gland cells that presumably produce and secrete digestive enzymes. Digestion and absorption occur mainly in the midgut.

for more ebook/ testbank/ solution manuals requests (mail 960126734@qq.com)

Circulation and Gas Exchange

Most thalassematids possess a simple closed circulatory system, although it is absent from some forms (e.g., *Urechis*), in which case the coelomic fluid contains red blood cells with hemoglobin. The circulatory system generally includes dorsal and ventral longitudinal vessels in the trunk and median and lateral vessels in the proboscis (Figure 15.30A). There is no major pumping organ (except in *Ikeda*); the blood is transported by pressures generated from body movements and by the weak musculature of the vessel walls. The main site of gas exchange in *Urechis* is provided with oxygenated water by cloacal irrigation—water being pumped in and out of the anus by muscle action. In other thalassematids gas exchange also occurs across the surface of the proboscis.

Excretion and Osmoregulation

The excretory structures of thalassematids include paired metanephridia and anal vesicles (Figure 15.30). The number of nephridia varies: one pair in *Bonellia* and *Metabonellia*; two pairs in *Echiurus*; three pairs in *Urechis*; and hundreds of pairs in *Ikeda*. When only one or a few pairs are present, the nephridia are in the anterior region of the trunk and lead to nephridiopores on either side of the ventral midline. The degree to which these nephridia function in excretion is debatable; they seem to function primarily in picking up gametes from the coelom, having relinquished the major excretory responsibility to the anal vesicles. Thalassematids are relatively poor osmoregulators, providing an explanation as to why they are only generally in fully marine habitats.

The **anal vesicles** are hollow sacs arising as evaginations of the cloaca near the anus (Figure 15.30). Each vesicle bears from about a dozen to as many as 300 ciliated funnels that open to the coelom. Few studies have been conducted on the function of these structures, but they apparently pick up wastes from the coelomic fluid and remove the material to the hindgut and anus.

Nervous System and Sense Organs

The nervous system of thalassematids is simple, although constructed in a fashion generally like other annelids. An anteriorly located nerve ring extends around the gut and dorsally forward into the proboscis. Ventrally, in the trunk, the nerve ring meets at a subesophageal ganglion that connects with a seemingly single ventral nerve cord extending the length of the body (Figure 15.30A–C). There are no ganglia in this system and no obvious evidence of segmentation in adults. However, immunohistochemical methods and confocal laser-scanning microscopic studies have proposed a metameric organization of the nervous system in different larval stages of *Urechis caupo* and *Bonellia viridis*, which corresponds to the segmental arrangement of ganglia seen in other annelids. Lateral nerves arise from the ventral nerve cord and extend to the body wall muscles. Associated with the simple nervous system and infaunal sedentary lifestyle of thalassematids is the absence of major sensory receptors. These animals are touch sensitive, especially on the proboscis, which can retract quickly upon detecting vibrations or water movements.

Reproduction and Development

Asexual reproduction is unknown in thalassematids, and little work has been done on the powers of regeneration. At least a few have remarkable healing capabilities. For example, *Urechis caupo* (Figure 15.28G)—the "fat innkeeper"—is often found in bay muds that are subjected to heavy pressure from clam diggers. In some of these tidal flats, nearly every *Urechis* specimen bears scars, some nearly completely across the body—signs that the animal has survived cuts from the clammers' shovels.

Thalassematid sexes are separate. The gametes are produced in special "gonadal" regions of the ventral peritoneum and released into the coelom to mature. When ripe, the gametes accumulate in the nephridia (or nephridium, Figure 15.30A–C) until spawning occurs. The nephridia often swell enormously when packed with eggs or sperm. In most cases, epidemic spawning takes place and is followed by external fertilization.

Echiuran development is like that of most other annelids, with spiral cleavage and lecithotrophic trochophore larvae (Figure 15.31C) that may drift in the plankton for up to three months as they gradually elongate to produce young worms (Figure 15.31D). The prototroch and the episphere regions develop into the proboscis, which is thus equivalent to the prostomium and peristomium in other annelids. The region behind the proboscis forms the trunk. As with other annelids the 4d mesentoblast proliferates the main trunk coelom.

Thalassematids are well known for the sexual dimorphism and environmental sex determination found in a clade that includes genera such as *Bonellia*, *Ikeda*, and *Metabonellia*. In such species, the females are quite large, reaching lengths of up to 2 m, including the proboscis. The males, however, which can be from a few millimeters to a centimeter or so long, are simple bodied, and they often retain remnants of larval ciliation. They live on the female's body or in her nephridia (Figures 15.28D,F and 15.31A). Experiments have shown that when exposed to females, the larvae usually metamorphose into dwarf males, but they normally differentiate into females when developing in the absence of other females. This sexual determination is apparently caused by a masculinizing hormone produced by the skin of the female worm.

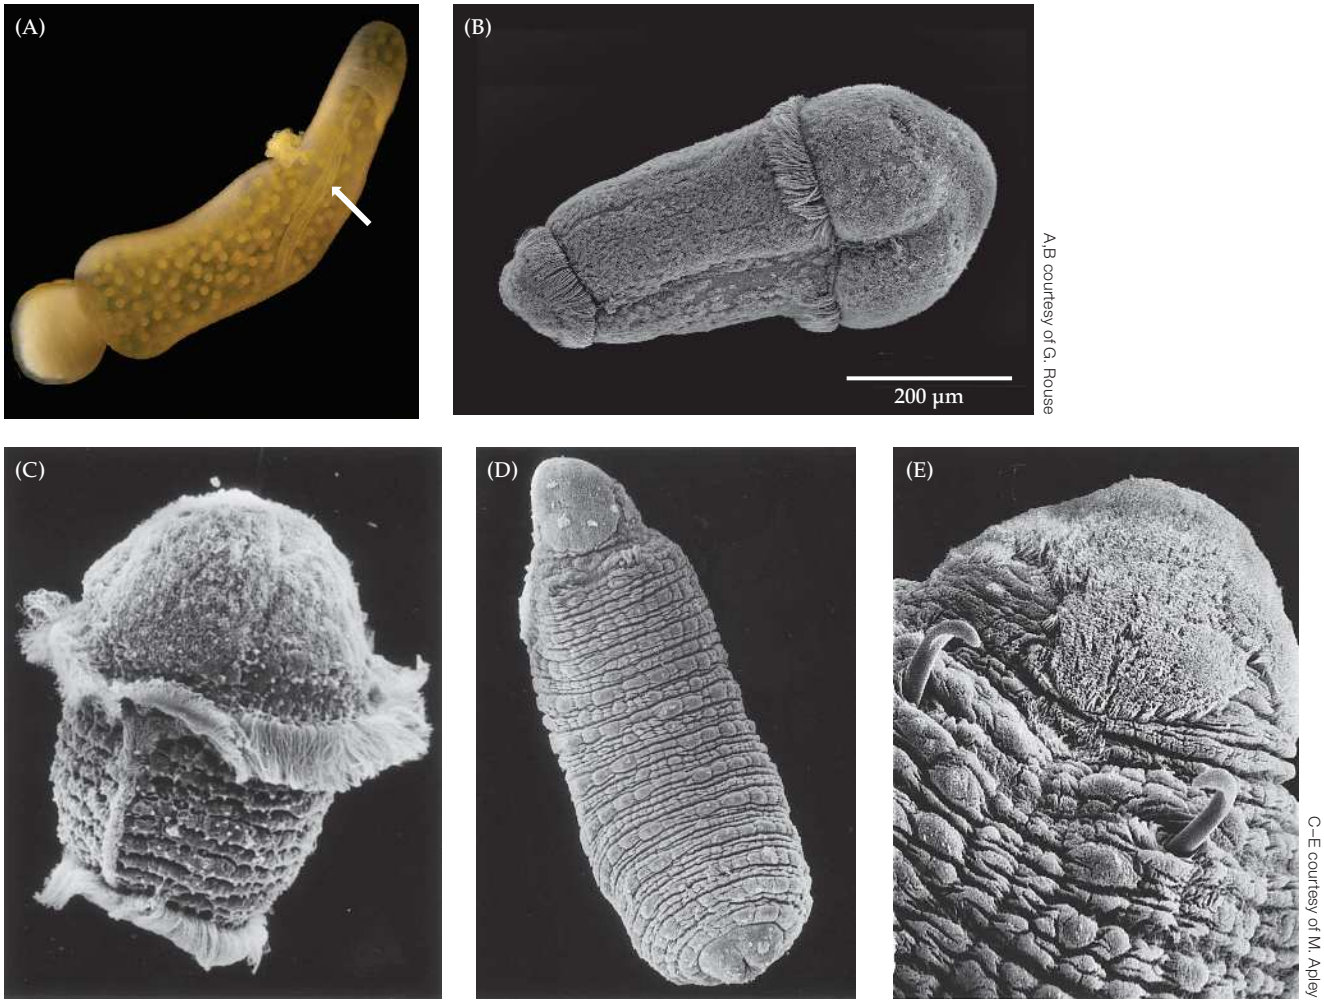

FIGURE 15.31 Reproduction in thalassematids. (A) A dwarf male (arrow) of *Metabonellia haswelli* inside the nephridium of a female, which is also packed with mature oocytes (yellow spheres). (B) *Metabonellia haswelli* trochophore larva in ventrolateral view, showing prototroch and telotroch and overall ciliation. This larva is sexually undifferentiated and will become a female if it settles on sediment, or a dwarf male if it settles on a female *Metabonellia*. (C) A *Urechis* trochophore larva (15 days) exhibits a prototroch, neurotroch, and telotroch. Note the segmented appearance of the trunk produced by distinct bands of epithelial cells. This has been dismissed previously as superficial but may be real. (D) A juvenile *Urechis*, after settling. (E) The anterior end of a juvenile (ventral view). Note the pair of hooked chaetae.

Siboglinidae: Vent Worms and Their Kin

Siboglinidae is an enigmatic family of tube-dwelling marine annelids containing four groups: Frenulata (Latin *frenulum,* "little bridle"), Vestimentifera (Latin *vestimentum*, "garment"; *ferre*, "to bear"), the genus *Sclerolinum* (Latin, *sclera,* "hard"; *linum*, "thread"), and the genus *Osedax* (Latin *Os*, "bone"; *edax*, "to devour"). Together these four worm groups comprise around 180 species of strange creatures that have been the subject of taxonomic and phylogenetic debate since their discovery some 100 years ago (Figures 15.1E, 15.32, and 15.33). We recognize the family name Siboglinidae, although for a while these worms were classified in two distinct phyla, Pogonophora and Vestimentifera. Frenulata (e.g., *Lamellisabella*, *Siboglinum*, *Polybrachia*), which contains most of the described species, live in thin tubes buried in sediments at ocean depths from 100 to 10,000 m. Most frenulates are less than 1 mm in diameter but can be 10 to 75 cm in length (Figure 15.32A–F). The tubes may be three or four times as long as the worm's body. The other main group, Vestimentifera (e.g., *Riftia*, *Tevnia*), is generally found at methane seeps or hydrothermal vents (Figure 15.32G–I). These can be very large worms, with *Riftia pachyptila* reaching well over 1 m in length and several cm in diameter. The anterior trunk of the body has a collar and two lateral extensions, which together make up the vestimentum, from which the group gets its name. One genus that is close to Vestimentifera, *Sclerolinum*, resides in wood fragments or other plant material or at seafloor mud volcanoes. A recently discovered group of siboglinids belongs to *Osedax* (Figure 15.32J–L), and all the more

for more ebook/ testbank/ solution manuals requests e-mail 960126734@qq.com

than 25+ known species consume the bones of vertebrates that have come to rest on the seafloor.

The body of most siboglinid species is divided into four regions (Figure 15.32A). The head (prostomium, as in other annelids) bears from 1 to over 200 separate thin palps or an elaborate crown of fused palps. These bear tiny side branches called **pinnules**. The **prostomium** (obscured in Vestimentifera) is followed by a short **peristomium** (possibly a segment) and then an elongate **trunk**, which is a single very lengthy segment

often bearing various annuli, papillae, and a ring of chaetae. Behind the trunk is a series of segments with more chaetae called the **opisthosoma**.

Internally, siboglinids possess a closed circulatory system and well-developed nervous system. There is an anterior pair of large nephridia, as seen in close relatives such as Cirratulida and Sabellida. There is no digestive tract in the adults. There has been some confusion about the overall body orientation of these animals. For many years it was unclear whether the main longitudinal nerve cord was dorsal or ventral. Those who argued it was dorsal used this to justify the status of phylum for Pogonophora. Furthermore, developmental studies demonstrated a transitory gut in at least one species. However, it now seems clear that the nerve cord is ventral, as in other annelids and in other protostomes.

Siboglinid Taxonomic History

Siboglinids have a complicated, though interesting, history. They were first studied in the early 1900s, following the expedition of the Dutch research vessel *Siboga* in Indonesia. The dredged, partial specimens (lacking the segmented opisthosoma) were given to the eminent French zoologist Maurice Caullery, who studied them for over 40 years and published several papers describing these strange worms. In 1914, Caullery named the originally collected specimens *Siboglinum weberi* and created the family name Siboglinidae for them, although he was unable to assign them to any known phylum. He suggested they were close to deuterostomes such as hemichordates, as they had what he interpreted to be a dorsal nerve cord. The next species to be described, *Lamellisabella zachsi* some 20 years later by a Russian annelid taxonomist (P. V. Uschakov), was placed as a new subfamily of Sabellidae. However, a Swedish annelid worker (K. E. Johansson) suggested that Uschakov had the worms upside down and said they were not annelids and coined the name Pogonophora for them as a new class of animals (again, without a phylum assignment). The problem in interpreting dorsal and ventral was related to the fact that adult animals lacked a mouth and a gut, features that normally helped with orientation. In 1944, Pogonophora was made a phylum and part of the Deuterostomia. A Russian specialist, A. V. Ivanov, described many new species of frenulate siboglinids in the following decades and developed an elaborate taxonomy of genera and families, strongly emphasizing that Pogonophora were deuterostomes. However, in 1964, the first whole specimens were recovered, with the segmented opisthosoma, and an annelid affinity for the group was again proposed by some workers. The discovery of the very large Vestimentifera in the late 1960s and 1970s, associated with seeps and vents, further complicated the controversies surrounding these animals as they were interpreted by one important worker (M. L. Jones) as being closer to annelids than to Pogonophora, leading to the two separate phyla, Pogonophora and Vestimentifera. By the 1990s, both morphology and DNA data began to make it clear that these worms should all be placed within Annelida. To clear up any lingering confusion, the original name, Siboglinidae (designated by Caullery), is now used for the group.

The Siboglinid Body Plan

The Tube, Body Wall, and Body Cavity

The elongate tubes of most siboglinids are composed of chitin and scleroproteins secreted by the epidermis. The tubes are often fringed, flared, or otherwise distinctively shaped and are frequently banded with yellow or brown pigment rings (Figures 15.1E and 15.32B,G). The upper end of the tube projects above the substratum so the worms' palps can extend into the water. The palps of Siboglinidae can be single, as seen in most species (*Siboglinum*, Figure 15.32C,D), or there can be a pair, or four as in *Osedax* (Figure 15.32J–L), and they also range in number from 14–40 (e.g., *Polybrachia*, Figure 15.32E) to hundreds (e.g., vestimentiferans, Figure 15.32G–I). The palps can be free from each other (e.g., *Osedax*, *Polybrachia*) or partially fused together by the cuticle in frenulates such as *Lamellisabella* and in all vestimentiferans. Vestimentiferans have a paired structure called the obturaculum as part of the crown, and its origin has yet to be resolved.

In frenulates the region immediately behind the prostomium is what appears to be a segment that bears a cuticular structure called the **frenulum**, while in vestimentiferans the equivalent region is called the **vestimentum**. These regions are likely involved in tube secretion. The bulk of the body, the trunk, is a single very elongate segment. In frenulates there is a girdle of chaetae halfway along the trunk (lending support to the idea of a single segment), but in Vestimentifera there are no chaetae on the trunk. The chaetae in front of the first opisthosomal septum in these groups are at the end of the trunk and so correspond to the girdle of uncini-type chaetae on the trunks of other siboglinids (Figure 15.5Q). In most siboglinids (except for *Osedax*) the remainder of the body is a short multisegmented region called the opisthosoma that has peglike or hooked chaetae. The body surface is covered by a typical annelid cuticle. There can be small papillae in various parts of the anterior and trunk-bearing thickenings of the cuticle referred to as **cuticular plaques**. The epidermis is mostly a cuboidal to columnar epithelium and includes various gland cells, papillae, and ciliary tracts. Beneath the epidermis is a thin layer of circular muscle and a thick layer of longitudinal muscle, the latter developed as bands or bundles in some parts of the body. There is a spacious coelom in the trunk, and extensions extend into the head region and palps.

Nutrition

Siboglinidae lack a functional digestive tract, and for many years the method of nutrition of these relatively large worms was puzzling. Early suggestions were that the worms subsist on dissolved organic matter from the seawater flowing across their palps and from the muddy sediments in which the animals are buried. Other suggestions were that suspended particulate organic matter and/or bacteria were being filtered from the water column. These ideas have now been supplanted by the realization that all siboglinids have symbiotic bacteria in their bodies, from which they derive their nutrition. This was first discovered in *Riftia pachyptila* by then graduate student Colleen Cavanaugh and colleagues (1981). *Riftia* and its relatives inhabit the sulfide-rich waters near hydrothermal vents or methane seeps, and symbiotic chemoautotrophic Gammaproteobacteria inhabit a region in the siboglinids' trunk called the **trophosome**. These symbionts generate ATP by carrying out sulfide oxidation and by reducing CO_2 to organic compounds. Transfer of organic matter from symbionts to host occurs through translocation of amino acids and other compounds released from the bacteria and through direct digestion of symbiont cells. It appears that free-living stages of the bacteria are taken in by a transitory digestive tract or through the skin by early juvenile stages of the worms. A trophosome with symbiotic bacteria is now known for all siboglinids that have been examined. *Osedax* is unusual in this regard; rather than chemoautotrophic Gammaproteobacteria, the trophosome houses heterotrophic Gammaproteobacteria (belonging to the Oceanospirillales clade). This is because *Osedax* is relying on the organic material in the bone, such as collagen, and possibly on fats. The Oceanospirillales bacteria can exploit these and then, in turn, be digested by the worms. In *Osedax* there are "roots" of tissue (Figure 15.32J–L) that ramify through the bone, and these roots contain the bacteria. The epidermis of the roots secretes acid to dissolve hard bone, allowing access to the proteins and fats.

Circulation, Gas Exchange, Excretion, and Osmoregulation

All siboglinids possess a well-developed closed circulatory system (Figure 15.33A). The major blood vessels are dorsal and ventral longitudinal vessels that extend nearly the entire length of the body. The dorsal vessel is swollen as a muscular pump in the anterior of the body. As in other annelids, blood flows anteriorly in the dorsal vessel and posteriorly in the ventral vessel. Anteriorly, the vessels branch extensively. Some of these vessels supply parts of the head region and lead to afferent and efferent vessels in the palps (Figure 15.33B). Exchange also occurs in the posterior part of the body through a series of connecting blood rings. In *Osedax* the blood vessels branch into the roots.

The blood contains hemoglobin in solution and a variety of cells and cell-like inclusions. Gas exchange probably takes place across the thin walls of the palps. In the species that live near hydrothermal vents, problems of oxygen supply and sulfur toxicity are especially critical. These worms, such as *Riftia pachyptila*, live where hot, anoxic, sulfurous vent water mixes with the surrounding cold, oxygenated water. The animals are thus exposed to potentially dramatic fluctuations in ambient temperatures and oxygen and sulfide availability. These worms possess very high concentrations of hemoglobin in the fluid of their body cavity as well as in their blood. This hemoglobin appears to retain its high affinity for oxygen across a wide temperature range. Furthermore, their blood contains a unique sulfide-binding protein, which serves to concentrate the sulfur and prevent sulfide toxicity and to transport the sulfur to the chemoautotrophic bacteria. Interestingly, similar adaptations are known in the burrowing annelid *Arenicola*, which typically lives in anoxic muds in shallow marine environments.

A pair of large anterior metanephridia lies in close association with the circulatory system, as seen in the closely related Cirratulida and Sabellida. In some Vestimentifera there may be a single fused exterior pore or two pores.

Nervous System and Sense Organs

The nervous system of siboglinids is largely intraepidermal. A well-developed nerve ring just behind the prostomium bears a large ventral ganglion. A single ventral nerve cord arises from this ganglion and extends through all body regions. In many cases there are ganglia (or at least nerve "bulges") at the junctions of the various body regions, and there is an enlargement of the nerve cord in the anterior part of the trunk. In the frenulates where this has been studied, the opisthosoma contains three distinct nerve cords that apparently bear segmental ganglia. The vestimentiferan nervous system has a single opisthosomal nerve cord without ganglia. The bone-devouring *Osedax* also has an intraepidermal nervous system, including the ventrally located brain! Sense organs are poorly understood. The palps probably contain tactile receptors, as the worms are sensitive to vibrations and can rapidly retract into their tubes if disturbed. No siboglinids are known to have eyes or nuchal organs.

Reproduction and Development

Nothing is known about asexual reproduction or regeneration in these animals. While there is simultaneous hermaphroditism known from one species (*Siboglinum fiordicum*), the sexes in Siboglinidae are otherwise separate, and worms possess a pair of gonads in the trunk. In males of frenulates and vestimentiferans,

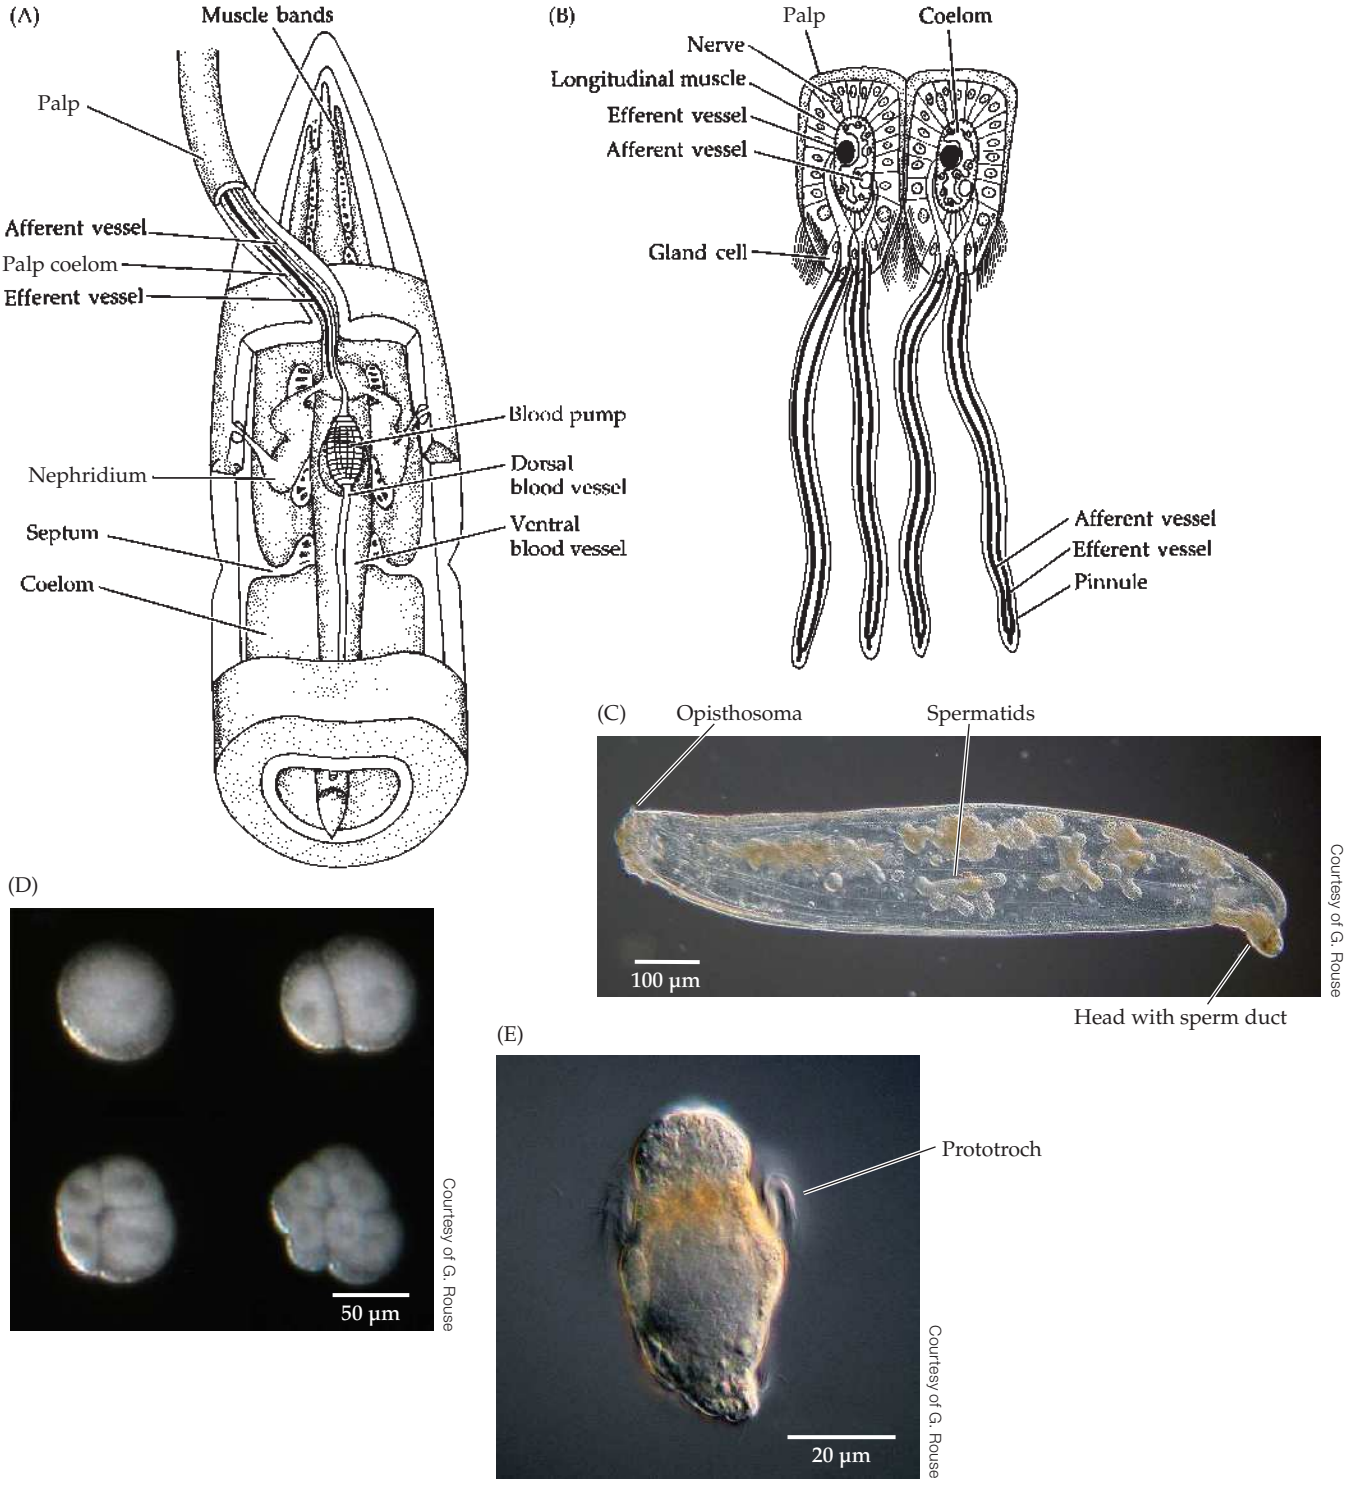

FIGURE 15.33 Siboglinidae anatomy. (A) The anterior end of the frenulate *Siboglinum* (cutaway dorsal view). (B) Two palps of the frenulate *Lamellisabella* (cross sections), showing elements of the circulatory system. (C) Dwarf male of *Osedax rubiplumus*. The male is basically an arrested larva; stage with a two-segmented opisthosoma. The body cavity contains developing sperm. (D) Fertilized egg and first three cleavage stages of *Osedax*. The eight-cell stage clearly shows normal spiral cleavage occurs in Siboglinidae. (E) Trochophore larva of *Osedax* (prior to formation of the opisthosoma). (A after A. V. Ivanov. 1962. *Pogonophora*. Academic Press, London.)

paired sperm ducts extend from the testes to gonopores located near the anterior end of the trunk. As sperm move along these ducts, they are packaged. In frenulates the package is a spermatophore, with an envelope around the sperm, while in vestimentiferans the sperm are in clusters called spermatozeugmata. *Osedax* is unusual in that the males are generally dwarfs (Figures 15.32L and 15.33C), which can be more than 100,000

times smaller than the female—developmentally arrested larvae that develop sperm. These live in the tubes of the females and use their limited yolk supply to make sperm before they die. A female can have up to 600 males in a "harem."

The female system of frenulates and vestimentiferans includes a pair of ovaries from which arise oviducts leading to gonopores on the sides of the trunk. In *Osedax*, the females have a large ovisac that lies in the "host" bone and can be up to one-third of the body mass. This leads to a single oviduct that runs dorsally along the trunk and ends in the plume of palps. The eggs of all siboglinids are spheroidal to elongate, and development is lecithotrophic.

Fertilization is internal in Vestimentifera and *Osedax*, and this is likely also the case for Frenulata. In frenulates and vestimentiferans, males release spermatozeugmata or spermatophores, which drift to the plumes and tubes of nearby females. The sperm end up in the oviduct, which can have sperm storage areas. In *Osedax* the sperm somehow end up in the ovary itself. Brooding of larvae in the tube occurs in some frenulates, while in all vestimentiferans and *Osedax* the fertilized eggs are apparently released into the water column. Individual *Osedax* females can release 400–800 eggs daily, and the larvae can live for several weeks in the plankton. Vestimentifera also produce numerous eggs, and these also live for a month or more as larvae. Such high fecundity is necessary, as the habitats for these worms are very restricted and most larvae are likely unsuccessful in finding a suitable place to settle.

Cleavage is spiral in all siboglinids where this has been studied, and early reports of radial cleavage now appear to be erroneous (Figure 15.33D). Trochophore larvae develop (Figure 15.33E) and add some segments that will later become the opisthosoma. In the dwarf male of *Osedax*, two segments are formed that have hooked chaetae. A transitory digestive tract occurs during development and in juveniles of at least some vestimentiferans and frenulates. Inner cells near the presumptive posterior end of the embryo proliferate spaces within the opisthosomal segments as they develop, a process strikingly like the teloblastic growth and schizocoely seen in other annelids.

Hirudinea: Leeches and Their Relatives

Hirudinea (Figures 15.34–15.40) are clitellate annelids whose closest relatives are Lumbriculidae. They have a fixed number of segments, which are traditionally numbered with Roman numerals (Figure 15.34C). In an unusual tradition with respect to other annelids, the prostomium and peristomium (when present) are counted as segments, and so the bodies of branchiobdellids are counted as having 15 segments (though they lack a prostomium), acanthobdellids have 29 or 30 segments (lacking both a prostomium and peristomium), and hirudinidans (leeches) have 34 segments. These segments are generally obscured by superficial annulations, giving the impression of many more segments (Figure 15.34). Externally, Hirudinea generally feature anterior and posterior suckers and clitellum, while lacking parapodia and chaetae (though Acanthobdellida have chaetae in a few anterior segments). Internally, acanthobdellids have a coelom and segmental septa typical of annelids, while in branchiobdellids there are at least a few segments with coelomic spaces. However, the coelom of leeches is reduced to a series of interconnected channels and spaces, without serially arranged septa.

We usually think of leeches as the bloodsuckers popularized in adventure stories and films, and this is arguably the ancestral state for Hirudinida. However, many hirudinidans are free-living predators, and some are scavengers. Most range from less than 0.5 to about 2 cm in length, although one species from tropical South America, *Haementeria ghilianii*, may reach 45 cm in length. Acanthobdellids and branchiobdellids are exclusively freshwater groups, while leeches occur in both fresh and salt water, and many live in moist terrestrial environments as well. Those that are full- or part-time parasites feed on the body fluids of a variety of vertebrate and invertebrate hosts. Some of these leeches serve as the intermediate hosts and vectors for certain protist, nematode, and cestode parasites.

Many Hirudinea are cylindrical, while others are flattened dorsoventrally. The body is usually divisible into five regions, although the points of division are somewhat arbitrary. The anterior-most head region is composed of the much reduced (or absent) prostomium and peristomium and the anterior body segments. The anterior region usually bears several eyes and a ventral mouth surrounded by the oral or anterior sucker (note the sucker is lacking in *Acanthobdella peledina*). In leeches, segments V–VIII form the preclitellar region, followed by the clitellar region (segments IX–XI). The clitellum is only apparent during periods of reproductive activity. The postclitellar or midbody region comprises segments XII–XXVII. The posterior region of the body includes the ventrally directed posterior sucker formed from seven fused segments (XXVIII–XXXIV). In branchiobdellids and acanthobdellids the counts are different, owing to their smaller numbers of segments.

Other than the suckers, gonopores, and nephridiopores, Hirudinea have few distinctive external features. In a few forms the body surface bears tubercles, and some such as the piscicolid *Branchellion* have lateral gills (Figure 15.34D). Chaetae are present on the first few segments of acanthobdellids, but they do not occur in any other Hirudinea.

The Hirudinean Body Plan

Body Wall and Coelom

A cross-sectional view of a leech is dramatically different from that of other annelids, in large part because of a thick dermal connective tissue layer beneath the epidermis and the reduction of the coelom (Figure 15.35). The typical circular and longitudinal muscles are present, as well as bands of dorsoventral and diagonal (oblique) muscles between the circular and longitudinal layers. The dense dermis fills the areas between the muscle bands. Septate coelomic compartments are present only in acanthobdellids (in the first five segments) and in the midbody region of branchiobdellids. In all Hirudinea, the coelom is limited to various channels and small spaces. These augment the circulatory system in rhynchobdellids (proboscis leeches) and completely replace it in arhynchobdellids (jawed leeches).

Support and Locomotion

Except for acanthobdellids, Hirudinea show a solid body construction, and the absence of a spacious coelom precludes kinds of locomotion seen in other annelids. They do not burrow but are mostly surface dwellers, and the suckers in branchiobdellids and hirudinidans serve as the points of contact with the substratum against which the muscle action can operate (Figure 15.36). Beginning with the posterior sucker attached, the circular muscles are contracted, making the entire body elongate forward, and then the anterior sucker is attached. Then the longitudinal muscles contract, shortening the body and drawing the posterior end forward. Some leeches are also capable of swimming by dorsoventral body undulations; this behavior is an important mechanism for locating and contacting nonbenthic hosts.

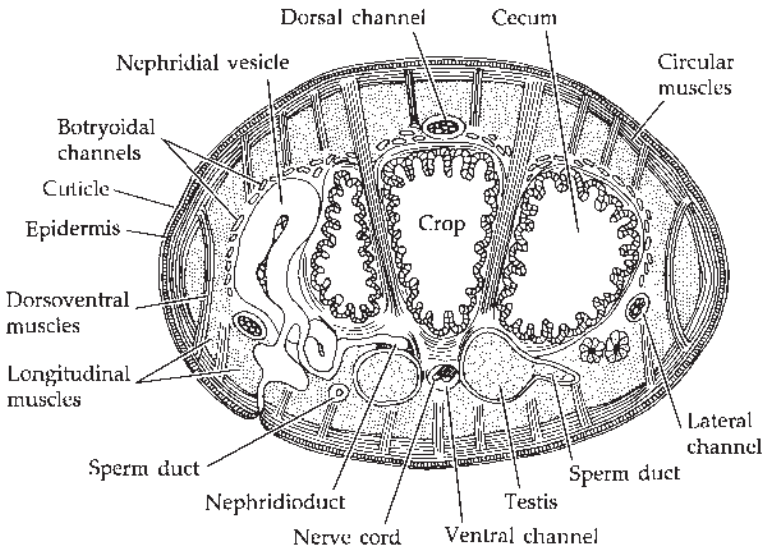

FIGURE 15.35 Body wall and general internal organization of *Hirudo* (cross section). The original circulatory system has been lost and replaced by coelomic channels.

Feeding and Digestion

Like that of most other annelids, the leech digestive tract includes a foregut, midgut, and hindgut (Figure 15.37). The foregut, as mentioned earlier, includes a mouth, buccal cavity, jaws or proboscis, pharynx, and esophagus. There are also masses of unicellular salivary glands that secrete hirudin in the jawed bloodsuckers and may produce enzymes to aid penetration of the proboscis in those parasitic forms that lack jaws. Posterior to the esophagus is the enlarged midgut, usually called the stomach or crop. This region bears large ceca in most leeches, providing a large storage capacity as well as a high surface area. In some kinds of leeches, the posterior midgut is structurally differentiated from the anterior portion. A short rectum connects the midgut to the anus, located dorsally near the junction of the body and the posterior sucker. Little is known about digestion in Hirudinea, except for some fragmentary information on blood-sucking leeches. Midgut enzymes apparently are limited to exopeptidases, which probably accounts for the extremely slow rate of digestion in these animals (a medicinal leech may take several months to digest the contents of a full blood meal).

Assessment of the distribution of blood-feeding and other feeding modes across the phylogeny of Hirudinida has led to the conclusion that blood feeding is the ancestral condition for the group, with several losses of this feeding mode across the group. The acanthobdellids *Acanthobdella peledina* and *Paracanthobdella livanowi* live on the skin, usually of fin rays, of freshwater fishes and suck the blood of their hosts, though they have been shown to also eat insect larvae. *Acanthobdella peledina* is found across northern Europe and Russia with *P. livanowi* limited to the Kamchatka Peninsula. There is a record also from Alaska, though the species identification needs further assessment. Branchiobdellids are tiny worms that live on freshwater crayfish. The anterior end of the pharynx bears a pair of toothed jaws (Figure 15.37). These animals eat other epizoites living on the host, but they also feed on the host's eggs and body fluids.

The majority of Hirudinida lineages ranked as families are ectoparasites that feed by sucking the blood or other body fluids from their hosts. The rest are predators on small invertebrates or scavengers on dead animal matter. Feeding involves either a protrusible pharyngeal proboscis or cutting structures in the form of slicing jaws or stylets. Members of the paraphyletic Rhynchobdellida possess a pharyngeal proboscis but lack jaws, whereas members of the clade Arhynchobdellida lack a proboscis but nearly all have jaws (Figure 15.34). Because of their medical importance, much work has been done on leeches, especially those that affect livestock, game animals, or humans. Blood-sucking leeches are not especially host specific, and most do not remain attached to a single host for long periods of time; many of these leeches may feed by other means when not attached to a suitable host. A few species of leeches feed exclusively on invertebrate hosts, including annelids (even other leeches), gastropods, and crustaceans, but most of them parasitize vertebrates. Some leeches are parasitic on vertebrates. For example, most Piscicolidae (Rhynchobdellida) feed on the blood of fishes (including some deep-sea and hydrothermal vent fishes (Figure 15.37D), whereas Ozobranchidae (another family of

Rhynchobdellida) seem to prefer aquatic reptiles such as turtles and crocodilians.

The European medicinal leeches such as *Hirudo medicinalis* and *H. verbana*, which normally feed on amphibians, will obligingly consume human blood. Overcollecting has meant that *H. medicinalis* is now classified as Near Threatened by the IUCN, and it is protected across much of its range. The North American medicinal leech is *Macrobdella decora*, and other species are used for medicinal purposes in Asia. The common name is derived from using these leeches to draw blood from people afflicted with a wide range of maladies for which such "bleeding" was once thought to be curative or restorative. Today, medicinal leeches are used to reduce hematomas in areas of the body that are difficult to treat surgically, and to avoid leaving scars. The anticoagulant pumped into the wound by the leech (hirudin) allows blood to continue to drain, even after the leech has been removed, and so promotes healing. In addition to the anticoagulant, some leeches produce several other chemicals, including anesthetics and vasodilators. When feeding, the leech anchors to the host by the suckers and presses the mouth against the surface of the host's body. Jawed leeches have three bladelike jaws, each shaped like a half circle. The jaws are set at roughly 120° angles to one another, so the cutting edges form a Y-shaped incision. Muscles rock the jaws to and fro, making slices in the host's skin. The leech releases an anesthetic as it makes its incisions, then it secretes hirudin into the wound, and blood is sucked from the host by the muscular pharynx. The anesthetic desensitizes the victim's skin, so the worms can go unnoticed while they take their blood meal. While the predatory leeches eat frequently, the bloodsuckers feed at widely spaced, very irregular intervals, depending on the availability of hosts. When they do feed, they gorge themselves with several times their own weight in blood (Figure 15.37D).

Circulation and Gas Exchange

Many leeches are relatively large and quite active. The drastic reduction of the coelom has led to a flattening of the body and the formation of extensive gut ceca or diverticula in some lineages. Both reduce internal diffusion distances. In Rhynchobdellida this system is a

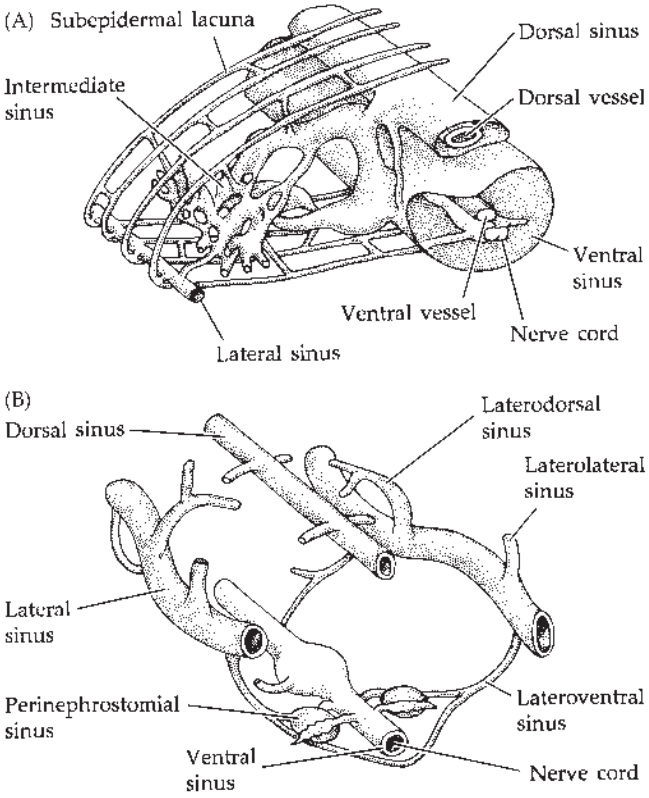

FIGURE 15.38 Coelomic and circulatory systems of two leeches. (A) A portion of the circulatory and coelomic systems of *Placobdella*, a rhynchobdellan leech in which the circulatory system persists and is associated with the coelomic channels. (B) A portion of the coelomic system in *Hirudo*, an arhynchobdellid leech. Here the circulatory system has been completely replaced by coelomic channels.

combination of a true closed circulatory system and the reduced coelomic spaces; in the Arhynchobdellida, the original circulatory system is completely replaced by one derived entirely from the reduced coelom. In both arrangements the circulatory fluid is moved through the system by the action of contractile vessels and by general body movements (Figure 15.38). Gas exchange is accomplished by diffusion across the body wall; gills are present only in some ozobranchids and piscicolids. Some leeches possess hemoglobin in solution in the circulatory fluid, thought to account for about 50 percent of their oxygen-carrying capacity.

Excretion and Osmoregulation

The excretory structures of Hirudinea are paired and segmentally arranged metanephridia that are usually absent from several anterior and posterior segments. The nephrostomes are ciliated funnels associated with coelomic circulatory vessels (where present). Ammonia is the main nitrogenous waste product eliminated via the nephridia. Apparently, particulate waste materials are engulfed by phagocytes, both in the coelomic fluid and in the "mesenchyme," but the eventual disposition of this material is not known.

Nervous System and Sense Organs

The nervous system of leeches has received, and continues to receive, a great deal of attention from biologists. The leech nervous system—even that of large leeches—is composed of very few neurons, and these individual nerve cells are sufficiently large that their circuitry has been traced in detail.

The nervous system includes a cerebral ganglion that is usually set back from the anterior end of the body at about the level of the pharynx (Figure 15.39). The cerebral ganglion, circumenteric connectives, and subenteric ganglion together form a nerve ring around the foregut. Two longitudinal nerve cords arise from the ventral portion of this ring and extend posteriorly through the body. The nerve cords are separate in some areas, but the segmental ganglia are fused. Peripheral nerves include abundant sensory neurons from the cerebral ganglion and segmentally arranged motor and sensory neurons from the ventral nerve cord ganglia.

Leeches are extremely sensitive to certain environmental stimuli, although their sensory receptors are relatively simple. They have from two to ten dorsal eyes of varying complexity, and special sensory papillae that bear bristles extending from the body surface. Except for the eyes, the functions of various leech sense organs are not well understood, and most of the information is based on behavioral responses to different stimuli. Leeches tend to be negatively phototactic. However,

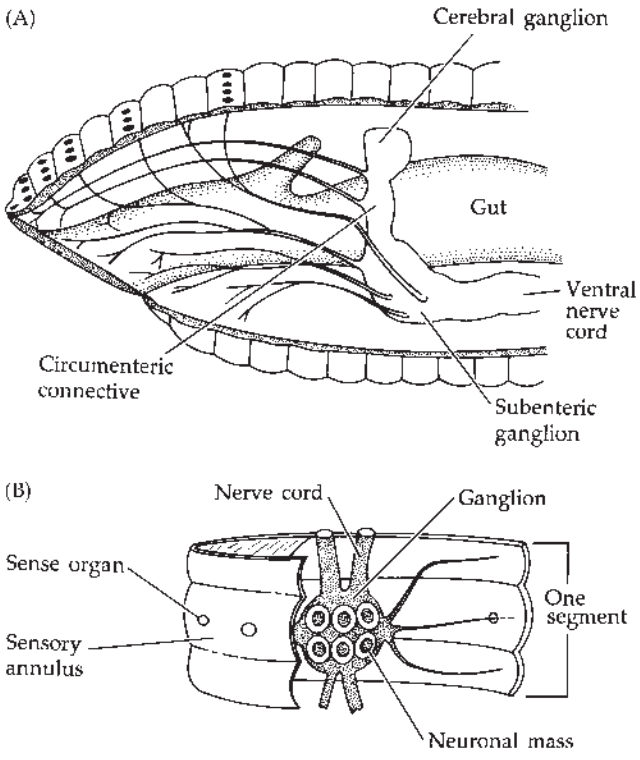

FIGURE 15.39 Leech nervous system. (A) The anterior nervous system (lateral view). (B) A generalized leech segment comprising three annuli, cut away to show segmental ganglion and innervation of epithelial sense organs.

for more ebook/ testbank/ solution manuals requests (e-mail 960126734@qq.com)

some of the blood-sucking species react positively to light when preparing to feed. This behavioral change likely causes the leech to move into areas where a host encounter is more likely. Most leeches can also detect movement in their surroundings, as evidenced by their responses to shadows passing over them. This reaction has been noted particularly in leeches that attack fishes. Leeches also respond to mechanical stimulation in the forms of direct touch and vibrations in their environments. They are also chemosensitive and attracted to the secretions of potential hosts. Some aquatic and even terrestrial leeches that prefer warm-blooded mammalian hosts are apparently attracted to points of relatively high temperatures in their surroundings, thus aiding in food location. Standing in a leech-inhabited pond is a great way to observe firsthand this rapid response, as these animals will detect your presence and begin swimming or crawling toward you within seconds.

Reproduction and Development

Hirudinea, like all Clitellata, are hermaphroditic and have complex reproductive organs (Figure 15.40) and direct development. The male reproductive system includes a variable number of paired testes, usually from five to ten pairs in leeches, arranged serially beginning in segments XI or XII (Figure 15.34C). The testes are drained by a pair of sperm ducts that lead to a copulatory apparatus and a single gonopore located midventrally on segment X. Leeches have a single pair of ovaries, which may extend through several segments. Oviducts extend anteriorly from the ovaries and unite as a common vagina, which leads to the female gonopore on the midventral surface of segment XI, just behind the male pore.

The copulatory apparatus of leeches is often complex and varies in structure among species. Each sperm duct is coiled distally and enlarges as an ejaculatory duct. The two ducts join at a common glandular, muscular atrium. In arhynchobdellids, the atrium is modified as an eversible penis. The rhychobdellids lack a penis, and the atrium functions as a chamber in which spermatophores are produced. In arhynchobdellids, mating worms align themselves so that the male pore of each rests over the female pore of the other. The penis is everted and inserted into the mate's vagina, where sperm are deposited. Fertilization takes place within the female reproductive system. Rhynchobdellid leeches use hypodermic impregnation. These animals grasp one

FIGURE 15.40 Leech reproduction. (A) Reproductive system of *Piscicola* (Hirudinida, Piscicolidae). (B) Copulating leeches. (C) *Erpobdella* with cocoon. (D) Leech with two broods of offspring against its ventral surface.

another by their anterior suckers and bring their male pores in alignment with a particular region of the mate's body. The spermatophores are released onto the clitellar region of the mate and then penetrate the body surface of the recipient, and the sperm emerge beneath the epidermis. The sperm migrate to the ovaries by way of the coelomic channels and sinuses. In some of the piscicolid leeches there is a special "target" area, beneath which is a mass of tissue called vector tissue that connects with the ovaries via short ducts.

Cocoon formation in leeches is like that in other clitellates, with the clitellum producing a cocoon wall and albumin (Figure 15.40C). However, as the cocoon slides anteriorly past the female gonopore, it receives the zygotes or young embryos rather than separate eggs and sperm. The cocoons are deposited in damp soil by terrestrial species and even by a few aquatic forms that migrate to land for this process (e.g., *Hirudo*). Most aquatic forms deposit their cocoons by attaching them to the bottom or to algae; a few attach them to their hosts (e.g., some piscicolids). A few freshwater leeches display some degree of parental care for their cocoons. Some of these bury their cocoons and remain over them, generating ventilatory currents. Others attach the cocoons to their own bodies and brood them externally (Fig 15.40D). The development of leeches is like that described for other clitellates. Except for a few species, the amount of yolk is relatively small and development time quite short.

Orthonectida: Extremely Simplified Annelids

Orthonectida was a small phylum of less than 30 marine species that are parasites of Acoela, other Annelida, Echinodermata, Mollusca, Nemertea, Platyhelminthes, and *Xenoturbella*. Their name refers to the adults' behavior in seawater when they leave their host—they swim in a straight line. Inside the host, the parasite forms a plasmodium that asexually generates germinal cells, resulting in clonal embryos and adults (Figure 15.41A). The adults are completely ciliated (Figure 15.41E), can be several hundred microns long, and break out of their host for sexual reproduction (Figure 15.42). For a long period Orthonectida was grouped as "Mesozoa" with another small group of minute parasites of cephalopods called Dicyemida or Rhombozoa (see Chapter 10), although since the late twentieth century dicyemids and orthonectids were usually given separate phylum status. Observations on the cuticle and epidermis raised the possibility of Orthonectida being derived annelids, and this has now been supported by phylogenetic evidence based on molecular data, though their exact placement within Annelida is still uncertain.

The ciliated swimming stages of orthonectids (the short-lived phase outside the host) are ellipsoidal to cylindrical in shape, with the females usually much larger than the males (Figure 15.41E). The smallest

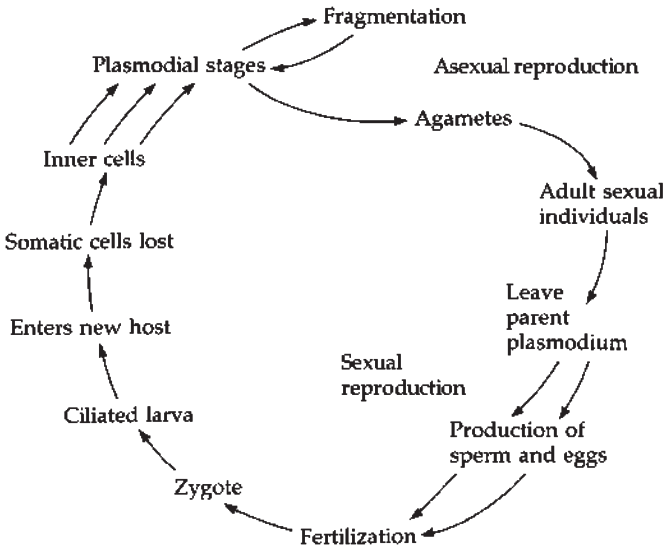

FIGURE 15.42 Orthonectida. Generalized life cyc|e of an orthonectid.

known female, *Intoshia variabili,* reaches just 80 by 20 μm, while the largest, *Ciliocincta sabellariae,* can be 265 by 26 μm. The one hermaphroditic species, *Stoecharthrum monnati*, can be more than 1.5 mm long. The epidermis is made up of ciliated and nonciliated cells and has a cuticle with notable similarities to Annelida, especially during development. A circular and longitudinal muscle system is present but composed of only a few cells. A serotonergic nervous system is also present, but there is no trace of any segmentation, nor excretory organs or a circulatory system. Gametes form in the males and females while they are still developing in the plasmodium (Figure 15.41B–D), and upon release into the seawater they are mature (Figure 15.41E). Females are filled with tiny oocytes 11–13 μm in diameter, and the sperm of males is also uniquely small. Mating occurs via copulation, and fertilization is internal. Females release free-swimming larvae (Figure 15.41F) through a genital pore, and these live for only a few hours before they must find and penetrate a host. The plasmodium phase inside the host has been interpreted as originating from the penetrating larval cells or is the host tissue reacting to such penetration. The plasmodium ramifies through the host, feeding on the host tissues by phagocytosis and pinocytosis. A plasmodium can give rise to daughter plasmodia by budding, and while both males and females can develop in one plasmodium, a single sex is mainly observed. This body miniaturization is also reflected in their genome: orthonectids hold the record of having the smallest animal genome, with one of the smallest numbers of genes recorded.

Annelid Phylogeny

There are undoubted annelid fossils that date back to the Cambrian period, with well-known examples being *Canadia* and *Burgessochaeta*. These show clear evidence of segmentation and chaetae, though it is a subject of debate as to whether they could be classified very closely with any extant lineage of annelids. But these were quite complex annelids, and the early origins of the group are obscure.

In addition to the recognition that the traditional classification (of Polychaeta, Oligochaeta, and Hirudinea) had to be replaced with a phylogenetic classification, the past few decades have seen a series of major changes in annelid membership as well, mainly due to molecular-based phylogenetic studies. Diurodrilidae, Echiura, Myzostomida, Sipuncula, Orthonectida, Pogonophora, and Vestimentifera, all of which were once considered outside Annelida, are now clearly seen as part of this phylum. Hence, Annelida now encompasses many animals that do not conform to the traditionally viewed unique features of the group, such as possession of body segmentation and chaetae. Even more problematic has been resolving the relationships among the groups that have long been regarded as part of the annelid radiation, a work that must still be regarded as very much in progress, especially with respect to the precise position of Myzostomida and many meiofaunal taxa.

While a deep understanding of the origin and evolution of annelids still eludes us, considerable progress has been recently made with the use of high-throughput sequencing technologies, which hold great promise. This means we will likely see a stable annelid phylogenetic tree emerge over the coming years. Our current knowledge of annelid relationships, as used in this chapter, is based on recent phylogenomic studies by Anne Weigert, Sónia Andrade, Torsten Struck, Chema Martín-Durán, and their colleagues (Andrade et al., 2015; Martín-Durán et al., 2021; Struck et al., 2015; Weigert et al., 2014), and these were used to generate the summary tree and classification used in this chapter (Figure 15.43). As future phylogenomic analyses are integrated with increasing knowledge of fossil annelids, we will be able to make better inferences as to the origin and evolution of this diverse group of animals.

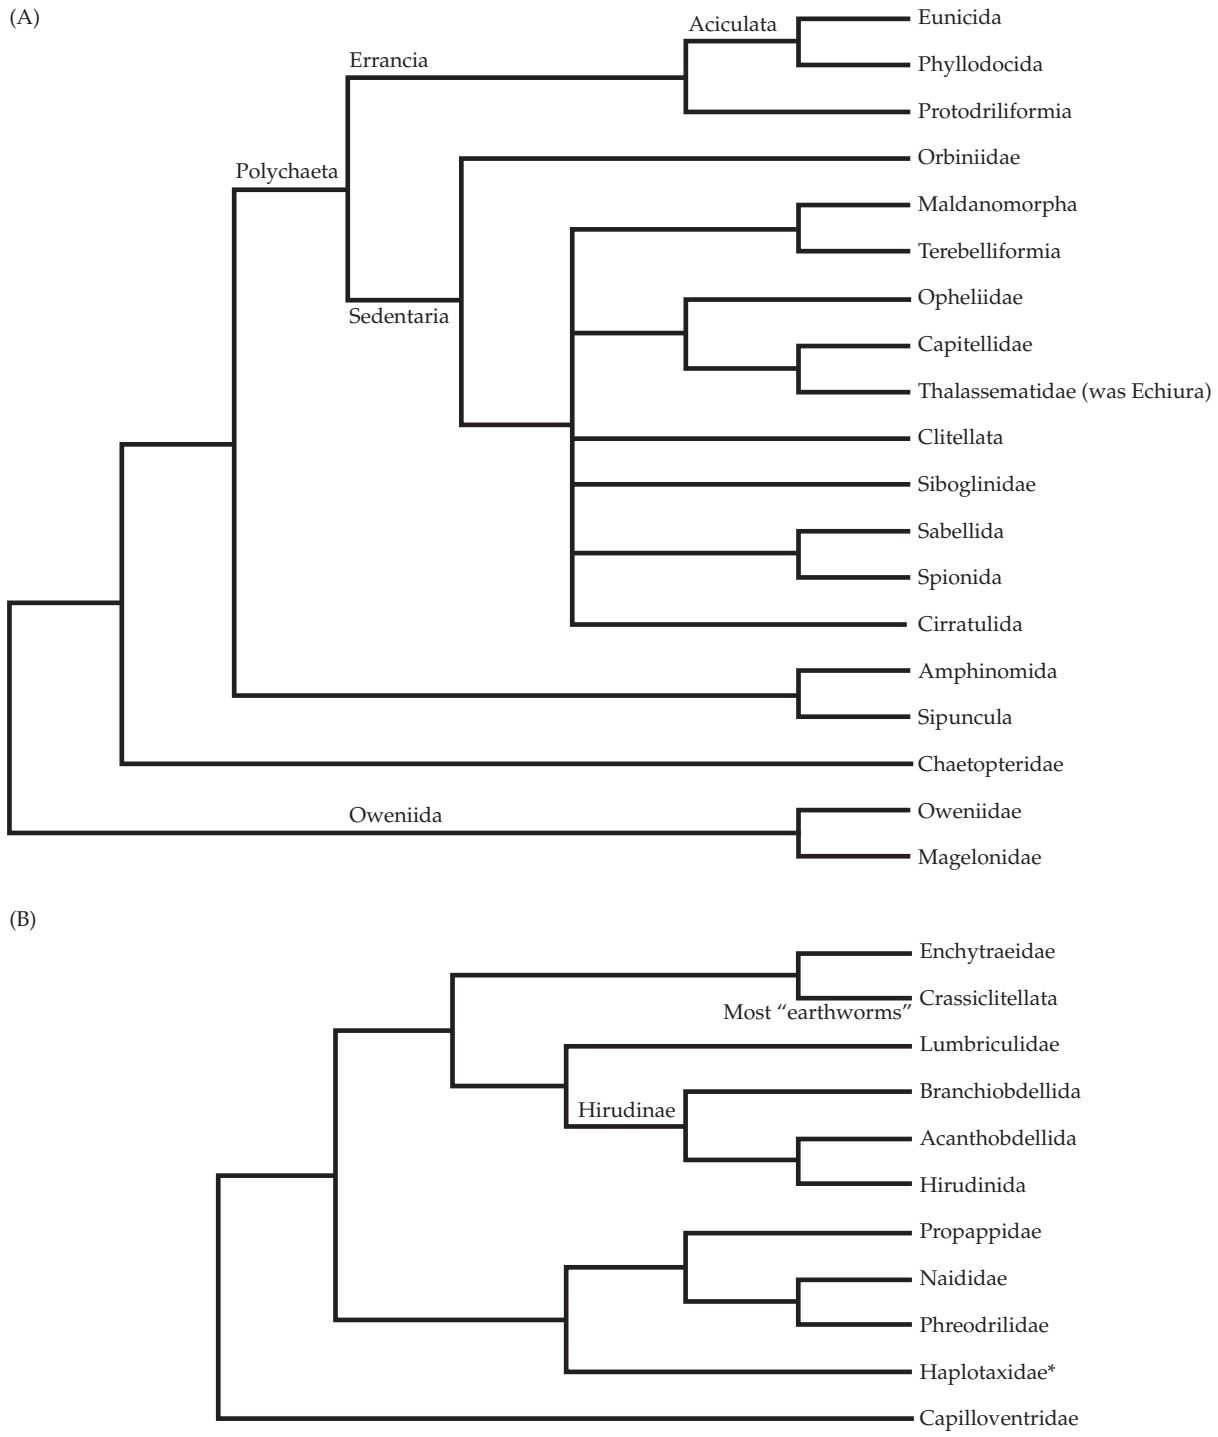

FIGURE 15.43 Phylogenetic relationships of annelids. (A) Annelida, based on areas of agreement in the phylogenomic analyses of Andrade et al. (2015), Weigert et al. (2014), Struck et al. Chapter Summary

This chapter introduced you to a large group of primarily segmented spiralian worms, the phylum Annelida. Annelids are lophotrochozoans, closely related to molluscs, nemerteans, and perhaps entoprocts. Annelid segmentation represents true metamerism, the result of teloblastic development—the proliferation of paired, segmental mesodermal bands from teloblast cells at a posterior growth zone in the embryo. The segmented annelid species all show serial homology. Annelids typically have a closed circulatory system, well-developed nervous system, and proto- and/or metanephridia. Development is holoblastic and spiral, and most marine species produce a trochophore larva (a feature shared with molluscs, nemerteans, and entoprocts). Among the better-known, clearly segmented annelids are marine sand worms and tube worms, earthworms, and leeches—the latter two comprising the clade Clitellata. However, a number of lineages in this phylum show secondary loss of obvious segmentation, and molecular phylogenetics has only recently revealed them to be highly modified annelids; these include orthonectids, sipunculans (peanut worms), and thalassematids (spoon worms, or echiurans). Annelids range in size from nearly microscopic marine meiofauna to earthworms exceeding 3 m in length. They can be found in almost all marine, freshwater, and damp terrestrial environments; they are especially common in shallow coastal waters. Many species are symbionts (commensals, mutualists, parasites) with other invertebrates and, in the case of leeches, some vertebrates.

Annelid classification is in a state of flux, and this is reflected in the absence of category names in this chapter (although taxon names ending in *idae* are generally regarded as family names). Because Clitellata (earthworms and leeches) arose from within the other annelids (i.e., from a group once called Polychaeta), the nonclitellates comprise a paraphyletic group. Therefore, many workers now redefine "Polychaeta" as a clade of annelids that includes only the two large groups Errantia and Sedentaria (Clitellata, Siboglinidae, and Thalassematidae are part of Sedentaria). Thus, three major groups of annelids are now viewed as nonpolychaetes: Oweniida, Chaetopteridae, and the Amphinomida + Sipuncula clade.

CHAPTER 16

The Lophophorates

Phyla Phoronida, Bryozoa, and Brachiopoda

For most of the twentieth century, three phyla—Phoronida, Bryozoa (= Ectoprocta), and Brachiopoda—all of which possess a unique feeding structure called a lophophore, had been regarded as a likely clade within the Deuterostomia. The primary unifying feature of the Lophophorata was the **lophophore** itself, a ciliated tentacular feeding structure, and the associated **epistome** (a muscular flap that functions to move captured food particles from the lophophore to the mouth). Their alliance with the deuterostomes had been based on a suite of developmental features, including radial and indeterminate cleavage, enterocoely, and development of the mouth secondarily rather than from the blastopore (i.e., "deuterostomy"). Further, in all three phyla the adult body is organized into three distinct parts, each with its own coelomic cavity (or paired cavities). This trait was originally termed **archicoely**, in reference to the "archicoelomate" concept, the idea that three regionalized body coeloms is a fundamental feature of Deuterostomia. This archicoelomate condition is also seen in the deuterostome phyla Echinodermata, Hemichordata, and Chordata. The developmental features were viewed as differentiating them from protostomes, in which the blastopore develops into the mouth and radial cleavage typically does not occur. In deuterostomes, the mouth is formed as a secondary opening (i.e., *deutero*, "second"; *stome*, "mouth") on the anterior end of the embryo.

However, with the advent of molecular phylogenetics, it is certain that the three lophophorate phyla are allied with spiralian protostomes, not deuterostomes, and aspects of their development seeming to have deuterostome-like characteristics are

Phoronida was revised by Scott Santagata, Bryozoa was revised by Claus Nielsen, and Brachiopoda was revised by Carsten Lüter.

likely secondarily derived or have been reinterpreted. It has long been suspected that something akin to radial cleavage might be the primitive cleavage pattern within Bilateria (most demosponges also have radial cleavage), and the discovery that the lophophorate phyla belong to the Spiralia suggests that radial cleavage and deuterostomy are retained plesiomorphic developmental features (or reacquired) of the lophophorate phyla. And in the protostome phylum Phoronida the mouth develops from a portion of the blastopore (protostomously), and both radial cleavage and spiral-like cleavage occur (the cleavage pattern may depend, at least in part, on the size of the egg). Specific brachiopods, on the other hand, develop the mouth by either protostome-like or deuterostome-like developmental patterns. Although bryozoan embryos cleave radially, the resulting blastomere arrangements and cell lineages exhibit several spiralian features. Molecular phylogenetics also places the former deuterostome phylum Chaetognatha within the protostome lineage. In other words, developmental programs appear to be more flexible (and homoplastic) than once thought, and even phyla outside the classic Deuterostomia clade can exhibit a deuterostome type of development

The archicoelomate concept recognizes three distinct body regions (an anterior **prosome**, middle **mesosome**, and posterior **metasome**), each with its own coelomic cavities (**protocoel**, **mesocoel**, and **metacoel**). This condition is also referred to as a tripartite or **trimeric body plan**. However, developmental research since 2000 has shown that the protocoel may not comprise a true coelom in all lophophorate species, or might be absent altogether in many, and we discuss this for each of the phyla. The great American zoologist Libbie Hyman noted in the 1950s that a correspondence between the adult coeloms of lophophorates and the trimeric body of deuterostomes was poorly supported by both embryology and adult morphology. In fact, Hyman was dismayed with the mix of characteristics found in the Lophophorata. She was actually inclined to classify them with protostomes, despite the enterocoelous coelom formation in brachiopods and the lack of spiral cleavage in bryozoans and brachiopods. She eventually found comfort in concluding that "the lophophorates constitute a connecting link between the Protostomia and the Deuterostomia, but the details of this connection cannot be stated." Hardly a more vague phylogenetic statement could be made.

With molecular phylogenetics confirming that lophophorates are protostomes, use of the terms "prosome," "mesosome," and "metasome" to describe their body plan is perhaps ambiguous, and the homology of these regions to those of deuterostomes is now called into question. The same holds for the Entoprocta, another protostome group whose body regions are often referred to as "prosome," "mesosome," and "metasome," despite lacking a coelom. The tentacular crown of pterobranchs (phylum Hemichordata; Chapter 25) also possesses mesosomal tentacles with a coelomic lumen. However, the homology between pterobranch tentacles and a true lophophore is likely invalidated because in the former case the tentacles do not fully surround the mouth.

Even though the lophophorate phyla are no longer considered deuterostomes, molecular phylogenetics does suggest they comprise a monophyletic group, the clade Lophophorata. However, the precise placement of this clade within the Lophotrochozoa remains enigmatic, and whether Entoprocta also belongs with Lophophorata remains unresolved, as some analyses ally them with Bryozoa while others group them with Cycliophora; in the latter case, they are outside the Lophophorata.

At first glance, what we consider here the three lophophorate phyla may not appear closely related to one another. However, in addition to molecular phylogenetic analyses, they are united by their common possession of a lophophore and epistome (although an epistome is absent in most bryozoans); no other animal phylum has these structures. The lophophore is a ciliated, tentacular outgrowth arising from the mesosome and containing extensions of the mesocoel. It surrounds the mouth but not the anus. All lophophorate animals are sessile, have a U-shaped gut, and typically have very simple, often transient, reproductive systems. Nearly all secrete outer casings in the form of tubes, shells, or compartmented exoskeletons, a character that has been used to justify an affinity to the other lophotrochozoans.

With the exception of a few freshwater bryozoans, the lophophorates are exclusively marine. All are benthic, living either in tubes (phoronids) or in secreted shells, or casings. The phoronids are a small group, comprising only two genera and around 15 known species of solitary or gregarious animals. Bryozoans, on the other hand, make up a diverse taxon of about 6,300 living species of colonial forms (with about 15,000 additional species being extinct). The brachiopods, or lamp shells, include about 440 extant species. However, the brachiopods have left a record of thousands of fossil species (over 12,000 described extinct species) as evidence of a greater past, and they were well established by the early Cambrian. Brachiopods flourished in both abundance and diversity from the Ordovician through the Carboniferous, but they have declined in numbers and kinds ever since.

Taxonomic History of the Lophophorates

The lophophorates have had a long and tortuous taxonomic history. The earliest records of lophophorates are of various bryozoans reported in the sixteenth century. With few exceptions, the early zoologists treated them as plantlike and included them in the taxon Zoophyta,

for more ebook/ testbank/ solution manuals requests: email 9781267340@qq.com

a misconception that persisted into the 1700s. In 1729, French physician and naturalist Jean-André Peyssonal finally established the animal nature of bryozoans, and in 1742 French naturalist Bernard de Jussieu noted the compartmentalized condition of the colonies and coined the term "polyps" to refer to the individual animals. Still, most well-known workers of the day (e.g., Linnaeus and Cuvier) continued to insist on allying them with the cnidarians in the group Zoophyta.

Eventually (in 1820), French zoologist and anatomist H. M. D. de Blainville noted the complete gut of the bryozoans and "raised" them above the cnidarians. By 1831, two names had been coined for these animals—Bryozoa (by German zoologist Christian Gottfried Ehrenberg) and Polyzoa (by the Englishman J. Vaughan Thompson). Just about the time bryozoans were being recognized as a separate group (under one name or the other), concurrent events confused the issue further. The entoprocts (= Kamptozoa) were described, and most workers included them with the Bryozoa, while others recognized a relationship between bryozoans and other lophophorate phyla. All of this became terribly entangled in 1843 with Henri Milne-Edwards's concept of a taxon Molluscoides, which he established to include bryozoans and compound ascidians (chordates). Hatschek later raised Bryozoa and Entoprocta to distinct phylum ranking in 1891. The brachiopods were known, at least from fossils, in the 1600s and were allied with the molluscs. This mistaken view was held until late in the nineteenth century.

Phoronids were first described from their larvae in 1846 by German zoologist Johannes Müller, who thought they were adults and named them *Actinotrocha brachiata*. In 1854, Karl Gegenbaur recognized these animals as larval stages. The adults were found in 1856 and described by British physician and zoologist T. Strethill Wright, who named them *Phoronis*. Finally, in 1867 the renowned Russian embryologist Alexander Kowalevsky studied the metamorphosis of "Actinotrocha" and established the relationship between the two stages. To this day, the name "actinotroch" persists as a general term for the phoronid larva.

In 1857, Albany Hancock recognized the relationship between brachiopods and bryozoans, but the whole matter was mixed up with confusion over the entoprocts and Milne-Edwards's Molluscoides. Hinrich Nitsche made a valiant attempt in 1869 to separate the entoprocts and bryozoans, and in the 1880s Otis Caldwell and Thomas Masterman both put forth the idea of a close relationship between the three lophophorate phyla. This view was supported by Hatschek in 1888, when he suggested the establishment of a phylum Tentaculata to include the classes Phoronida, Bryozoa, and Brachiopoda (but excluding the entoprocts), thus establishing the grouping we recognize today as Lophophorata. Since that time several attempts to unite some or all of these animals into a single taxon have been made, including Anton Schneider's Lophophorata in 1902 (originally only for phoronids and bryozoans). Hyman (1959) retained separate phylum status for the three groups, an arrangement that has remained popular ever since.

In the recent past, some workers revived the idea of a possible entoproct-ectoproct affinity and argued that the two groups are closely allied with Cycliophora in a grouping called Polyzoa. However, this is not supported by the most recent large-scale phylogenetic work. An alliance between Bryozoa and Entoprocta can also be rejected on the basis of direct comparative grounds. Entoprocts do not possess the lophophore-epistome complex. Furthermore, they lack any vestiges of a coelom or trimeric body plan. The feeding currents are virtually opposite in the two groups, and the methods of food capture and transport are entirely different. Entoprocts possess ducted gonads, and bryozoans do not. Cleavage in entoprocts is spiral, whereas it is radial in bryozoans. Larval forms and particularly metamorphosis are clearly different in the two groups. Similarities such as budding and U-shaped guts are superficial and common to many colonial sessile animals. Thus, we conclude that Bryozoa and Entoprocta are distantly related protostomes, a conclusion supported by some recent molecular phylogenetic studies but not yet fully resolved. The name Ectoprocta is often used in lieu of Bryozoa, acknowledging the fact that the anus lies outside the lophophore ring, whereas in the Entoprocta it lies within the lophophore ring (and the mouth is on the rim carrying the tentacle crown).

The Lophophorate Body Plan

All lophophorates are built for benthic life and suspension feeding, the latter being a primary function of the lophophore itself. The anterior body region, or prosome, is reduced to a small flaplike structure called the epistome (lost in some lineages), which is associated with an overall reduction of the head, the elaboration of the mesosome as the lophophore, and a sessile lifestyle. The metasome houses the bulk of the viscera. The U-shaped gut is clearly advantageous for living encased in tubes, compartments, and shells; such animals do not "foul their nests," as it were. We have seen similar adaptations in some other groups with comparable habits, such as the recurved gut of sipunculans and the ciliated fecal-removal grooves of some tube-dwelling polychaetes. In lophophorates, this condition not only prevents fecal accumulation in the encasement, but generally brings the anus close to rejection currents produced by the cilia on the lophophore. In recent years, it has been shown that an epistome coelom (the protocoel) is absent in some phoronids and brachiopods, and all gymnolaemate bryozoans, whereas in phylactolaemate bryozoans there is an open connection between the epistomal cavity and the lophophoral coelom.

The phoronids most clearly display the mentioned traits and retain the vermiform shape of the probable ancestral form. Evolutionarily, bryozoans have exploited asexual reproduction, colonialism, and small size. Relieved of long-distance internal transport problems, the bryozoans have lost the circulatory and excretory systems. The brachiopods evolved a pair of valves or shells that encase and protect the body, including the lophophore. Thus, instead of exposing the lophophore in the water (as phoronids and bryozoans do), the brachiopods draw water into their mantle cavity for suspension feeding, an action analogous to that in bivalve molluscs. Sessile animals with soft parts (e.g., the lophophore), living on benthic surfaces, are exposed to potentially high levels of predation—thus the selective advantage of the brachiopod shell is clear. The phoronids are motile to the extent that their bodies can be swiftly retracted within their tubes, protecting the soft parts. Bryozoans are entirely anchored in their casings, but the lophophore itself is uniquely retractable into the body, as the result of a unique arrangement of muscles and hydraulic mechanisms.

Phylum Phoronida: The Phoronids

All phoronids occupy a cylindrical tube of their own secretion in which they can move freely. The animals typically occur in aggregations that, in some species, result from asexual reproduction. Their chitinous tubes are usually cemented to hard substrata or buried vertically in soft sediments (Figure 16.1; Box 16A). They are assigned to only two genera, *Phoronis* and *Phoronopsis*, of questionable monophyly, and around 15 widely distributed species. The phylum name was apparently derived from the Latin term *Phoronis*, the surname of Io (who, according to mythology, was changed into a cow and roamed the Earth, eventually to be returned to her former body). Recall that these worms were first described from larval stages drifting in the sea, and only much later were the adults recognized as part of the same life cycle. Adult phoronids are found in intertidal sands or mud flats, and to depths of about 400 m.

BOX 16A Characteristics of the Phylum Phoronida

1. Vermiform lophophorates with two or three coelomic cavities
2. Adult mesoderm derived from both embryonic ectoderm and endoderm
3. Body divided into flaplike epistome (prosome), lophophore-bearing collar (mesosome), and elongate trunk (metasome)
4. Gut U-shaped, anus close to mouth
5. One pair of metanephridia in metasome (trunk)
6. Closed circulatory system
7. Gonochoristic or hermaphroditic, with transient peritoneal gonads
8. With indirect life histories; usually with a unique actinotroch larva
9. Radial and spiral-like, indeterminate cleavage; coeloblastulae gastrulate by invagination; blastopore becoming mouth (protostomous)
10. Marine benthic tube dwellers

The Phoronid Body Plan

Most adult phoronids range from 1 to 25 cm in length. The vermiform body shows little regional specialization, except for the distinct lophophore and a modest inflation of the end bulb, which houses the stomach and also aids in anchoring the animals in their tubes. The slitlike mouth is located between the tentacle-bearing lophophoral ridges and is overlaid by a flap, the epistome. The lateral aspects of the ridges are distinctly coiled and flank the dorsal anus and paired nephridiopores (Figures 16.2 and 16.3). Using the terms "anterior" and "posterior" when referring to phoronids can be misleading. During metamorphosis, the true anterior (mouth-bearing) and posterior (anus-bearing) ends are brought very close together by rapid growth and enlargement of the ventral surface (Figure 16.4). The dorsal surface is reduced to the small area between the adult mouth and anus. Because of these conditions, we refer to the "ends" of the adult worm as the lophophoral end and the stomachic (= ampullar) end (Figure 16.1A).

Body Wall, Body Cavity, and Support

The phoronid body wall includes an epidermis of columnar cells overlaid by a very thin cuticle. Within the epidermis are sensory neurons and various gland cells (Figure 16.2A), the latter being responsible for the production of mucus and chitin for building the tube. The epidermis of the lophophore is densely ciliated. Internal to the epidermis and its basement membrane is a thin layer of circular muscle, some limited diagonal muscle, and a thick layer of longitudinal muscle that allows for fast retraction of the animal into its tube. A peritoneum lines the longitudinal muscles and forms the outer boundary of the coelom.

Although the coelom was long described as being tripartite, there is structural variation among species in the epithelial lining of the most anterior cavity, the "protocoel." Ultrastructural investigations have shown that the myoepithelial lining of the epistome lacks adherent cell junctions (a key component of true epithelial tissues) in at least two *Phoronis* species. However, adherent junctions are present in the myoepithelial lining of the epistome of *Phoronopsis harmeri*. True epithelial layers comprise the coelomic linings of the collar (mesocoel) and trunk

Dissociated cells at top are produced from the histolysis of hood tissues.

(metacoel) body regions in both *Phoronis* and *Phoronopsis*. Regardless of the validity of the protocoel as a true coelomic cavity, as an anatomical structure it is limited to a single small cavity within the epistome of only some species. The unpaired mesocoel comprises a coelomic ring in the lophophoral collar and extends into each tentacle (Figure 16.2B). The protocoel and mesocoel are connected to one another along the lateral regions of the epistome. The metacoel forms the main trunk coelom, which is separated from the mesocoel by a transverse septum. Ontogenetically, the metacoel is an uninterrupted cavity with only one midventral mesentery. However, secondary mesenteries form later in development, yielding four longitudinal spaces (Figure 16.2A). The coelomic fluid contains several kinds of freely wandering cells, or coelomocytes, including phagocytic amebocytes.

Body support is provided by the hydrostatic qualities of the coelomic chambers and by the tube. The muscles of the body wall are rather weak, particularly those in the circular layer, and once removed from their tubes, phoronids are capable of only limited movement. Normally, however, the body wall of the end bulb is pressed against the tube, holding the worm in place. When disturbed, the animal simply contracts into the tube; the lophophore itself is not retractable.

The tube is secreted by epidermal gland cells. When first produced, the chitinous secretion is sticky, but upon contact with water it solidifies to a flexible parchmentlike consistency. Sand grains and bits of other material adhere to the tube during the sticky phase of tube formation in those phoronids that inhabit soft substrata (e.g., *Phoronopsis harmeri*). In some species the tubes intertwine with one another, with the whole tangled aggregation attached to a substratum or actually embedded in calcareous stone or shells (e.g., *Phoronis hippocrepia*).

The Lophophore, Feeding, and Digestion

The tentacles of the **lophophore** are hollow, ciliated outgrowths of the mesosome, and each contains a blind-ended blood vessel and a coelomic extension (Figure 16.2B). The tentacles are in a double row, arising from two ridges, in a circle or a spiral as is *Phoronopsis californica* (Figures 16.1, 16.2, and 16.3). The ridges lie close to one another and form a narrow food groove in which the slitlike mouth is located (Figure 16.1C). Because the sides of the lophophoral ridges are coiled, many tentacles are compacted into a small area.

Phoronids are ciliary-mucus suspension feeders. The lophophoral cilia generate a water current that passes down between the two rows of tentacles and then out between the tentacles. Food particles are trapped in mucus lining the food groove and then passed along the groove by cilia to the mouth. As the current passes between the tentacles and out of the area of the food groove, some water flow is directed over the anus and nephridiopores away from the animal (Figure 16.1C).

The digestive tract is U-shaped, but simple and not coiled (Figure 16.2C). The mouth is overlaid by the epistomal flap and leads inward to a short buccal tube, which is followed by an esophagus and a narrow prestomach. Within the end bulb the gut expands into a stomach, from which emerges the intestine. The intestine bends up toward the lophophore and leads to a short rectum and the anus. The gut is supported by peritoneal mesenteries (Figure 16.2A).

The majority of the digestive tract is apparently derived from endoderm, except that the anus and the initial formation of the larval intestine are formed from an ectodermal invagination. Some parts are muscular, but only weakly so, and much of the movement of food is by ciliary action. A middorsal strip of densely ciliated cells arises in the prestomach and extends into the stomach, and it is probably responsible for directing food along that portion of the gut. Gland cells occur in the esophagus, but their function remains uncertain. Transitory syncytial bulges in the stomach walls are the sites of intracellular digestion in that organ.

Circulation, Gas Exchange, and Excretion

Phoronids contain an extensive circulatory system composed of two major longitudinal vessels between which blood is exchanged in the lophophoral and stomachic ends of the body (Figure 16.2D,E). Various names have been applied to these vessels, depending on their positions in the body. These terms are often confusing because the positions of vessels vary along the length of the trunk, and they are not clearly dorsal, medial, lateral, or ventral as the names imply. Therefore, preference is given here to the terms "afferent" and "efferent," which refer to the direction of a vessel's blood flow relative to the lophophore.

The afferent vessel extends unbranched from the region of the end bulb to the base of the lophophore. For most of its length it lies more or less between the descending and ascending portions of the gut. In the mesosome the afferent vessel forks, forming an afferent "ring" (U-shaped) vessel at the base of the lophophoral tentacles. A series of lophophoral vessels, one in each tentacle, arises from the afferent ring. Each of these vessels joins with an efferent "ring" vessel (also U-shaped), which drains blood from the lophophore. Thus, the afferent and efferent blood rings lie against one another, and they generally share openings into the lophophoral tentacles within which blood moves back and forth, as there is just a single vessel in each tentacle. One-way flap valves largely prevent backflow into the afferent ring.

The arms of the efferent ring unite to form the main efferent blood vessel, which extends through the trunk. This vessel connects with numerous branches or simple blind diverticula called capillary ceca, which bring blood close to the gut wall and other organs. In the end bulb, surrounding the stomach and first part of the intestine, blood flows from efferent to afferent vessels through spaces composing the **hemal** (**stomachic**) **plexus** (Figure 16.2D,E). Blood actually leaves the vessels here and flows through spaces between the organs and their bordering layers of peritoneum. Thus, technically speaking, the system is open at this point; however, blood flow is directed within the confines of these passages. Blood is moved through the circulatory system largely by muscular action of the blood vessel walls.

The intimate association of blood and the stomach wall suggests that nutrients are picked up from the stomach by the circulatory fluid and transported throughout

for more ebook/ testbank/ solution manuals requests: email 9781266734@qq.com

the body. The tentacles of the lophophore are also probably the most important sites of gas exchange. Oxygenated blood flows from the lophophore into the efferent vessel and is then distributed to all parts of the trunk. The blood contains nucleated red corpuscles, with hemoglobin as the respiratory pigment.

A pair of metanephridia lies in the trunk, and each bears two nephrostomes opening to the metacoel (Figures 16.2E and 16.3A). In each nephridium, the nephrostomes—one large and one small—join a curved nephridioduct, which leads to a nephridiopore adjacent to the anus. Although virtually nothing is known about excretory physiology in phoronids, particulate crystalline matter has been observed exiting the nephridiopores and probably represents precipitated nitrogenous waste products. The nephridia also function as pathways for the release of gametes. Osmoregulatory problems are presumably insignificant in subtidally occurring phoronid species. However, little is known about the osmotic challenges faced by those species inhabiting intertidal and/or estuarine habitats.

Nervous System

The nervous system of phoronids is rather diffuse and lacks a distinct cerebral ganglion. This condition is no doubt related to the sedentary lifestyle and overall reduction in cephalization in these worms. Most of the nervous system is intimately associated with the body wall, being either intraepidermal or immediately subepidermal. Throughout the body a layer of nerve fibers is present between the epidermis and the circular muscle layer. Simple sensory neurons project out from this layer, either singly or in bundles, and extend to the body surface as the only receptor structures. Motor neurons extend inward to the muscle layers.

The central nervous system includes a group of basiepidermal neuronal cell bodies concentrated between the mouth and the anus (the so-called dorsal "ganglion" or neural plexus) connected to a collar nerve ring, which lies at the base of the lophophore and is continuous with the basiepidermal nerve layer. A proposed shared character among the nervous systems of phoronids and bryozoans may be present in the smallest phoronid species, *Phoronis ovalis*, which has two anterior ganglia. One of these ganglia is similar to that of other phoronid species, but the second, inner ganglion may be morphologically similar to the cerebral ganglion of bryozoans, thus retaining a potential plesiomorphic character (since *P. ovalis* is likely to be the sister group to all other living phoronid species). The collar nerve ring connects with frontal and abfrontal nerves of the tentacles and also with motor nerves that innervate some of the longitudinal muscles in the metasome. In addition, a bundle of sensory neurons extends from the nerve ring to each of the lophophoral organs.

Phoronids possess one or two longitudinal giant motor fibers in the trunk (absent in *Phoronis ovalis*). When only one longitudinal fiber is present, it lies on the left side. This fiber actually originates within the right side of the nerve ring, through which it passes to emerge on the left side. This nerve fiber is intraepidermal except where it extends inward along the left nephridium. In those species where two longitudinal fibers are present, the right one originates on the left side of the nerve ring and extends to the opposite side of the body.

Reproduction and Development

Asexual reproduction by transverse fission or by a form of budding has been documented in a few species. Phoronids are also capable of regenerating lost body parts, and various parts of the lophophoral end are capable of autotomy.

Phoronids have benthic adults and planktotrophic larvae, although one, *Phoronis ovalis*, has creeping lecithotrophic larvae. Both gonochoristic and hermaphroditic species of phoronids are known, and in the latter case some are simultaneous hermaphrodites (e.g., *Phoronis ijimai*, = *P. vancouverensis*). Phoronids spawn their fertilized eggs or early embryos into the environment and most brood their embryos among the tentacles of the adults or inside the mother's tubes, although in some species the entire development occurs in the water column. Recently, one species, *Phoronis embryolabi* (which lives commensally in burrows of an axiid shrimp), has been shown to be potentially viviparous, which would result in females releasing fully developed larvae into the environment.

The gonads are transient and form as thickened areas of the peritoneum around the hemal plexus (Figure 16.2D). The resulting mass of gamete-forming tissue and blood sinuses is sometimes called vasoperitoneal tissue. Gametes proliferate into the metacoel and typically are carried to the outside via the nephridia. Fertilization is usually internal, as in *Phoronopsis harmeri* (= *P. viridis*). In this species, the male lophophoral organs produce elaborately shaped spermatophores (Figure 16.3C) that are transferred to the metanephridial opening or tentacles of the females. In these females the lophophoral organs are called **nidamental glands** and serve as brooding areas. The complicated internal fertilization process in *Phoronopsis harmeri* was elucidated by Russel Zimmer. Spermatophores contacting the nephridiopore release ameboid masses of V-shaped sperm, which travel down the metanephridial funnels into the base of the trunk coelom near the ovary. If a spermatophore contacts a female's tentacle instead, the sperm enter the lophophoral coelom by lysis of the tentacular wall and then proceed to digest their way through the septum separating the mesocoel and metacoel into the trunk coelom, where fertilization occurs. Although fertilization has not actually been observed,

Zimmer's experimental data, coupled with the fact that fertilized ova occur internally, suggest that this scenario is the likeliest explanation.

Developmental strategy differs among species, the particular pattern depending in part on the size of the egg and whether or not the embryo is brooded. The ova of broadcast-spawning species contain little yolk and develop quickly to planktotrophic **actinotroch larvae** (Figure 16.4). In species that possess nidamental glands, fertilization is followed by brooding until release at the actinotroch stage. The eggs of these species are moderately rich in yolk, providing nutrients for the embryos during the brooding period. *Phoronis ovalis* lacks nidamental glands, but the yolky eggs are shed into the maternal tube where they are brooded. Development in *P. ovalis* does not include a typical actinotroch; instead, the embryos emerge through the autotomized lophophoral end as ciliated, sluglike larvae that have a short, planktonic life. Based on the expression of some evolutionarily conserved transcription factors, there is support for the idea that the actinotroch is derived from a "head-larva".

Since their first description, the evolutionary affinities of phoronids have been debated, as some developmental and morphological characters seemingly support both a deuterostome and protostome (spiralian) origin. Early reports of spiral-like cleavage in species that broadcast-spawn smaller (~60 μm) eggs have been corroborated by confocal and 4-D time-lapse microscopy. In these species (e.g., *Phoronis pallida*) the embryos have oblique (rather than perpendicular) cell divisions at the third and subsequent cleavages, accompanied by alternating dextral-sinistral twists, as in typical spiral development, although the products of cell division are equal. Species with larger (~100 μm) eggs typically have radial cleavage (e.g., *Phoronis ijimai*). In both cases, a coeloblastula forms and gastrulates largely by invagination. Cell labeling and other embryological experiments show that some of the larval mesoderm is derived from ectodermal cells, especially where the ectoderm is in contact with the endoderm; the remaining mesoderm is derived from the endoderm. Furthermore, a portion of the blastopore forms the mouth. Along with these developmental and morphological features, molecular phylogenetic evidence supports the relation of phoronids to brachiopods and bryozoans as well as more typical spiralians such as annelids, nemerteans, and molluscs (i.e., the Lophotrochozoa).

As noted, all phoronids except *Phoronis ovalis* produce distinctive **actinotroch larvae** (Figure 16.4A,D). The fully formed actinotroch bears a preoral hood, or lobe, over the mouth. As the actinotroch develops, an inpocketing (called the metasomal or juvenile trunk sac) forms on the ventral surface. At settlement and metamorphosis this sac everts, extending the ventral surface such that the anus and mouth remain close to one another as the gut is drawn out into the characteristic U shape. As discussed previously the structure of the hood "coelom" of some *Phoronis* species varies and may obliterate late in larval development. However, the hood coelom of *Phoronopsis harmeri* apparently has a true epithelial lining, at least a portion of which may be carried over during metamorphosis to form the coelomic lining of the juvenile epistome. Metamorphic remodeling of the larva into the juvenile form varies somewhat among species, but, in general, the neural and muscular tissues of the hood undergo histolysis. In some species the larval tentacles are remodeled into the juvenile lophophore during metamorphosis (Figure 16.4), but in other species the larval tentacles are shed, and the initial juvenile lophophore forms from separate tentacle rudiments. All of these dramatic tissue rearrangements can occur in as little as 15–20 minutes, after which the juvenile worms begin to secrete their tubes.

Phylum Bryozoa: The Moss Animals

Bryozoa (Greek *bryon*, "moss"; *zoon*, "animal"), sometimes called Ectoprocta (Greek *ecto*, "outside"; *procta*, "anus"), comprise sessile colonies of zooids living in marine and freshwater environments (Box 16B; Figure 16.5). Most colonies are the product of budding from a single, sexually produced individual called an **ancestrula**, but colonies may also develop from various types of resting bodies. The colony form differs

BOX 16B Characteristics of the Phylum Bryozoa

1. Organisms always colonial, with zooids developing through budding from a metamorphosed larva or from existing zooids
2. Each zooid consists of a polypide, which can be retracted into a cystid
3. Polypide composed of a ciliated tentacle crown used in suspension feeding, a U-shaped gut, a simple nervous system, and various muscles associated with extension and retraction into the cystid
4. Cystid wall consists of an extracellular gelatinous or chitinous cuticle, with a calcified basal layer in some groups, the epidermis, and the peritoneum; various types of muscles associated with the body wall
5. There are no discrete circulatory or excretory organs
6. Zooids are hermaphroditic in many species, but some species have male and female zooids within the same colony; gametes differentiate from transient patches of the body wall peritoneum or the funiculus
7. Cleavage radial and holoblastic; development indirect with planktotrophic cyphonautes larva or with lecithotrophic coronate or shelled larva; all internal larval organs degenerate after settling
8. Mostly sessile (a few colonies are movable or float) in marine or freshwater habitats

greatly among species, and the bushy species were earlier treated as plants, so specimens can be found in older herbariums. Each zooid typically consists of a **polypide**, with a tentacle crown and the gut. These can be retracted into a **cystid**, which is the body wall of the individual zooid or the wall that is common to several zooids (Figure 16.6). Marine bryozoans are known from all depths and latitudes, mostly growing on or attached to solid substrata. A few species form free colonies that creep on the bottom (see Figure 16.8E). An Antarctic species forms gelatinous colonies on floating pieces of ice. A few species occur in fresh and brackish water. Large gelatinous colonies of *Pectinatella magnifica* are frequently encountered in streams and ponds in North America east of the Mississippi River. Meter-large floating colonies of the same species occur in Lake Shoji in Japan, where they are called *ojassie* (Figure 16.5L). Marine littoral regions in most parts of the world harbor luxuriant growths of bryozoans that often cover large areas of rock surfaces and algal fronds. Some species have coral-like growth forms that can create miniature "reefs" in shallow-water habitats. Others form dense bushlike colonies or gelatinous spaghetti-like masses. Many encrusting forms grow on the shells or exoskeletons of other invertebrates, and some bore into calcareous substrata. Most members of the gymnolaemate family Hippoporidridae grow on mollusc shells inhabited by hermit crabs, where evidence suggests a mutualistic relationship between the bryozoans and the crustaceans. Two classes are recognized here, Phylactolaemata and Gymnolaemata, and this is supported both by morphological and phylogenomic studies, but some authors treat the Stenolaemata as a third class. The fossil record suggests that the cheilostomes evolved from stem-group ctenostomes. About 6,300 living species are recognized, and there is a rich fossil record going back to the Early Ordovician.

CLASSIFICATION OF PHYLUM BRYOZOA

CLASS GYMNOLAEMATA Mainly marine bryozoans. Colonies with chitinous or calcified cystids; in calcified species, the cystid walls are primarily calcium carbonate, often with aragonite on the outer surface of the frontal walls; zooids rather small, monomorphic in some species, but especially the cheilostomes show several types of heterozooids; tentacle crowns circular or slightly oblique.

SUBCLASS EURYSTOMATA A highly diverse group of almost exclusively marine bryozoans. Colony form is extremely variable, soft or calcified, encrusting to arborescent; body wall lacks a continuous layer of muscles; zooids variably modified from basic cylindrical form; zooids joined by pores through which cords of tissue extend (the stolonal funiculus) and join with their neighbor's funiculus.

ORDER CTENOSTOMATA Colonies vary in shape from forms with hydroidlike individual zooids developing from free or creeping stolons to compact colonies; skeleton leathery, chitinous, or gelatinous, not calcified; openings through which tentacle crowns protrude lack operculum; zooids generally monomorphic. (e.g., *Aethozoon, Alcyonidium, Amathia, Bowerbankia, Flustrellidra, Nolella, Victorella*)

ORDER CHEILOSTOMATA Colony form varies, but generally of box-shaped zooids with calcareous walls; orifice with operculum; zooids often polymorphic; embryos usually develop in various types of brooding structures. (e.g., *Bugula, Callopora, Carbasea, Cellaria, Conopeum, Cornucopina, Cribrilaria, Cryptosula, Cupuladria, Electra, Eurystomella, Flustra, Hippothoa, Integripelta, Primavelans* (formerly *Hippodiplosia*), *Membranipora, Metrarabdotos, Microporella, Pentapora, Porella, Pyripora, Rhamphostomella, Schizoporella, Selenella, Thalamoporella, Tricellaria*)

SUBCLASS STENOLAEMATA Largely extinct; only surviving subgroup is Cyclostomata. Exclusively marine. Polypides housed in tubular, calcified skeletal compartments; zooids cylindrical or trumpet shaped, rarely polymorphic; each polypide surrounded by a coelomic sac, where the inner wall covers the gut, whereas the outer wall is free, forming the unique, so-called membranous sac, which consists of the coelomic epithelium, a series of tiny ring-shaped muscles, and a basal membrane; the body cavity outside the membranous sac, the exosaccal cavity, is continuous throughout the colony, either through small interzooidal pores or through larger common cavities; funiculus inside the coelomic cavity, not connecting neighboring zooids; reproduction involves specialized female zooids in which the fertilized egg develops through polyembryony, such that the embryos in a gonozooid are a clone. (e.g., *Actinopora, Crisia, Diaperoecia, Disporella, Hornera, Idmodronea, Tubulipora*)

CLASS PYLACTOLAEMATA Freshwater bryozoans. Colonies with chitinous or gelatinous cystids; zooids cylindrical, large, and monomorphic; tentacle crown large and usually horseshoe shaped; body wall muscles well developed; body cavity of the zooids in open connection throughout the colonies; a cord of tissue, the funiculus, extends from the gut to the body wall, but not between zooids; most produce asexual resting bodies called statoblasts. (e.g., *Cristatella, Hyalinella, Lophophus, Lophopodella, Pectinatella, Plumatella*)

The Bryozoan Body Plan

Bryozoan specialists have developed a complicated terminology, especially concerning the morphology of the cystids, and some terms have, quite confusingly, been given various definitions. Early workers mistakenly thought that bryozoan zooids were actually

composed of two organisms, the skeletal outer wall and the internal soft parts, which they named the cystid and polypide, respectively. These terms were redefined by Hyman (1959) and now have good meaning relative to the functional morphology of bryozoans. The **cystid** comprises the outer body wall—that is, the nonliving and living housing of each zooid. The **polypide** includes the **tentacle crown** (the lophophore) and soft viscera that can be protruded and retracted from the cystid (Figure 16.6). The opening in the cystid through which the tentacle crown extends is termed the **orifice** and bears a flaplike, chitinous covering, or operculum, in the cheilostomes.

The nature of the body wall differs among bryozoans, as does the form of the colony. It is entirely gelatinous or chitinous in the Ctenostomata and Phylactolaemata, but it has an inner calcified layer called the **zoecium** in the Cheilostomata and Cyclostomata (Figure 16.7). Many studies are based on colonies that have been cleaned of all organic material so that the specific characters of the calcified and often highly ornamented zoecia can be studied.

The Gymnolaemata include a bewildering array of colonial forms (Figure 16.5A–I). Some of the ctenostomes have colonies in which the zooids arise from runners or stolons on the substratum (e.g., *Triticella*, *Bowerbankia*). This apparently represents the ancestral gymnolaemate pattern as suggested by the fossil record. In the other forms, the zooids are more or less closely packed, with pores between neighboring zooids. These colonies may be sheet shaped and encrusting on stones or algae, erect and leaf shaped or arborescent, or in a few cases discoidal and free-living.

In addition to the variation in overall form among the colonies, zooids of many cheilostomes and some cyclostomes are polymorphic within a colony. Typical tentacle-crown-bearing, feeding zooids are called **autozooids**. The widespread *Membranipora* normally consists only of autozooids. Most other colony types have both the normal autozooids and various types of nonfeeding zooids, called **heterozooids**. Among these, **kenozooids** are reduced individuals modified, for example, for attachment to a substratum; various types of attachment discs, "holdfasts," and stolons are in this category. Many cheilostomes possess heterozooids called **avicularia**, each of which bears an operculum modified as a movable mandible (or jaw), which articulates against a rigid extension of the body wall called the **rostrum** (Figure 16.8). Some avicularia occur in the general layer of zooids, while others are large and situated at the side of the branched colonies (Figure 16.8D), but a much more common type is smaller and situated on the frontal wall or on the ovicells. A special type of avicularium is the pedunculate or bird's-head avicularium, which looks like the head of a parrot; it is attached to the colony through a stalk and able to perform nodding movements (Figure 16.8B,C). Avicularia, which were first described by Charles Darwin in 1845 based on observations of a bugulid made aboard the *Beagle*, probably function primarily to defend the colony against small organisms and keep the surface clean of debris.

Another type of heterozooid is the **vibraculum** (Figure 16.8A,E), which is thought to be a modified avicularium, with a flagellum-like operculum that sweeps over the colony surface. Vibracula may help remove sediment particles and other material, but convincing evidence for this function is wanting. In the free-living, discoidal cheilostomes, such as *Selenella* and *Cupuladria*, the vibracula are used in locomotion (Figure 16.8E).

Most members of the Phylactolaemata display either plumatellid or lophopodid colony forms (Figure 16.5K,L). **Plumatellid** colonies are erect or prostrate and often highly branched, like *Plumatella*. In **lophopodid** colonies, the gelatinous body wall forms the surface of irregular clumps from which the tentacle crowns protrude, as seen in *Pectinatella* and *Lophophus*. The colonies of the remarkable *Cristatella* are gelatinous, sluglike, and capable of locomotion, gliding over the substratum powered by the action of the cilia of the tentacle crown.

The Body Wall, Coelom, Muscles, and Movement

The body wall comprises the outer secreted body wall, the underlying epidermis, and the peritoneum. The outer body wall may be uncalcified or have a strong calcified inner layer (the zoecium). Sheets of circular and longitudinal muscles are present between the epidermis and peritoneum in phylactolaemates, but these muscle sheets are specialized in the other groups to form various groups of separate muscles.

Many bryozoans possess ornate and species-specific surface sculpturing including spines, pits, and protuberances. Experiments indicate that the cheilostome *Membranipora membranacea* undergoes a rapid growth of new protective surface spines after being grazed by predatory nudibranchs. Some bryozoans also produce chemicals used as defense against would-be predators. These chemicals are probably all synthesized by symbiotic bacteria.

The mechanisms of polypide retraction and extension (protraction) differ among bryozoan species. The specific mechanism depends largely upon the arrangement of muscles, the degree of rigidity of the cystid, and the morphology of the coelomic compartments, which function as a hydrostatic skeleton (see Figure 16.6).

In all bryozoans, the main coelom provides a fluid-filled space with muscles acting directly or indirectly to increase hydraulic pressure for extension of the polypide. Thus, when the coelom is compressed, the polypide is partially forced out of the cystid, thereby extending the tentacle crown. The retractor muscles, which originate at the basal part of the cystid wall and insert on the thickened basal membrane surrounding the mouth, serve to pull the polypide back within the cystid. Generally, the methods of polypide extension are common to all bryozoans, but the muscle groups involved differ considerably in their morphology. Here we describe a few examples of how these movements are accomplished and, at the same time, illustrate variations on the basic bryozoan body plan.

The phylactolaemates show the simplest mechanism. They extend their polypides by contracting the muscles of the flexible body wall around the common body cavity. This action imposes pressure directly on the coelomic fluid and is similar to the mechanism seen in many other coelomate animals. These bryozoans possess a ring-shaped, muscular diaphragm just internal to the orifice through which the tentacle crown protrudes. The diaphragm relaxes as the tentacle crown is protracted and serves to partially close off the orifice when the tentacle crown has been withdrawn by retractor muscles (Figure 16.6E).

Ctenostomes possess an uncalcified, flexible body wall composed of gelatinous, chitinous, or leathery material. Contraction of transverse parietal muscles pulls the cystid walls inward, thereby causing an increase in

coelomic pressure that then extends the tentacle crown (Figure 16.6B). Retraction of the tentacle crown is accomplished by the usual retractor muscle, which is aided by longitudinal parietal muscles that pull in the atrial chamber. When the tentacle crown is fully retracted, a sphincter contracts to close the orifice and, in some species, fold a pleated collar over the end of the zooid.

Cheilostomes and cyclostomes show many intricate variations in the method of polypide extension and retraction, but they all rely on the constant volume of the coelom, which functions as a hydrostatic skeleton.

Cheilostomes have cystids that are calcified to various degrees. A completely stiff body wall would make polypide movements impossible, so various areas of the cystids are uncalcified and can be moved in or out by groups of special muscles of the body wall. In most species, the zooids are more or less boxlike (rather than erect or tubular). The outer surface of the box that bears the orifice is called the frontal surface. It has a partly uncalcified and flexible part called the **frontal membrane**, and contraction of parietal protractor muscles pulls the frontal membrane inward, thus increasing coelomic pressure and pushing out the polypide (Figure 16.6C). There are, of course, variations on this general theme. An operculum closes over the orifice when the polypide is retracted, but the exposed frontal membrane presents a weakness in the defense against predation, and many species have evolved more or less complicated protective structures (Figure 16.9). Some forms, known as the **cribrimorphs**, bear hard spines that project over the membrane and in some cases actually meet and fuse to form a cage above the vulnerable area (Figure 16.7C). In others a calcified partition, called the frontal shield or **cryptocyst**, lies beneath the frontal membrane, separating it from the soft parts within. The cryptocyst bears pores through which the protractor muscles extend (Figure 16.9). The most drastic modifications are seen in the so-called **ascophoran** type (Figure 16.9), in which the frontal wall is heavily calcified except for a small pore below the orifice. This opening, the ascopore, leads into the invaginated sac-shaped frontal membrane, called the **ascus**. The parietal muscles insert on the ascus. Cheilostomes are the most diverse and species-rich group of bryozoans.

Cyclostomes have erect, tubular zooids surrounded by heavily calcified zoecia (Figure 16.6D). The inflexibility of the body wall and the absence of well-developed sheets of muscles preclude use of direct compression, so they have evolved a mechanism of polypide protraction unique among the bryozoans. The structural features associated with this mechanism comprise a synapomorphy on which this group was established as a separate subclass. The key structure is the membranous sac, which is the detached peritoneum of the cystid wall plus its basal membrane and a series of tiny ring muscles. It is attached by ligaments to the body wall and separates the coelom from the outer exosaccal cavity. Distally, the

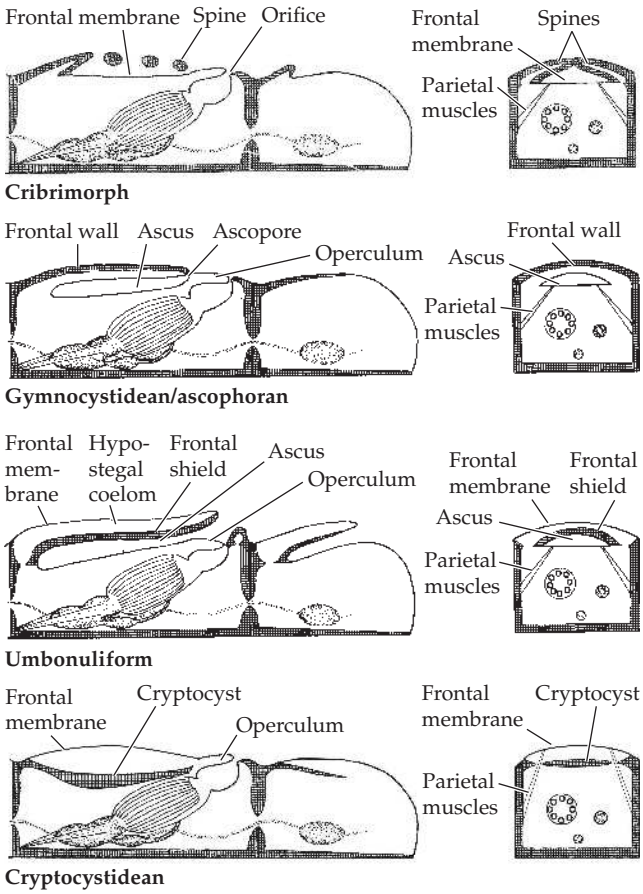

FIGURE 16.9 Frontal walls. Diagrams of four different types.

exosaccal space harbors a series of fine atrial dilator muscles. Protraction of the polypide involves relaxation of the retractor and atrial sphincter muscles and contraction of the atrial dilators and the ring muscles of the membranous sac. With the constant volumes of both the coelom and the exosaccal cavity, the polypide is squeezed out. When a zooid is retracted by the large retractor muscles, the atrial dilators are relaxed and a special atrial sphincter effectively closes the inner end of the atrium.

Zooid Interconnections

As discussed in Chapter 4, clear definitions of the term "colony" are sometimes elusive. This difficulty arises because it is not always easy to tell where one individual ends and another begins, or because the degree of structural and functional communication among individuals is uncertain or variable. Bryozoan zooids, at least autozooids, are clearly demarcated by the elements of the polypide (tentacle crown, gut, ganglion, and so on); however, the way in which the zooids are interconnected differs among groups.

In phylactolaemates the coelom is continuous among zooids, uninterrupted by septa (Figure 16.6E). Each zooid bears a tubular tissue cord called a **funiculus**

for more ebook/ testbank/ solution manuals requests: email 9781266734@qq.com

that extends from the inner end of the curved gut to the body wall. All other bryozoans lack extensive coelomic connections, and the zooids are separated by various sorts of structural components.

Stoloniferous Eurystomata (e.g., *Bowerbankia*; Figure 16.6B) have septa spaced along the stolons between the zooids. A cord of tissue passes along the stolons and through pores in each septum. This cord, called a **stolonal funiculus**, connects with the funiculus of each zooid arising from the stolon. In most nonstoloniferous Eurystomata the cystid walls of adjacent zooids are penetrated by pores with tissue plugs, which, again, usually connect with the funiculus of associated zooids. In the cheilostomes the pores are covered by pore plates with a number of small openings.

The walls of adjacent zooids of cyclostomes bear interzooidal pores or common distal cavities that allow communication of exosaccal coelomic fluid (Figure 16.6D). The funiculus is contained within the coelom with the rest of the viscera and attaches the gut to the body wall. The exchange of nutrients between zooids, for example, between the feeding autozooids and the nonfeeding gonozooids, remains a mystery.

It is clear that bryozoan zooids are interconnected structurally, either by direct sharing of coelomic spaces or by funicular tissue, except for the enigmatic cyclostomes. Functionally, these connections provide a means of distributing materials through the colony, and perhaps they serve in other communal activities as well. Other special functions of the funiculus are discussed later in the chapter.

The Tentacle Crown, Feeding, and Digestion

The tentacle crown (which is a lophophore) is horseshoe shaped in the phylactolaemates (except for *Fredericella*) and circular in the gymnolaemates and cyclostomes. The tentacles are ciliated, with the cilia arranged in characteristic bands related to the feeding mechanism. Bryozoans are suspension feeders, although supplemental methods may also be used. They feed largely on protists, but some species are able to capture and ingest larger organisms.

Upon extension, the tentacles of the circular tentacle crowns of gymnolaemates and cyclostomes are erected in a funnel or bell-shaped arrangement around the mouth. Each tentacle bears four or five ciliary bands along its length, one frontal tract (lacking in the cyclostomes), and a pair of laterofrontal and lateral bands (Figure 16.10). During normal suspension feeding, the lateral cilia create a current that enters the open end of the funnel, flows toward the mouth, and then exits between the tentacles. Some food particles are carried directly to the area of the mouth by the central flow of water. Other potential food, however, moves peripherally with the current toward the intertentacular spaces. When a particle contacts the rather stiff laterofrontal cilia, a tentacle flick is initiated, moving the particle toward the central current (Figure 16.10E). Additional flicks may occur if particles have not reached the central current. A localized reversal of power stroke direction is initiated in the lateral cilia, and the particle may be tossed onto the frontal edge of the tentacle. The particle is repeatedly bounced in this fashion and is moved toward the mouth under the influence of a current generated by the frontal cilia.

Many bryozoans supplement suspension feeding by various means that allow them to capture relatively large food particles, including live zooplankton. Some species, such as *Bugula neritina*, are capable of trapping zooplankton or large algae by folding their tentacles over the prey and pulling it to the mouth. A number of bryozoans rock or rotate the entire tentacle crown, apparently sampling reachable water for food.

All the polypides in a colony transport water toward the surface of the colonies. This is no problem for branching, bushy types, but in colonies forming larger sheets the water must flow away again, and this has led to the formation of various types of **excurrent chimneys**. Polypides may simply bend away from a small area, which then creates a chimney. Large colonies of *Membranipora* show regularly spaced areas without polypides, which function as excurrent chimneys (Figure 16.11A). Other chimneys may be formed by small groups of nonfeeding male zooids or pregnant zooids with degenerated polypides. In leaf-shaped colonies (e.g., *Pentapora*), the leaf edges may function as excurrent areas (Figure 16.11B). The generation of strong excurrent water flow away from the colony surface helps to push nonfood material and feces far enough to reduce the possibility of recycling. Such currents, which move larger amounts of water over the tentacle crowns than could be moved by individual zooids, may be especially important to colonies inhabiting quiet water.

The digestive tract is U-shaped (Figures 16.6B,C and 16.12). The mouth lies within the tentacle ring, and in the Phylactolaemata it is overlain by an **epistome**. Cilia around the mouth keep the captured particles rotating in front of the mouth, and from time to time the mouth is opened, and in the gymnolaemates the particles are sucked into the triradiate pharynx by contraction of the radiating epitheliomuscular cells (Figure 16.6F). A valve separates the lower end of the pharynx from the descending portion of the stomach, which is called the **cardia** and in some species is modified as a grinding gizzard. The cardia leads to a central stomach from which a large cecum arises; the funiculus attaches to the bottom of the cecum. The ascending portion of the stomach, or **pylorus**, arises from the central stomach and leads to a proctodeal rectum and the anus, which lies outside the tentacle crown ring. A sphincter controls the flow of material from the pylorus to the rectum. The phylactolaemates have a flat, funnel-shaped, ciliated pharynx without radiating muscles, and the hindgut is elongated as an intestine.

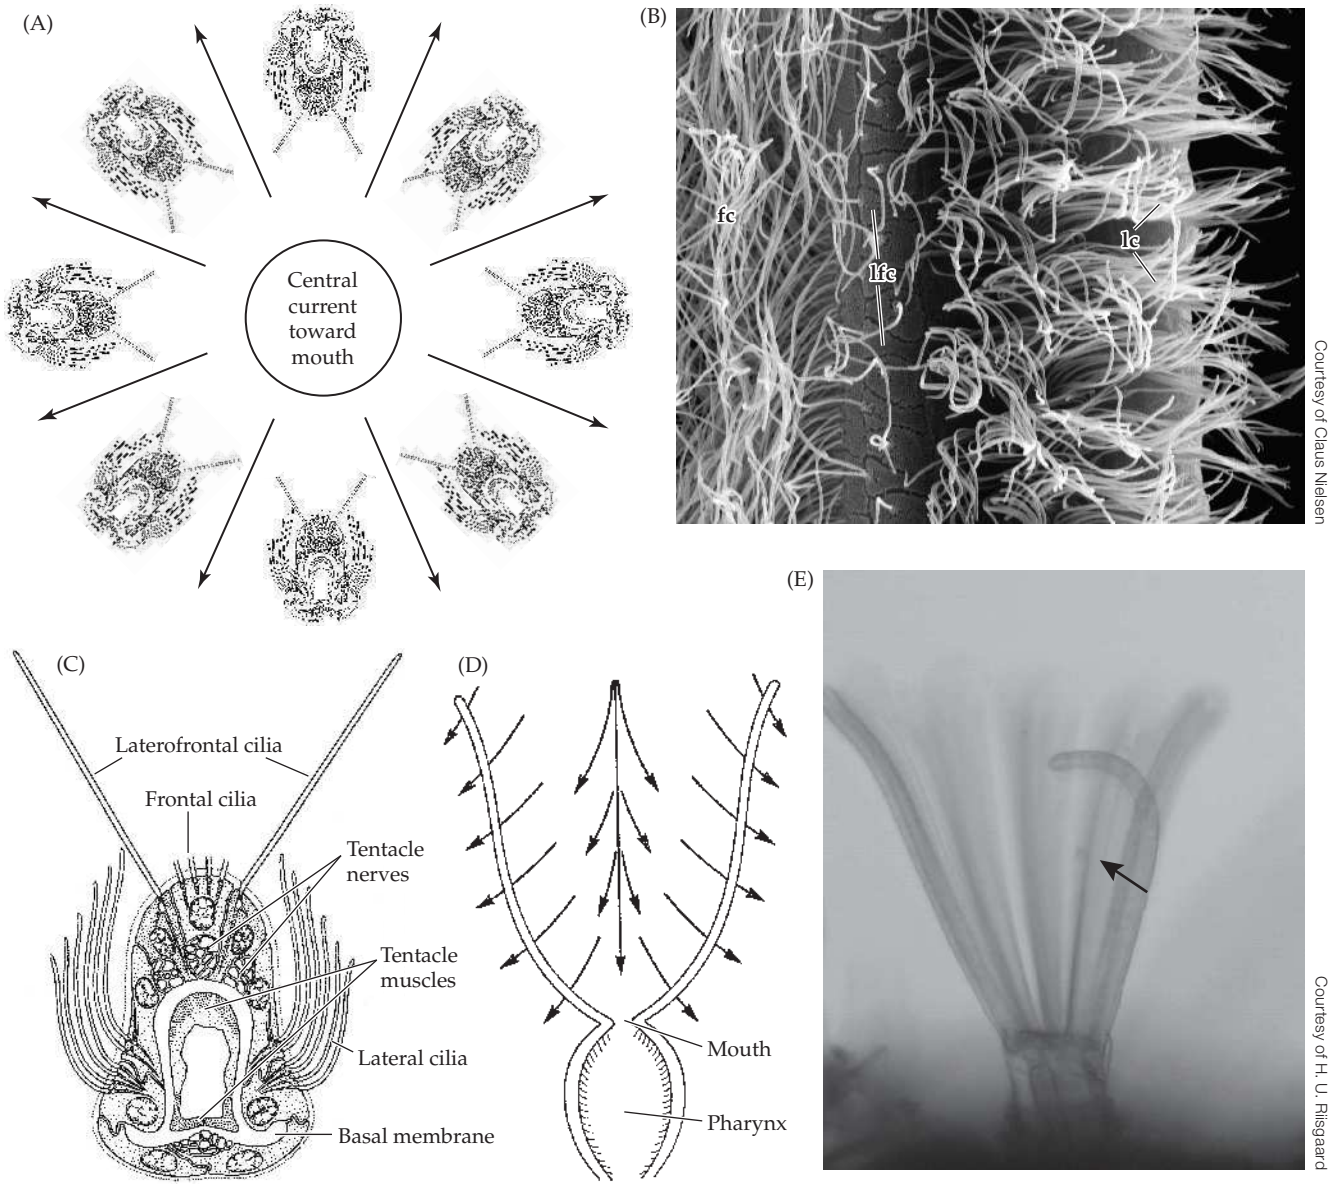

FIGURE 16.10 Tentacles and filter feeding. (A) Diagram of transverse section of a tentacle crown; the directions of the water currents set up by the lateral cilia are indicated. (B) SEM of one side of a tentacle of *Flustrellidra* with the three ciliary bands: frontal cilia (fc); lateral cilia (lc; note the metachronal waves); laterofrontal cilia (lfc, unnaturally curved due to fixation). (C) Transverse section of a tentacle of *Electra* (based on TEM). (D) Diagram of ciliary currents set up by the lateral cilia. (E) Tentacle flick. Note the small alga (arrow) that has just been pushed into the central current.

Digestion begins extracellularly in the cardia and central stomach, and it is completed intracellularly in all parts of the stomach. Food is moved through the gut by peristalsis and cilia. Undigested material is rotated and formed into a spindle-shaped mass by the cilia of the pylorus and then passed to the rectum for expulsion.

Circulation, Gas Exchange, and Excretion

There is no structural circulatory system in bryozoans, so movement of metabolites within single zooids is by diffusion. Given the small size of these animals, intrazooid diffusion distances are small, and the coelomic fluid provides a medium for passive transport. Interzooid circulation is facilitated by the common coelom in phylactolaemates, the cystid pores in cyclostomes, and the funicular cords of most Eurystomata. Gas exchange occurs across the walls of the extended parts of the polypide, particularly the tentacle crown. Bryozoans contain no respiratory pigments, and gases are carried in solution.

Nondigested particles and waste products accumulate in the cells of the stomach. The elimination of these wastes is not fully understood, but apparently it occurs at least in part by the cyclic degeneration of the polypides that form structures called **brown bodies**. New

FIGURE 16.11 Excurrent chimneys. (A) *Membranipora*; the dark areas of empty cystids form the excurrent chimneys. (B) Diagram of a cross section of four leaves of a colony of *Primavelans* (formerly *Hippodiplosia*) showing the incoming currents set up by the tentacles (medium arrows), the currents along the colony surface below the tentacles (short arrows), and the excurrents (long arrows) at the edge of the leaves.

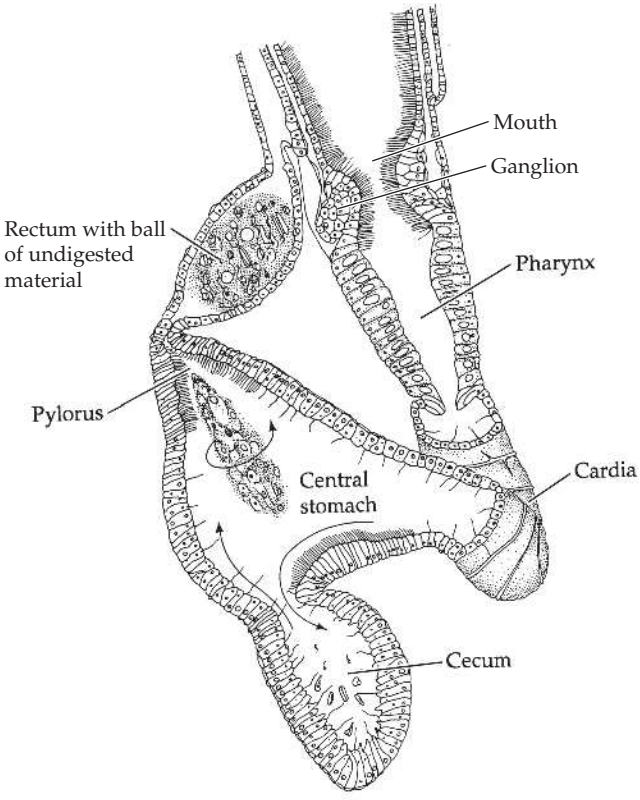

FIGURE 16.12 The gut of *Cryptosula*. The ingested particles rotate in the stomach and the rectum.

polypides are then formed through the usual budding process from the area of the orifice. In some Eurystomata the brown body is left within the basal part of the cystid, and the number of regenerated polypides can be assessed by the number of brown bodies. In other species, the brown body is taken up into the gut of the developing polypide and expelled as the first fecal pellet when the new polypide first protrudes from the cystid. In most stoloniferous ctenostomes, the old cystid with its brown body drops from the colony, and an entire new zooid regenerates from the stolon. In all cases, it is presumed that metabolic wastes are precipitated and concentrated in the brown bodies and thus eliminated or at least rendered inert.

Nervous System and Sense Organs

In concert with the sessile lifestyle and the lack of a discrete head in bryozoans, the adult nervous system and sense organs are predictably reduced. A neuronal mass, or cerebral ganglion, lies on the anal side of the pharynx (Figure 16.6B,C). Arising from this structure is a circumoral nerve ring. Nerves extend from the ring and ganglion to the viscera, and motor and sensory nerves extend into each tentacle. Interzooidal nerve fibers have been reported in some species, but their function remains unclear. The only known receptors are tactile cells on the tentacles (the laterofrontal ciliary cells [Figure 16.10B,C] and single cells on the abfrontal side) and on the sensory papilla of the avicularia (Figure 16.8B). The Eurystomata larvae have an apical organ, which supposedly is sensory, and a ciliated **pyriform organ** that is used in testing the substratum before settling. At least some bryozoans exhibit a marked negative geotaxis prior to settling. Experiments suggest that this geotaxis is a direct response to gravity, but the mechanism mediating this phenomenon is unknown. Many of the coronate

(A) Uncleaned with the outer periostracum and the opercula retained. (B) Cleaned zoecium of a similar part of the colony; kenozooid (ke). (C) Diagram of a median section of a female and a "male" zooid. (D) Part of a colony with rows of female and "male" zooids; the upper labeled ovicell (ov) is newly formed and still empty, and large cherry-red eggs can be distinguished in the body cavity of the females; the lower ovicell contains a newly deposited egg. (E) SEM of newly released larva (note heavy ciliation). (F) The composite ancestrula with one zooid with protruded tentacles and three developing zooids.

larvae have well-developed ocelli and are positively phototactic while free swimming. Settlement is often accompanied by a shift to a negative phototaxis.

Reproduction and Development

Sexual reproduction Bryozoan colonies are hermaphroditic. Some species may produce sperm and eggs in the same zooid (e.g., *Membranipora*), whereas other species (e.g., cyclostomes) have colonies with separate male and female zooids of very different shapes. Rather diffuse ovaries usually arise from transient patches of the peritoneum on the cystid wall. Testes usually develop on the funiculus (Figure 16.6C). Sperm differentiates in the body cavity, and the ripe sperm move to the coelom at the base of the tentacles and are eventually shed through small temporal pores at the tips of the abfrontal tentacles. The sperm enter the body cavity of a zooid with a ripe egg, probably through the supraneural pore located between the bases of two abfrontal tentacles, or the intertentacular organ, to fertilize the eggs. The few cheilostomes and ctenostomes that spawn fertilized

eggs into the water (e.g., *Electra*, *Membranipora*, *Hislopia*, and some species of *Alcyonidium*) have the supraneural pore elevated on a pedestal called the **intertentacular organ** (Figure 16.6A). However, most species brood the eggs in more or less elaborate structures.

Phylactolaemates brood their embryos in embryo sacs produced by invaginations of the body wall. The eggs may leave the supraneural pore and become implanted into the embryo sacs in a method like that observed in ctenostomes (e.g., *Victorella*), but the process has not been observed.

Some ctenostomes (e.g., *Triticella*) attach the eggs to the atrial wall so that they become freely exposed when the polypides protrude. Others (e.g., *Victorella*) deposit the fertilized egg into a brood pouch formed by the atrial wall, and a further specialization is that the fertilized eggs are retained in the retracted atrium where the whole development takes place while the polypide degenerates (e.g., *Bowerbankia* and species of *Alcyonidium*).

A variety of brooding methods occur among cheilostomes, usually involving the formation of an external brooding structure called an **ovicell** (Figures 16.6C, 16.7A,B, 16.13A–D, and 16.14A). In many genera (e.g., *Fenestrulina*, *Primavelans*, and *Tegella*), the developing female zooids induce the developing distal zooid (male or female) to produce an ovicell by a specialization of the proximal part of the frontal wall (Figure 16.13A–D). Some species deposit a very large egg into the ovicell, where the development to the free-swimming lecithotrophic larval stage takes place. The opening is usually covered by the operculum of the maternal zooid. Other species desposit a small egg into the ovicell, which is closed by an extension of the distal wall of the maternal polypide. This extension is called the **oecial vesicle** and functions as a placenta that nourishes the developing embryo (e.g., *Bugula*) (Figure 16.14A).

Bryozoans undergo radial, holoblastic, nearly equal cleavage to form a coeloblastula or a stereoblastula. Subsequent development differs greatly among groups, but in all cases it involves a free-swimming dispersal form. Very little solid information exists on the derivation and fates of germ layers in bryozoans. This is especially true for mesoderm and coelomic linings.

In phylactolaemates, the fertilized egg enters a brood sac formed from the cystid wall, and later stages receive nourishment from the maternal zooid through various types of placentas. The coeloblastula develops into a cystidlike stage lacking endoderm and then generates one or more polypides through a normal budding process. This "larva" is ciliated and escapes the embryo sac for a short swimming life before settling and metamorphosing.

The coeloblastulae of Eurystomata undergo a gastrulation where four cells divide and one of each pair of daughter cells is shunted to the blastocoel as presumptive endoderm and mesoderm. Free-swimming larvae are eventually produced. Most of the species that free spawn have a characteristic laterally compressed, triangular larva called a **cyphonautes**, which

(C–E) Larva, settling, and metamorphosis. (C) Median section of the larva. (D) The adhesive sac is everted in contact with the substratum, and a fine pellicle has been secreted; the everted pallial epithelium covers the upper side of the ancestrula, and the corona has become internalized. swims by means of a ring of cilia at the "lower" edge of the triangular shells (Figure 16.15A,B). This larval type is found in both basal ctenostome and cheilostome groups. These larvae feed by means of the U-shaped ciliated ridge, which resembles and functions like one side of an adult feeding tentacle. They have a complete gut and may remain in the plankton for months, whereas the larvae of brooding species lack a digestive tract and lead very short, pelagic lives

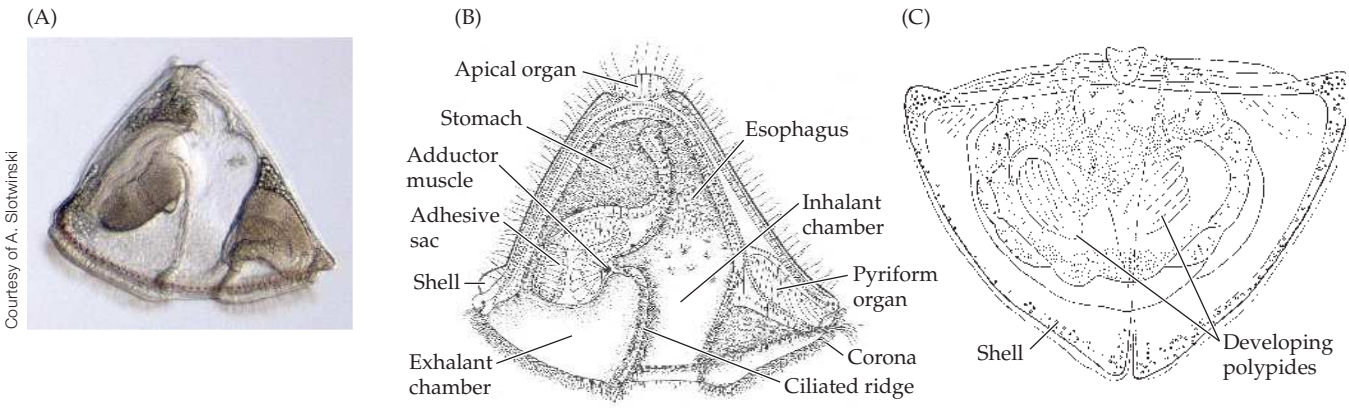

FIGURE 16.15 Larvae of *Membranipora*. (A) Cyphonautes larva. (B) Diagram of the morphology of the cyphonautes larva. (C) Newly settled larva; the shells are still covering the young ancestrula, which is developing a pair of polypides.

(Figures 16.13E and 16.14B). These more or less globular larvae are called **coronate larvae**, because the ciliation that covers almost the whole body is believed to be the extended ciliary ring of the cyphonautes larva. Despite these differences, Eurystomata larvae have some fundamental similarities. For example, they possess a complicated apical organ, a sensory pyriform organ complex, and a pouchlike **adhesive sac**, which are important in settling and metamorphosis (Figures 16.13E, 16.14B, and 16.15B).

In the cyclostomes, each colony contains only one or a few female zooids. When the small female zooid has become fertilized, its tentacles degenerate, and the zooid grows to a large, pear-shaped (Fig. 16.5G) or irregular **gonozooid**, nourished by the neighboring autozooids. The fertilized egg cleaves to form a ball of cells, which then undergoes a budding process, forming secondary embryos, which in turn bud tertiary embryos. Dozens of small, solid, asexually produced embryos may result from a single primary ball of cells. This phenomenon, called **polyembryony**, is very unusual in the animal kingdom. Each embryo develops cilia and escapes as a completely ciliated larva with an invagination at both poles, one representing the apical organ/pole and the other being the adhesive sac. The larva settles after a short free period and undergoes a metamorphosis similar to that described for the coronate Eurystomata larvae, with the frontal wall covered by the everted chitinous covering of the apical invagination.

Many bryozoan larvae are at first positively phototactic, and many possess pigment spots with a group of modified cilia that are thought to be light sensitive. Following a planktonic phase, the larvae usually become negatively phototactic and swim toward the bottom as they become competent (i.e., preparing to settle onto the substrate). Once in contact with the substratum, the pyriform organ complex is apparently used to test for chemical and tactile cues reflecting the suitability of the substratum for settling. Once a proper surface has been selected, the adhesive sac everts and secretes sticky material for attachment. After attachment, there is a thorough reorganization of tissue positions accompanied by histolysis of larval structures.

In gymnolaemates, the first zooid, the ancestrula, usually has one polypide, but two or more polypides are found in several species (Figures 16.13F and 16.15C). The settling cyphonautes larva everts the adhesive sac, which spreads out along the substratum and secretes the basal wall of the ancestrula. The shells open widely and become detached, while the underlying pallial epithelium secretes the frontal wall. The corona becomes enclosed in an inner ring-shaped cavity. Metamorphosis of the various types of coronate larvae shows considerable variation on this theme. In one type (e.g., *Bugula*; Figure 16.14C–E), the periphery of the everted adhesive sac extends along the sides of the settled larva finally to cover the whole outer wall of the larval body; thus, the whole cystid wall originates from the adhesive sac. In other types (e. g., *Bowerbankia*), the adhesive sac retracts again, and the pallial epithelium expands to cover the whole surface of the ancestrula.

Asexual reproduction As in all colonial animals, asexual reproduction is an integral part of the life history of bryozoans and is responsible for colony growth and regeneration of zooids. Each colony begins from the tissues of a metamorphosed larva, which develops one or a few zooids from the body wall, or in some Eurystomata from a mass of undifferentiated cells (called a **blastema**) connected with the apical organ. As in sexual reproduction, this first zooid or group of zooids that develops before feeding begins is called the ancestrula (Figures 16.7C and 16.13F). The ancestrula undergoes budding to produce daughter zooids, which subsequently form more buds, and so on. The initial group of daughter zooids may arise in a chain-like series, a plate, or a disc; the budding pattern determines the growth form of the colony and is highly variable among species. The ancestrula is usually of a shape different from that of the budded zooids (Figure

16.7C), and in a few species, changes in zooid morphology along the growing colony have been observed.

Budding involves only elements of the body wall. In most Eurystomata, a partition forms that isolates a small chamber, the developing zooid, from the parent zooid. The bud initially includes only components of the cystid and an internal coelomic compartment. A new polypide is then generated from the living tissues of the bud (the epidermis and the peritoneum). The epidermis and peritoneum invaginate, the former producing the tentacle crown and the gut. The peritoneum produces all of the new coelomic linings and the funiculus. Budding in phylactolaemates is similar, except that the polypide develops first and only becomes isolated from the parent zooid in some species. Budding among cyclostomes is in need of further investigation.

In addition to budding, freshwater bryozoans (Phylactolaemata) reproduce asexually by the formation of **statoblasts** (Figures 16.6E and 16.16). These structures are extremely resistant to drying and freezing and are often produced in huge numbers during adverse environmental conditions. Statoblasts generally form on the funiculus and include peritoneal and epidermal cells plus a store of nutrient material. Each cellular mass secretes a pair of chitinous protective valves, differing among species in shape and ornamentation. The parent colony usually degenerates, freeing the statoblasts. Some statoblasts sink to the bottom, but others float by means of enclosed gas spaces and are thus called floatoblasts. Some bear surface hooks or spines and are dispersed by passive attachment to aquatic animals or vegetation (Figure 16.16A). With the return of favorable conditions, the cell mass generates a new zooid, which sheds its outer casing and attaches as a functional individual (Figure 16.16B).
