Members of the phylum Brachiopoda (Greek *brachium*, "arm"; *poda*, "feet") are called lamp shells because the shape of their exoskeleton resembles historical oil lamps (Box 16C; Figure 16.17). They have been known since at least the early Middle Ages, and their images were published in books in the late sixteenth century. All are solitary, marine, benthic creatures, although they often aggregate, forming clumps of individuals. The body, including the lophophore, is enclosed between a pair of dorsoventrally oriented valves. Unlike bivalve molluscs, with two lateral shells that hinge dorsally, brachiopod shells are arranged dorsal and ventral and hinge posteriorly. Most brachiopods are attached to the substratum

BOX 16C Characteristics of the Phylum Brachiopoda

1. Enterocoelic, coelomate lophophorates
2. Epistome present, with or without coelomic lumen
3. Body enclosed between two shells (valves), one dorsal and one ventral
4. Usually attached to the substratum by a stalk, the pedicle, or cemented by the ventral valve
5. Valves lined (and produced) by mantle lobes formed by outgrowths of the body wall and creating a water-filled mantle cavity
6. Lophophores circular to variably coiled, with or without internal skeletal support
7. Gut U-shaped; anus present (Linguliformea, Craniiformea) or absent (Rhynchonelliformea)
8. One or two (Rhynchonellida) pairs of metanephridia
9. Circulatory system rudimentary and open
10. Most gonochoristic with mixed or indirect life histories
11. Indirect developers with lecithotrophic larvae
12. Gametes developing from transient gonadal tissue on peritoneum of metacoel
13. Cleavage holoblastic, radial, and nearly equal; coeloblastulae usually with gastrulation by invagination; blastopore giving origin to mouth, or blastopore closing and mouth (and anus) forming secondarily
14. Solitary, benthic, marine

by a fleshy **pedicle** (Figure 16.18A,B), although some species lack a pedicle (e.g., *Novocrania*) and usually cement themselves directly to a hard substratum. On the other hand, some species that possess a pedicle do not form permanent attachments, such as *Anakinetica cumingi*, which lies free, and *Lingula* spp., which anchor in loose sand (Figures 16.17G,H,J and 16.18B). A few species possess both unattached and attached populations (e.g., *Neothyris lenticularis* and *Magasella sanguinea*).

The valves of the brachiopod shell are unequal and are attached to one another either posteriorly, by a tooth-and-socket hinge (Rhynchonelliformea), or simply by muscles (Linguliformea, Craniiformea). Rhynchonelliform brachiopods normally "sit" ventral side up, the pedicle usually arising from the ventral valve through a shell opening called the **foramen**. Most extant brachiopods measure 2 to 4 cm along the greatest shell dimension but range from less than 1 mm to over 9 cm in extreme cases. Although they are known from nearly all ocean depths, they are most abundant on the continental shelf.

The approximately 440 living species of brachiopods represent a small surviving fraction of the 12,000 to 15,000 extinct species that have been described. Their rich fossil record dates back at least 541 million years (earliest Cambrian), and possible stem-group brachiopods may be present even earlier in the fossil record. Brachiopods, especially rhynchonelliforms, were among the most abundant animals of the Paleozoic, but they declined in numbers and diversity after that time. Exceptionally preserved linguliforms are especially well known from the Cambrian Chengjiang biota, and there was a prolific radiation in the phylum during the Ordovician Period. It has been proposed that competition with epibenthic bivalve molluscs was at least partly responsible for the reduction in brachiopod diversity following their Paleozoic success. We recognize three living subphyla of Brachiopoda.

CLASSIFICATION OF THE BRACHIOPODA

SUBPHYLUM LINGULIFORMEA Valves not hinged, attached by muscles only; valves of organophosphatic composition, including apatite (calcium phosphate), chitin, collagen, and proteins; pedicle usually with intrinsic muscles and a coelomic lumen; lophophore without

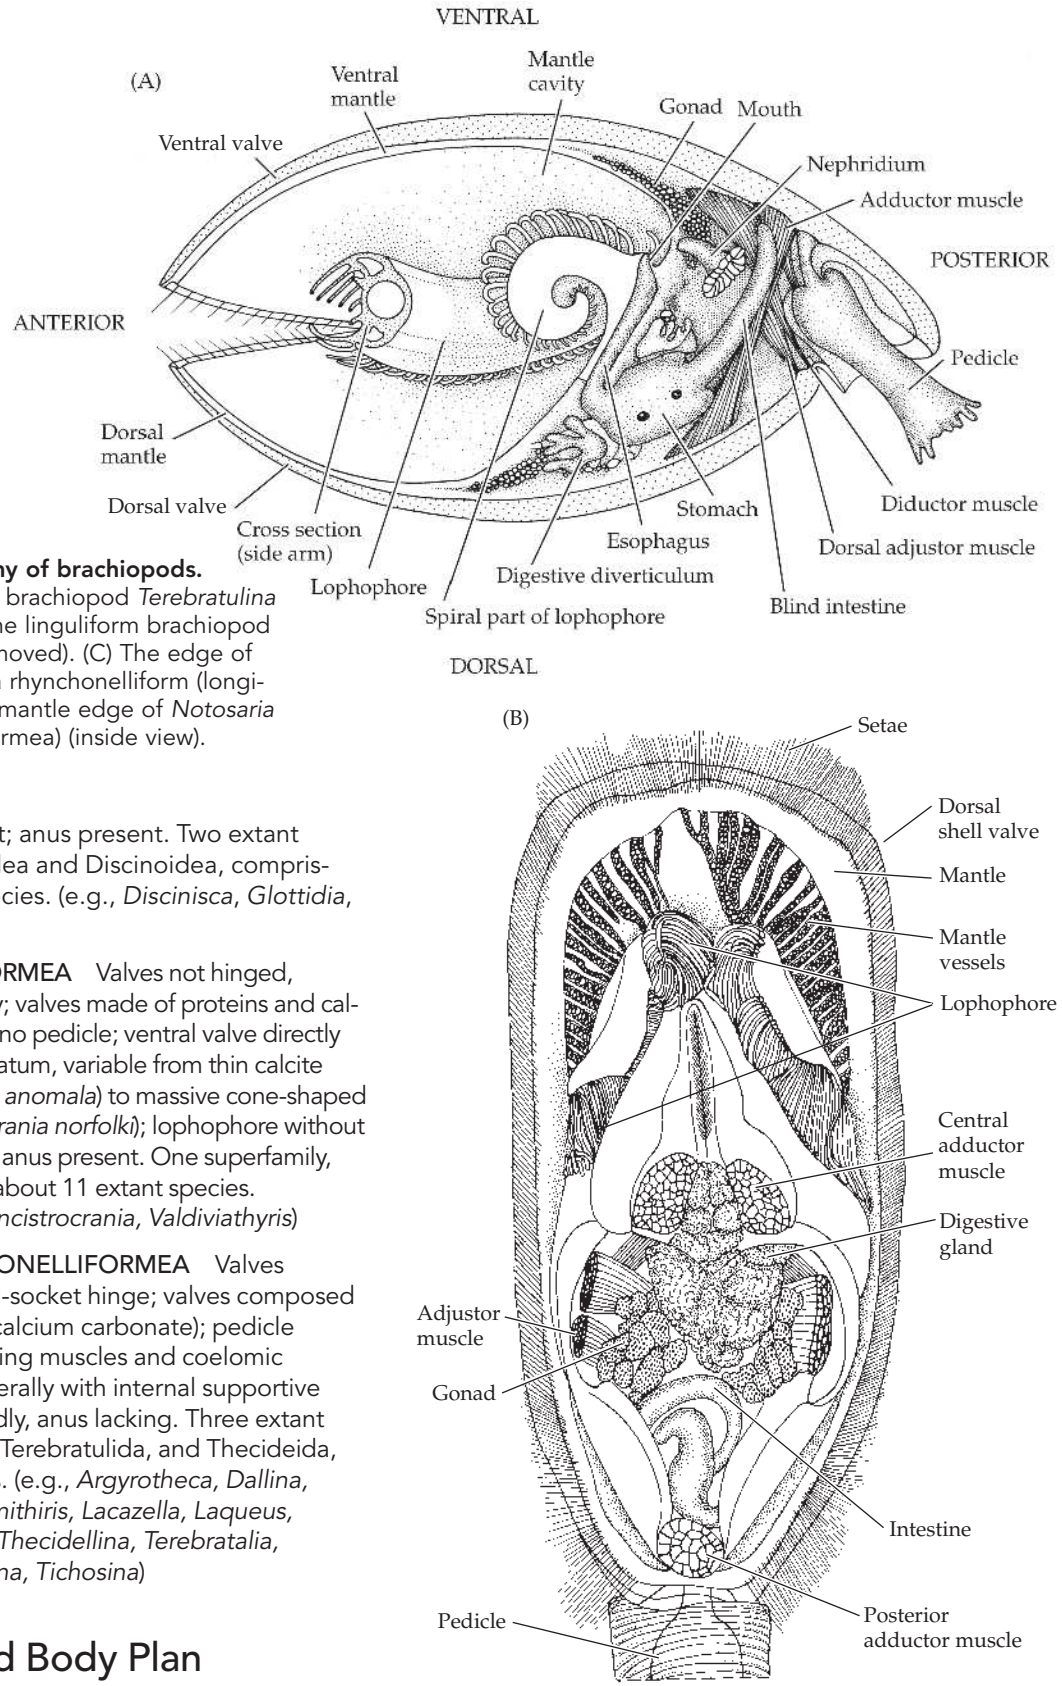

FIGURE 16.18 Anatomy of brachiopods. (A) The rhynchonelliform brachiopod *Terebratulina* sp. (cutaway view). (B) The linguliform brachiopod *Lingula* (ventral valve removed). internal skeletal support; anus present. Two extant superfamilies, Linguloidea and Discinoidea, comprising about 25 extant species. (e.g., *Discinisca*, *Glottidia*, *Lingula*, *Pelagodiscus*)

SUBPHYLUM CRANIIFORMEA Valves not hinged, attached by muscles only; valves made of proteins and calcite (calcium carbonate); no pedicle; ventral valve directly cemented to hard substratum, variable from thin calcite lamella (e.g., *Novocrania anomala*) to massive cone-shaped valve (e.g., *Neoancistrocrania norfolki*); lophophore without internal skeletal support; anus present. One superfamily, Cranioidea, comprising about 11 extant species. (e.g., *Novocrania*, *Neoancistrocrania*, *Valdiviathyris*)

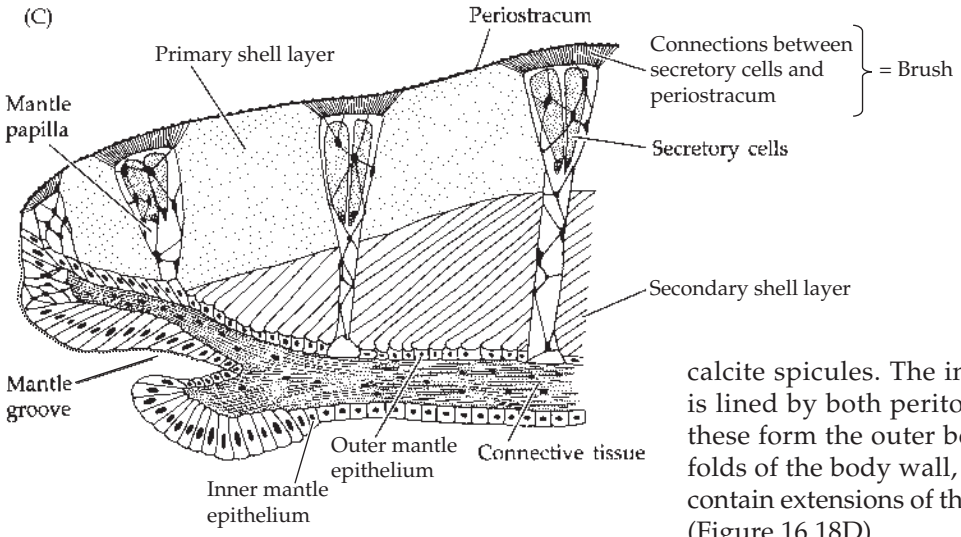
SUBPHYLUM RHYNCHONELLIFORMEA Valves articulated by tooth-and-socket hinge; valves composed of proteins and calcite (calcium carbonate); pedicle usually present, but lacking muscles and coelomic lumen; lophophore generally with internal supportive elements; gut ends blindly, anus lacking. Three extant orders: Rhynchonellida, Terebratulida, and Thecideida, with around 400 species. (e.g., *Argyrotheca*, *Dallina*, *Frenulina*, *Gryphus*, *Hemithiris*, *Lacazella*, *Laqueus*, *Liothyrella*, *Magellania*, *Thecidellina*, *Terebratalia*, *Terebratella*, *Terebratulina*, *Tichosina*)

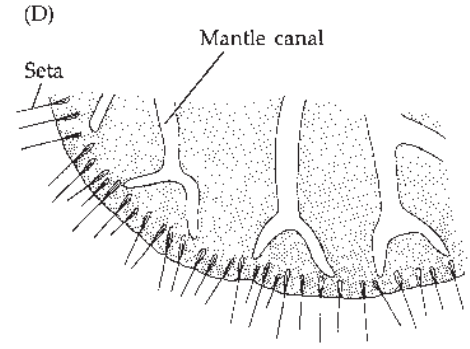
The Brachiopod Body Plan

The Body Wall, Coelom, and Support

The shells of brachiopods comprise an outer organic **periostracum** and an inner structural layer or layers composed variably of calcium carbonate (calcite), calcium phosphate (apatite), proteins, chitin, and collagen. Extant discinids may have siliceous nanoparticles covering their periostracum. Various spines were also present in some fossil species in multiple lineages as outgrowths of the shell and served to anchor the animals in place (Figure 16.17I). In a fashion similar to that of molluscs, brachiopod shells are secreted by a **mantle**. This mantle is divided into a dorsal and a ventral mantle formed as an outgrowth of the body wall (Figure 16.18). The

for more ebook/ testbank/ solution manuals requests: email 9911267344@qq.com





periostracum is secreted by the mantle edges in a periostracal slot, and the inner shell layer by the general mantle surface, the outer mantle epithelium. Shells of many brachiopods bear perforations, or punctae, extending from their inner surfaces nearly to the periostracum and containing tiny tissue extensions of the mantle (Figure 16.18), quite similar to the aesthetes found in chitons. The function of these mantle papillae is unknown, but some workers have suggested that they might serve as areas for food storage and gas exchange or in some way deter the activities of borers. Shells that lack perforations are termed impunctate.

The soft mantle lines and is attached to the dorsal and ventral valves of the shell and forms the water-filled mantle cavity, which houses the lophophore. The mantle edges often bear chitinous setae, which may protect the fleshy tissue and perhaps serve to prevent the entrance of large particles into the mantle cavity. Once thought to be a striking convergence with the annelid chaetae, the presence of chaetae/setae in both groups, with nearly identical ultrastructure and development, is used as a possible synapomorphy of lophotrochozoans. The mode of chaetogenesis has also been proposed to be related to spiculogenesis in molluscs.

The epidermal cells of the mantle and general body surface vary from cuboidal to columnar and are monociliated. Beneath the epidermis is a connective tissue layer of varying thickness, which in some species may house mesenchymal cells and can produce calcite spicules. The inner surface of the body wall is lined by both peritoneal and myoepithelial cells; these form the outer boundary of the coelom. Being folds of the body wall, the dorsal and ventral mantle contain extensions of the coelom, called **mantle canals** (Figure 16.18D).

The pedicle is an outgrowth of the body wall, arising from the posterior area of the ventral valve. In linguliforms it contains all the usual layers beneath the epidermis, including connective tissue, muscles, and a coelomic lumen. However, the pedicle of rhynchonelliforms lacks muscles and a coelomic cavity. In the latter case extrinsic muscle bands from the body wall itself operate the pedicle. In brachiopods that attach firmly, the tip of the pedicle bears papillae or fingerlike extensions that adhere tightly to the substratum.

The coelomic system of brachiopods includes the typical mesocoel and metacoel as the lophophoral and body coeloms, respectively. The epistome is solid in rhynchonelliforms, but in linguliforms it may contain coelomic cells that are continuous with the lophophoral mesocoel. The coelomic fluid includes various coelomocytes, some of which contain hemerythrin.

The Lophophore, Feeding, and Digestion

Like that of phoronids and bryozoans, the lophophore of brachiopods comprises a ring of tentacles surrounding the mouth. In brachiopods, however, the lophophore is produced as a pair of tentacle-bearing arms that extend anteriorly into the mantle cavity. The overall shape of the lophophore varies among taxa, from a simple circular or U shape to forms with highly coiled arms. The brachiopod lophophore also differs in that it is always contained within the protection of the valves and is essentially immovable. In most brachiopods, the lophophore and tentacles are held in position by coelomic pressure, whereas in most rhynchonelliforms the dorsal valve produces a lophophore-supporting structure, the brachidium. In some groups (e.g., Thecideida) the dorsal valve has ridges and grooves, instead of an erect lophophore skeleton, that help support and position the lophophore.

In order to pass a water current through the mantle cavity, the two valves must be opened slightly. The mechanisms of valve operation differ among members of the three subphyla. In hinge-bearing rhynchonelliforms, there are two pairs of muscles responsible for

valve movements—whereas a pair of diductor muscles opens the valves (Figures 16.18A,B and 16.19A), the adductor muscle pair is responsible for shell closure. Linguliforms and craniiforms lack a hinge and do not possess diductor muscles. Instead, the gape is produced by contraction of the posterior adductor or the umbonal muscle and relaxation of different anterior muscle groups. Central adductor muscles are mainly used to close the valves. As both shell opening and closure depend on either rapid or long-lasting active muscle contraction, diductor and adductor muscles contain striated as well as smooth fibers.

Feeding currents are generated by the lophophoral cilia. Specific incurrent and excurrent flow patterns occur, varying with shell morphology and the shape and orientation of the lophophore. In any case, water is directed over and between the tentacles before it is passed out of the mantle cavity (Figure 16.20A). Each tentacle bears lateral and frontal ciliary tracts (Figure 16.20B). The lateral cilia of adjacent tentacles overlap and redirect food particles from the water to the frontal cilia by beat reversal. The frontal cilia beat toward the base of the tentacles, helping to direct trapped food. The lophophoral ridge, or brachial axis, bears a brachial food groove within which food material is moved to the mouth (Figure 16.20C). Brachiopods feed on nearly any appropriately small organic particles, especially phytoplankton.

The digestive system is U-shaped (Figures 16.18A and 16.19B,C). The mouth is followed by a short esophagus, which extends dorsally and then posteriorly to the stomach. A digestive gland covers most of the stomach and connects to it via paired ducts. The intestine extends posteriorly, where it ends blindly in rhynchonelliforms or recurves as a rectum terminating in an anal opening in inarticulated brachiopods. In the latter case the anus opens either medially (craniiforms) or on the right side of the animal (linguliforms). The absence of an anus is almost certainly a secondary loss in rhynchonelliforms and can be traced back to differences in the fate of the blastopore during early embryonic development, in comparison to craniiforms. Little is known about digestion in brachiopods, but some work on *Lingula* indicates that it occurs intracellularly in the digestive gland.

Circulation, Gas Exchange, and Excretion

The brachiopod circulatory system is open, much reduced, and largely unstudied. A contractile heart lies in the dorsal mesentery just above the gut (*Novocrania* possesses several "hearts"). Leading anteriorly and posteriorly from the heart, the blood vessels form channels within the connective tissue of the mesenteries, thus no true vessels are present. These channels branch to various parts of the body, but the pattern of circulation is not fully understood. It appears that the blood is separate

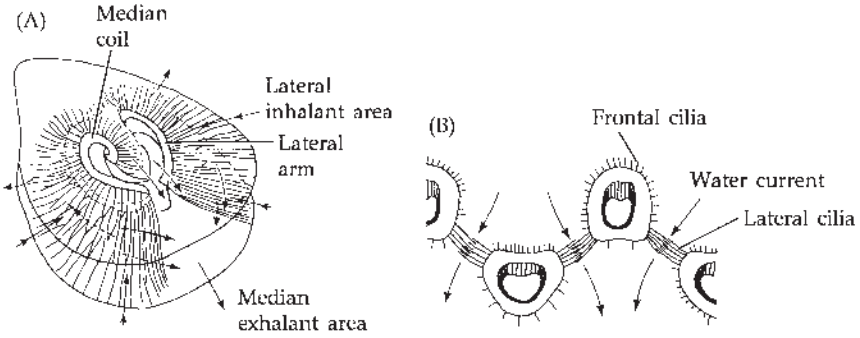

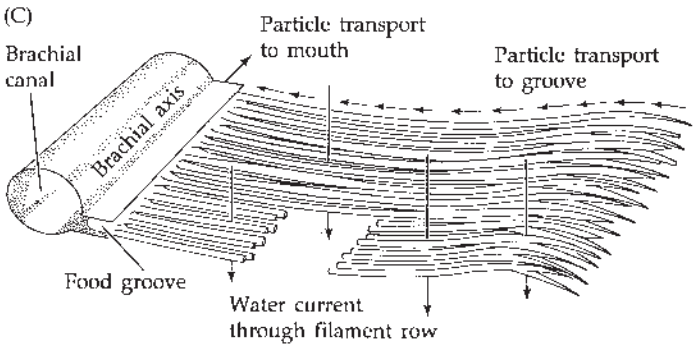

FIGURE 16.20 Feeding currents in brachiopods. (A) Feeding currents (arrows) of *Calloria inconspicua* (Rhynchonelliformea). (B) Lophophoral tentacles (section). The water (arrows) passes over lateral ciliary bands. (C) A portion of a lophophore. Food particles are transported along tentacles and the brachial food groove (arrows). (C after M. J. S. Rudwick. 1962. *Zool J Linn Soc* 44: 592–615.)

from the coelomic fluid, although both contain certain similar cells. The function of the circulatory system is thought to be largely restricted to nutrient distribution.

Gas exchange probably occurs across the general body surface, especially the lophophore tentacles and mantle. These structures not only provide large surface areas but also are sites over which water moves and is brought close to underlying coelomic fluid. This general arrangement and the presence of hemerythrin in certain coelomocytes suggest that the coelomic fluid, not the blood, is the medium for oxygen transport.

Brachiopods possess one or two pairs of metanephridia, with the nephrostomes opening to the metacoel. The nephridioducts exit through pores into the mantle cavity. The nephridia function as gonoducts as well as discharging phagocytic coelomocytes that have accumulated metabolic wastes. In the distal part of the metanephridia (nephridial canal), columnar cells absorb large quantities of coelomic fluid by endocytosis suggesting secondary urine formation as in other metanephridial systems. However, primary urine formation through a podocyte filter system from the blood vessel into the coelom has only been assumed for the periesophageal coelom in the rhynchonellid *Hemithiris psittacea*.

Nervous System and Sense Organs

The nervous system of brachiopods, as in many sessile invertebrates, is somewhat reduced. A dorsal ganglion and a ventral ganglion lie against the esophagus and are connected by a circumenteric nerve ring. Nerves emerge from the ganglia and nerve ring and extend to various parts of the body, especially the muscles, mantle, and lophophore (Figure 16.19D). As usual, the array of sense organs in these animals is compatible with their lifestyle. The mantle edges and setae are richly supplied with sensory neurons, probably tactile receptors. There is also evidence that brachiopods are sensitive to dissolved chemicals, perhaps through surface receptors on the tentacles or mantle edge. Members of at least one burrowing species of *Lingula* possess a pair of statocysts that are associated with orientation in the substratum. Larvae of some rhynchonelliform groups possess eyes composed of two photoreceptor cells almost certainly mediating their photonegative behavior prior to settlement and metamorphosis. Comparable to the vertebrate eye, brachiopod larval eyes contain a ciliary opsin as the photosensitive pigment. The larval nervous system in brachiopods has been shown to contain both serotonergic and histaminergic neurons.

Reproduction and Development

Asexual reproduction does not occur in brachiopods. Most species are gonochoristic, with gametes developing from patches of transient gonadal tissue derived from the coelomic epithelium in the metacoel. Gametes are released into the metacoel and escape through the metanephridia. In most cases both eggs and sperm are shed freely, and fertilization is external. A few species, however, brood their embryos until the larval stage is reached. In these cases sperm are picked up in the water currents of females, and the eggs are retained in a brooding area where they are fertilized. *Argyrotheca*, for example, broods its embryos in special caverns formed by the mantle epithelium. Species of Thecideida form brood pouches in either the dorsal or ventral valves as derivatives of the lophophore epithelium. Others retain their embryos on the arms

(E) Three-lobed stage of *Terebratalia transversa* (Rhynchonelliformea) with two dorsolateral rows of red eyespots on the apical lobe. (F,G) Two subsequent metamorphic stages of *Laqueus erythraeus* (Rhynchonelliformea). Mantle lobe inversion starts immediately after attachment of the larva to the substrate. (H) Hatchling of *Lingula anatina* (Linguliformea) already equipped with two shelled mantle lobes and a ciliated lophophore rudiment.

of the lophophore, in special regions of the mantle cavity, or in modified depressions in a valve.

Cleavage is holoblastic, radial, and nearly equal; it leads to the formation of a coeloblastula. Gastrulation is by invagination, except in the brooding form *Lacazella mediterranea*, where it apparently occurs by delamination. The blastopore closes and the mouth forms secondarily (i.e., deuterostomy, in *Novocrania anomala*) or gives origin to the mouth (i.e., protostomy, in *Terebratalia transversa*). This transition from protostomy to deuterostomy is determined by the differential activity of Wnt signaling, together with the timing and location of mesoderm formation. The anus, when present, breaks through late as the gut grows and approaches the body wall. Mesoderm formation starts by proliferation of archenteral cells and subsequent separation from the larval gut anlage. Only during metamorphosis do the mesoderm cells diverge, thereby opening a lumen, the coelom. The origin of the prospective coelomic epithelium from archenteral cells can be interpreted as enterocoely.

Whether the developmental pattern is mixed or fully indirect, all brachiopods eventually enter a free-swimming stage (Figure 16.21). Although these planktonic forms differ morphologically, they have been compared to trochophore larvae, in which case the ciliary band around the apical lobe could be interpreted as homologue to the prototroch of a traditional trochophore, but this is controversial. Whereas lingulid brachiopods hatch as planktotrophic stages ("free-swimming juveniles") with a thorough and a first-formed ("embryonic") shell, all other groups hatch as nonfeeding stages. In discinids the hatchling has typical larval characters (e.g., larval setae) but quickly develops tentacles, a functional digestive system, and a first-formed shell while still in the planktonic stage. Craniiforms and rhynchonelliforms have a lecithotrophic larval stage that only develops tentacles and a shell and starts feeding upon settlement and metamorphosis.

In linguliforms, such as *Lingula*, the lophophore of the planktonic stage (Figure 16.21) can be protruded out from between the mantle lobes and can function to propel and feed the larva. As the mantle lobes and shell bear some weight, this developmental stage immediately sinks when the lophophoral tentacles are retracted into the mantle cavity. Extension of the growing pedicle while on the seafloor marks the start of the juvenile's benthic life. Thus, there is no drastic metamorphosis at the time of settling.

The free-swimming larvae of rhynchonelliforms are regionalized into an anterior (apical) lobe, a mantle lobe, and a pedicle lobe (Figure 16.21C–F). As craniiforms lack a pedicle throughout their life, their larval body has only an apical and a posterior lobe, the latter bearing three pairs of larval setal bundles. After a short larval life of a few days to weeks (depending on the ambient temperatures), the nonfeeding brachiopod larvae settle and metamorphose. As the pedicle lobe attaches to the substratum (only rhynchonelliforms), the mantle lobes flex forward over the anterior lobe. The now exterior surfaces of the mantle lobes commence secretion of the valves, while the anterior lobe differentiates into the body and the lophophore.

Chapter Summary

This chapter introduced you to the important clade Lophophorata—three phyla united by their possession of a unique, ciliated, tentacular feeding structure called the lophophore (and its associated epistome, which functions to move captured food particles form the lophophore to the mouth). The three lophophorate phyla (Phoronida, Bryozoa, Brachiopoda) are typically sessile, benthic suspension feeders (a few bryozoans have floating colonies) with U-shaped guts (which are advantageous for animals living encased in tubes, compartments, or shells). Phoronids are vermiform tube dwellers, usually living together in aggregations, and typically with a unique actinotroch larva. Bryozoans are colonial, with zooids that develop through budding and produce planktonic larvae. Brachiopods are solitary and shelled (with dorsal and ventral valves, as opposed to the right and left shells of bivalve molluscs), and they produce planktonic larvae. Major research areas important to our understanding of these three phyla are to resolve the nature of their "tripartite" body cavities, to find their exact phylogenetic placement with respect to other lophotrochozoans, and to determine the developmental mechanisms involved in producing the brachiopod shells and setae and the bryozoan housings, as well as whether these are related to modes of chaetogenesis, spiculogenesis, and shell formation in other lophotrochozoans.

CHAPTER 17

Rouphozoa

The Phyla Platyhelminthes (Flatworms) and Gastrotricha (Hairy-Bellied Worms)

Since the eighteenth century, flatworms had generally been considered basal bilaterians because of their superficially simple-appearing and acoelomate body, their lack of a through gut (absence of an anus) or structural circulatory system, and other features. But during the late twentieth century molecular phylogenetic studies began to suggest otherwise, and by the 2010s phylogenomic analyses were indicating that platyhelminths and gastrotrichs were sister groups embedded well within the spiralian clade (and not placed near the base of Bilateria).

Introduction to Rouphozoa

Struck et al. (2014) introduced the name Rouphozoa for the Platyhelminthes-Gastrotricha clade; a derivative of the Greek word *rouphao*, for "ingestion by sucking," in reference to the common feeding mode of many of the free-living species. Although this mode of feeding is not uncommon among animals with strong sucking pharynxes, and the plesiomorphic state within Platyhelminthes is a pharynx simplex that engulfs instead of sucking prey, the name has stuck. In fact, few straightforward anatomical apomorphies seem to exist that define Rouphozoa, and both phyla seem to be characterized by features that are plesiomorphic for the Spiralia in general (dense body ciliation, protonephridia, etc.). One putative synapomorphy of Rouphozoa is the presence of duo-gland organs, described below, although similar organs also exist in other groups as well (e.g., annelids, nematodes). Both phyla are acoelomate, and their precise placement among the spiralian protostomes remains unresolved. Nevertheless, the clade Rouphozoa has continued to enjoy strong phylogenomic support since Struck and his colleagues first proposed it.

The Phylum Platyhelminthes (Flatworms)

The phylum Platyhelminthes (Greek *platy*, "flat"; *helminth*, "worm") includes nearly 30,000 extant species of free-living and parasitic worms, and more than 100,000 undescribed species have been estimated to exist. Platyhelminths are triploblastic, nonsegmented, bilaterally symmetrical, acoelomate, soft-bodied, dorsoventrally flattened worms (Box 17A). They display a variety of body forms (Figure 17.1) and inhabit a wide range of environments. About 75% of all described species are parasitic, mostly belonging to the Monogenea and Trematoda (the flukes) and Cestoda (the tapeworms).

(F) *Pseudobiceros bajae*, an intertidal polyclad flatworm from the Sea of Cortez, Mexico (also see chapter opener photo, *Pseudobiceros bedfordi*). (G) The strikingly colored polyclad *Pseudoceros ferrugineus*. (H) The familiar freshwater triclad *Girardia tigrina* (formerly *Dugesia tigrina*). (I) A polyclad flatworm in the genus *Thysanozoon*, a predator on small invertebrates, including barnacles. (J) A marine polyclad, *Eurylepta californica*. (K) *Hylocelis californica* (formerly *Alloioplana californica*), a common polyclad on the Pacific Coast of North America. (L) *Acanthomacrostomum* sp., a meiofaunal flatworm that has a layer of calcareous spicules just below the epidermis. This skeletal framework may provide protection and support in aiding in locomotion. (M) The liver fluke *Fasciola hepatica* (Digenea). (N) Anterior end of the tapeworm *Taenia* (Cestoda).

These parasites infect hundreds of millions of people around the globe, the most prominent being five species of human blood flukes in the genus *Schistosoma* that infect 200 million people worldwide with schistosomiasis (also known as bilharzia, or snail fever). Most of the free-living forms live in marine and freshwater benthic habitats and comprise a diverse, paraphyletic group formerly known as "turbellarians"; a few are terrestrial and some are commensal or parasitic in or on other invertebrates. Free-living marine flatworms are often some of the most colorful and graceful creatures found in shallow temperate to tropical waters and tide pools, and flatworms can be found down to the hadal zone of deep ocean trenches. As their name suggests, most flatworms are strikingly flattened dorsoventrally, although the body shape varies from cylindrical to flattened forms with broadly oval to elongate and ribbon-like shapes; a few bear short tentacles at the anterior

BOX 17A Characteristics of the Phylum Platyhelminthes

1. Free-living or parasitic, nonmetameric worms (Cestoda are strobilated)
2. Triploblastic, acoelomate, bilaterally symmetrical; often dorsoventrally flattened
3. Spiral cleavage (in some nonparasitic lineages) and 4d-derived mesoderm; many others with highly modified cleavage pattern
4. Complex, though incomplete, gut usually present; gut absent in some parasitic forms (Cestoda)
5. Cephalized, with a central nervous system comprising an anterior cerebral ganglion and (usually) longitudinal nerve cords connected by transverse commissures (ladderlike nervous system)
6. Multiciliated epidermal cells (few cilia per cell in Catenulida)
7. With protonephridia as excretory/osmoregulatory structures
8. Without discrete circulatory or gas exchange structures
9. With unique system of neoblast cells
10. Mucus typically produced by rhabdoids/rhabdites
11. Most hermaphroditic, with complex reproductive system and biflagellate sperm (aflagellate in Catenulida and Macrostomida)
12. Direct or indirect development, with distinct larvae in Polycladida (Götte's and Müller's larvae)

end or have other elaborations of the body surface. The free-living forms range from less than 1 mm to about 30 cm long (land planarians) or even 40 cm in some Lake Baikal flatworms of the genus *Baikalobia*; although most familiar species are 1–4 cm long, the vast majority of free-living flatworms are "microturbellarians." The largest of all platyhelminths are certain tapeworms that attain lengths of several meters (a tapeworm that infests blue whales grows to 10 m in length!).

Platyhelminths are triploblastic (i.e., they have true endomesoderm) and bilaterally symmetrical, show clear cephalization, and possess sophisticated excretory and reproductive organ systems. The solid (acoelomate) body plan usually includes a relatively dense mesenchyme (often called "parenchyme") between the gut and the body wall. The mesenchyme is not homogeneous, but comprises a multitude of differentiated cell types and small open spaces or **lacunae**. Within the mesenchyme of most flatworms are discrete excretory–osmoregulatory structures, the protonephridia, which are found in many invertebrate taxa, especially among protostomes. Most flatworms possess complex reproductive systems and an incomplete yet complex gut with a single opening serving for both ingestion and egestion. The mouth leads to a pharynx of varying complexity and then to a blind intestine. The gut is entirely lacking in tapeworms, as well as in a few other symbiotic species.

Taxonomic History and Classification

In his first edition of *Systema Naturae* (1735), Linnaeus established two phyla to encompass all of the known invertebrates. To one he assigned the insects and to the other the rest of the invertebrates. Linnaeus called this latter taxon Vermes (Greek, "worms"). By the thirteenth edition of *Systema Naturae* (1788), the various groups of flatworms had been placed together in the order Intestina. During the early 1800s, several biologists, including Lamarck and Cuvier, questioned and rejected the concept of the taxon Vermes, although the name continued to surface from time to time and actually persisted into the twentieth century as a dumping ground for almost any creatures with wormlike bodies (and many that were not so wormlike).

During the nineteenth century, the flatworms were eventually separated from most other groups of wormlike creatures. In 1851, C. Vogt isolated the flatworms and the nemerteans as a single taxon, which he called the Platyelmia, a name changed to Platyelminthes by Karl Gegenbaur in 1859. (Unfortunately, Gegenbaur also resurrected the phylum Vermes.) Gegenbaur's Platyelminthes (now Platyhelminthes) was eventually raised to the rank of phylum, comprising four classes: Turbellaria, Nemertea, Trematoda, and Cestoda. In 1876 Charles Minot dropped the nemerteans from this assemblage, although many workers did not accept this change for several decades. The legendary zoologist Libbie Hyman (1951) asserted the monophyly of Platyhelminthes, a view shared by Tor Karling (1974), Peter Ax (1985), and Ulrich Ehlers (1985), who recognized three clades (Acoelomorpha, Catenulida, and Rhabditophora) that have since each been supported by molecular phylogenetic studies. Later analyses of morphology and the advent of molecular gene sequence analyses have supported the monophyly of Catenulida + Rhabditophora (although these two major flatworm clades still lack unambiguous morphological synapomorphies) but suggested acoelomorphs were basal bilaterians rather than flatworms (see Chapter 9). With the removal of Acoelomorpha (which includes Acoela and Nemertodermatida), Platyhelminthes is now viewed as a monophyletic phylum.

The internal classification of flatworms has been subjected to frequent revisions. However, two recent studies by independent groups of researchers targeted platyhelminth phylogeny by analyzing different sets of thousands of genes (Egger et al. 2015, Laumer et al. 2015). These genomic studies, published at nearly the same time, resulted in nearly the same phylogeny. Our summary tree (see Figure 17.34) and classification are based primarily on this recent work. However, students can expect continued reorganization of the flatworms in the near future. There are over 6,500 species of free-living flatworms, over 12,000 species of flukes, and over 8,000 species of tapeworms.

The free-living flatworms (formerly classified as "turbellarians," a category now known to be a paraphyletic group, although the name is still sometimes loosely used for the non-neodermatan platyhelminths) were previously grouped into two taxa on the basis of whether yolk is deposited within the cytoplasm of the ova (**endolecithal ova**) or separately, in special cells outside the ova (**ectolecithal ova**). Those with endolecithal ova were placed in the Archoophora and those with ectolecithal ova in the Neoophora. These names have been abandoned (but Euneoophora is used in some classifications) as formal taxa because they are now known to define nonmonophyletic groups of species. However, the names are still descriptive because the placement of yolk, as well as the uterine structures that mediate this process, provide additional characters for describing the various flatworm orders. The patterns also have important implications in the early development of these animals.

PLATYHELMINTHES CLASSIFICATION

SUBPHYLUM CATENULIDEA Catenulids (Figure 17.1A). Simple anterior pharynx and saclike gut; mesenchyme sometimes reduced to a fluid matrix (making them effectively blastocoelomate); sometimes with statocyst bearing 1 to 3 statoliths; brain lies at base or middle of preoral lobe; with a ciliated ventrolateral groove between base of preoral lobe and the rest of the body; tubules of excretory system mediodorsal; with a single biflagellate protonephridium; male genital opening dorsal and anterior; female ducts and accessory organs are lacking; with endolecithal ova and spiral cleavage. Catenulids are elongate freshwater and marine forms. A single order, Catenulida. (e.g., *Catenula*, *Paracatenula*, *Stenostomum*)

SUBPHYLUM RHABDITOPHORA With lamellated rhabdites, a duo-gland adhesive system and multiflagellate terminal cell in the protonephridia; most taxa with biflagellate sperm.

INFRAPHYLUM MACROSTOMORPHA Rhabditophora with duo-gland adhesive organ consisting of viscid gland and releasing gland necks emerging in a common collar of anchor cell microvilli; with a postoral neural commissure, and a protrusible pharynx simplex; with aflagellate sperm, endolecithal ova, and spiral cleavage.

ORDER HAPLOPHARYNGIDA Minute worms (to 6 mm long) with a simple proboscis and pharynx; proboscis separate from pharynx and beneath the anterior tip of the body (reminiscent of nemerteans); anal pore weakly developed, but permanent; brain encapsulated by a unique membrane; oviduct posterior to male genital apparatus; male copulatory organ consists of a posterior prostatic vesicle and an anterior stylet apparatus. One genus (*Haplopharynx*) and at least three species.

ORDER MACROSTOMIDA Macrostomids (Figure 17.1B). Simple pharynx; simple, saclike gut; with endolecithal ova and a common oviduct anterior to the male genital apparatus; small and predominately interstitial forms; marine and freshwater. (e.g., *Acanthomacrostomum*, *Macrostomum*, *Microstomum*)

INFRAPHYLUM TREPAXONEMATA Rhabditophorans with biflagellate sperm bearing a 9 × 2 + "1" pattern of microtubules.

SUPERCLASS AMPLIMATRICATA With a tendency to express an ample extracellular matrix; with spiral cleavage.

ORDER POLYCLADIDA Polyclads (Figure 17.1F,G,I–K). A diverse group of relatively large free-living flatworms with endolecithal ova; nearly all are marine; common in littoral zones throughout the world, especially in the tropics; predominately benthic and free-living. Some are so large and colorful as to be easily mistaken for sea slugs; some cases of mimicry are known. Many swim by graceful undulations of the body margins. A few are pelagic or symbiotic. (e.g., *Eurylepta*, *Hoploplana*, *Leptoplana*, *Notoplana*, *Planocera*, *Prostheceraeus*, *Pseudobiceros*, *Pseudoceros*, *Stylochus*, *Thysanozoon*)

ORDER PRORHYNCHIDA Freshwater and terrestrial flatworms, often bearing prominent anterior auricles and an anteriorly situated, complex pharynx; ovaries lecithoepitheliate, consisting of two kinds of cells, vitellocytes embracing the growing oocytes, both types of cells produced by a common proximal germinal tissue. (e.g., *Geocentrophora*, *Prorhynchus*). Some classification schemes place the freshwater Prorhynchida and the marine Gnosonesimida within the Lecithoepitheliata, a taxon comprised of about 30 species united on the basis of an intermediate condition between endolecithal and ectolecithal ova, but recent research considers Lecithoepitheliata to be nonmonophyletic.

SUPERCLASS GNOSONESIMORA Marine forms with apparent lecithoepithelial development of ova but closer structural and molecular affinities to Euneoophora; with ectolecithal ova (cleavage not yet described).

ORDER GNOSONESIMIDA A single marine genus is known (*Gnosonesima*), bearing a coniform bulbous pharynx.

SUPERCLASS EUNEOOPHORA Rhabditophorans whose ovary is divided into germinal and vitelline cell producing parts; with ectolecithal ova.

CLASS RHABDOCOELA Rhabdocoels. Bulbous or sometimes plicate pharynx; simple saclike gut

without diverticula; ectolecithal ova produced by ovaries that are usually fully separate from the yolk glands; spiral cleavage.

ORDER DALYTYPHLOPLANIDA A diverse group of free-living or ecto- or endosymbionts of marine and freshwater invertebrates (Figures 17.6B and 17.10). Molecular data suggest three main groups: neodalyellids, with an anterior mouth (e.g., *Anoplodium*, *Graffilla*, *Pterastericola*); thalassotyphloplanids, mostly marine species with the mouth not anterior (e.g., *Kytorhynchus*, *Mesostoma*, *Typhlorhynchus*); and limnotyphloplanids, mostly freshwater species (e.g., *Castrella*, *Dalyellia*, *Microdalyellia*). Limnotyphloplanids are small symbionts on freshwater decapod crustaceans, although a few live on other invertebrates or on turtles. (i.e., *Temnocephala*)

ORDER KALYPTORHYNCHIA Kalyptorhynchs (Figures 17.1E and 17.11E). Mouth not terminal; with a complex eversible proboscis at anterior end that is separate from the mouth and pharynx; free-living marine and freshwater species. (e.g., *Cheliplana*, *Cystiplex*, *Gnathorhynchus*, *Gyratrix*)

CLASS PROSERIATA Freshwater and marine free-living flatworms lacking lamellate rhabdites; bearing a cylindrical plicate pharynx; simple gut; spiral cleavage.

ORDER UNGUIPHORA Proseriates with pigment in the mantle cells of rhabdomeric receptors, and usually without a statocyst; molecular studies suggest that this order is in need of revision, and also that the enigmatic genus *Ciliopharyngiella* may belong here. (e.g., *Nematoplana*, *Polystyliphora*)

ORDER LITHOPHORA Proseriates without pigment in the mantle cells and usually with a statocyst; recent molecular studies indicate that this order is monophyletic and suggest that the families Coelogynoporidae and Calviriidae as well as Otoplanidae, Archimonocelididae, and Monocelididae may belong in this group. (e.g., *Calviria*, *Coelogynopora*, *Otoplana, Otoplanella*, *Archimonocelis*, *Monocelis*)

CLASS ACENTROSOMATA Rhabditophorans lacking genes controlling formation of centrosomes, leading to loss of highly regulated spiral cleavage (and, in some lineages, blastomere anarchy) during early development.

SUBCLASS ADIAPHANIDA Although there are no clear synapomorphies for this clade, it is strongly supported by molecular analyses; the name is from the ancient Greek word for "opaque," referring to the fact that most species have opaque bodies.

ORDER TRICLADIDA Triclads (Figures 17.1C,H, 17.2, and 17.6A). Freshwater, marine, terrestrial, and symbiotic forms; cylindrical plicate pharynx; gut three-branched with numerous diverticula; two germinaria located at anterior end of germovitelloducts. Most are free-living, including the familiar planarians. This taxon is monophyletic and used to be grouped into 3 suborders based largely on their ecology (marine, freshwater, and land planarians), but now they divide into Maricola and Continenticola, as the former suborder Terricola nests within the former Paludicola. Notable triclad genera include *Bdellocephala*, *Bdelloura*, *Bipalium*, *Crenobia*, *Dugesia* [formerly *Planaria*], *Endeavouria*, *Geoplana*, *Obama*, *Polycelis*, *Procotyla,* and *Schmidtea*.

ORDER PROLECITHOPHORA Prolecithophorans. Pharynx plicate or bulbous; gut simple; sperm aflagellate, with extensive membranous folds. Reduction of duo-gland adhesive system complete; genitalia variable but male aperture often opens forward, female reproductive system often opens to a common pore; small, free-living, marine, and freshwater. (e.g., *Plagiostomum*, *Urastoma*)

ORDER FECAMPIIDA Fecampiidans. Endoparasites of various marine invertebrates and vertebrates; lacking a pharynx and intestine; with a ciliated epidermis but with vertical ciliary rootlets reduced. (e.g., *Fecampia*, *Glanduloderma*, *Ichthyophaga, Kronborgia*)

SUBCLASS BOTHRIONEODERMATA

INFRACLASS BOTHRIOPLANATA Freshwater / terrestrial flatworms bearing a three-branched, diverticulated gut, and medial-posteriorly directed plicate pharynx; multiple follicular vitellaria.

ORDER BOTHRIOPLANIDA Monospecific, *Bothrioplana semperi,* a freshwater/terrestrial scavenger and predator on small invertebrates.

INFRACLASS NEODERMATA Flukes and tapeworms. Ciliated larval epidermis shed and replaced by a syncytial neodermis with subepithelial nuclei (the tegument); locomotory epidermal cilia bearing a single rootlet; epithelial sensory receptors with collars.

COHORT TREMATODA Digenean and aspidogastrean flukes (Figures 17.1M and 17.3A,B,E,F). With one or more suckers; lacking prohaptor and opisthaptor; male copulatory organ is a cirrus; 1 to 3 hosts during the life cycle, often including a mollusc; most are endoparasitic.

SUPERORDER ASPIDOGASTREA Aspidogastrean flukes.

ORDER ASPIDOGASTRIDA With a complex ventral sucker formed by lateral growth and

for more ebooks/tests/manuals request to Email 9601267734@qq.com

subdivision of posterior part of sucker. Most with a single host (a mollusc) in life cycle; second host, when present, a turtle or a teleost fish; oral sucker absent. (e.g., *Aspidogaster*, *Cotylaspis*)

ORDER STICHOCOTYLIDA With complex ventral sucker formed by linear growth and subdivision of anterior part of sucker. Most with single host (a lobster) in life cycle; second host, when present, is a chondrichthyan fish. (e.g., *Stichocotyle*, *Rugogaster*)

SUPERORDER DIGENEA Digenean flukes.

ORDER DIPLOSTOMIDA Endoparasites of tetrapods; adult genital pore posterior to the ventral sucker; some with blood-dwelling adult stages. Usually with complex 3-host life cycles but occasionally with 2; first intermediate host is a mollusc. Includes the schistosomes. (e.g., *Schistosoma, Sanguinicola, Trichobilharzia, Tylodelphys*)

ORDER PLAGIORCHIIDA An extraordinarily diverse order of vertebrate endoparasites with a wide range of life cycle characteristics and hosts. Usually with at least a 2-host life cycle; first intermediate host is a mollusc. Fasciolosis is a snail-borne disease causing serious public and veterinary health problems worldwide, caused by infection with *Fasciola hepatica* or *F. gigantica* through foods or water contaminated with metacercarial cysts. (Other notable genera include *Echinostoma, Opisthorchis* [= *Clonorchis*], *Microphallus*, *Parorchis*)

COHORT MONOGENEA Monogenean flukes (Figure 17.3C). Oral sucker (prohaptor) reduced or absent; posterior hook-bearing sucker (opisthaptor) present; ventral sucker (acetabulum) absent; gut bifurcate; 3 rows of cilia on oncomiracidium larva; life cycle involves only 1 host. Most are ectoparasitic, usually on fishes (some occur on turtles, frogs, hippos, copepods, or squid); a few are endoparasitic in ectothermic vertebrates. Although previously classified according to the relative complexity of the opisthaptor (Figure 17.8; simple, Monopisthocotylea; complex, Polyopisthocotylea), the evolutionary relationships within and among these taxa remain unclear. Nine orders are now recognized. Monogenea and Cestoda constitute a clade called Cercomeromorpha.

ORDER CAPSALIDEA Capsalids. Gill and skin ectoparasites of elasmobranch and teleost fishes; flattened, leaflike bodies with a simple aseptate or septate opisthaptor; with 3 pairs of median sclerites and 14 small hooklets at the periphery of the opisthaptor. (e.g., *Capsala*, *Benedeniella*, *Trochopus*)

ORDER CHIMAERICOLIDEA Gill parasites of holocephalan fishes. (e.g., *Chimaericola*)

ORDER DICLYBOTHRIIDEA Gill parasites of acipenseriform fishes. Oral sucker absent; mouth ventral; lateral sclerites on opisthaptor absent. (e.g., *Diclybothrium*, *Paradiclybothrium*)

ORDER DACTYLOGYRIDEA Gill parasites of freshwater teleost fish; body with opisthaptor bearing 2–4 anchors with 14–16 marginal hooks, and 4 eyespots. (e.g., *Dactylogyrus*, *Ancyrocephalus*)

ORDER GYRODACTYLIDEA Skin and gill parasites of freshwater fish; body fusiform with terminal cephalic lobes; opisthaptor forms a half oval and is armed with 16 marginal hooks and a pair of median anchors (hamuli) stabilized with median bars. (e.g., *Gyrodactylus*, *Paragyrodactyloides*, *Acanthoplacatus*)

ORDER MAZOCRAEIDEA Gill parasites of clupeid and scombrid fishes; oncomiracidium with 1 pair of fused eyes; opisthaptor with 2 pairs of lateral sclerites. (e.g., *Clupeocotyle*, *Mazocraes*, *Grubea*)

ORDER MONOCOTYLIDEA Gill and ectodermal tissue parasites of mostly tropical elasmobranchs; opisthaptor with a single central and multiple peripheral suckers (loculi), often armed with hamuli and marginal hooks. (e.g., *Monocotyle*, *Potamotrygonocotyle*)

ORDER MONTCHADSKYELLIDEA Gill parasites of tropical reef fishes. (e.g., *Montchadskyella*)

ORDER POLYSTOMATIDEA Skin, gill, and urogenital parasites of aquatic and semiaquatic tetrapods; opisthaptor well developed with 3 pairs of suckers or 1 sucker pair. (e.g., *Polystoma*, *Oculotrema*, *Metapolystoma*)

COHORT CESTODA Tapeworms and their relatives (Figures 17.1N and 17.4). Exclusively endoparasitic; in most, the body consists of an anterior scolex, followed by a short neck, and then a strobila composed of a series of "segments" or proglottids, although basal taxa are monozoic (not strobilated); digestive tract absent. Previous classifications recognized several subclasses; until taxonomic uncertainty is resolved, we recognize 16 orders.

ORDER AMPHILINIDEA Endoparasites in the guts or coelomic cavities of cartilaginous and certain primitive bony fishes, less commonly in turtles; leaflike bodies, lacking scolex and monozoic (not strobilated); 10 minute hooks may be present at posterior of body if retained from decacanth larvae that may develop in crustaceans. (e.g., *Amphilina*, *Austramphilina, Gyrometra*)

ORDER GYROCOTYLIDEA Intestinal parasites of holocephalan fishes although also

reported in sharks; body stout, monozoic with a muscular anterior attachment organ; posterior body terminates in a rosettelike adhesive organ; lateral margins often ruffled; life cycles are unknown. (e.g., *Gyrocotyle, Gyrocotyloides*)

EUCESTODA

ORDER BOTHRIOCEPHALIDEA Gut parasites of teleost fishes and occasionally in acipenseriforms and amphibians; body strobilated with proglottids wider than long; scolex with a pair of bothria; occasionally with hooks; life cycle with 2–3 hosts, usually a crustacean first host and a teleost second host. (e.g., *Bothriocephalus*, *Triaenophorus*, *Polyonchobothrium*)

ORDER CARYOPHYLLIDEA Intestinal parasites of cypriniform and siluriform fishes; body monozoic (not strobilated); scolex often simple; with 2-host life cycles; oligochaetes as intermediate hosts. (e.g., *Archigetes*, *Paraglaridacris*)

ORDER CYCLOPHYLLIDEA Intestinal parasites of birds and mammals; body variable in size, scolex with 4 suckers, rostellum is present, may be armed or not; most species are hermaphrodites although the family Dioecocestidae is gonochoristic; highly diverse and possibly the most derived order of cestodes; life cycles with 2–3 hosts with diverse invertebrate and vertebrate species as intermediate and paratenic hosts. (e.g., *Dipylidium*, *Hymenolepis*, *Moniezia*, *Taenia*)

ORDER DIPHYLLIDEA Intestinal parasites of Chondrichthyes fishes; body strobilated with midventral genital pores; scolex with 2 bothria and a cephalic peduncle; life cycles are poorly known but larval stages occur in marine crustaceans and molluscs. (e.g., *Echinobothrium*, *Ditrachybothridium*)

ORDER DIPHYLLOBOTHRIIDEA Intestinal parasites of piscivorous vertebrates, usually mammals; body strobilated but with variable external differentiation; scolex always unarmed, usually with paired attachment grooves (bothria); with 2- to 3-host life cycles; copepod crustaceans as first intermediate hosts, second intermediate hosts within vertebrates. (e.g., *Diphyllobothrium*, *Ligula*, *Spirometra*)

ORDER LECANICEPHALIDEA Small intestinal parasites of rays and occasionally sharks; although probably paraphyletic, species are characterized by a scolex with 4 suckers or bothria and an apical structure that may have tentacles, cones, or additional suckers; life cycles are poorly known but may include molluscs, crustaceans, and teleosts as intermediate hosts. (e.g., *Polypocephalus*, *Quadcuspibothrium*, *Corrugatocephalum*)

ORDER LITOBOTHRIIDEA Intestinal parasites of lamniform sharks; scolex with apical sucker and several muscular, cruciform pseudosegments; life cycles are unknown. (e.g., *Litobothrium*)

ORDER ONCHOPROTEOCEPHALIDEA Small to medium-sized intestinal parasites of Chondrichthyes, as well as of freshwater fish, amphibians, reptiles, and occasionally mammals; strobila polyzoic, with proglottids, or with few anapolytic (nondetaching) proglottids; with lateral, irregularly alternating genital pores; scolex often with 4 muscular bothridia, unarmed or with 1 pair of hooks; occasionally with a rostellum-like apical structure; life cycles include 1 or 2 intermediate hosts (crustaceans or fish); this order has subsumed the former order Proteocephalidea and part of the Tetraphyllidea. (e.g., *Proteocephalus*, *Chambriella*, *Brachyplatysoma, Acanthobothrium*, *Platybothrium*)

ORDER PHYLLOBOTHRIIDEA Small to medium-sized intestinal parasites of sharks, batoids, and ratfish; strobili polyzoic and with proglottids, scolex often with 4 muscular bothridia. (e.g., *Calyptrobothrium*, *Chimaerocestos*, *Marsupiobothrium*)

ORDER RHINEBOTHRIIDEA Intestinal parasites of freshwater stingrays; scolex often with bothridial stalks. (e.g., *Spongiobothrium*)

ORDER SPATHEBOTHRIIDEA Intestinal parasites of Chondrichthyes and teleost fishes; body strobilated without external differentiation of proglottids; male and female genital pores close together and alternating dorsally and ventrally the length of the body; with 2-host life cycles; crustaceans as intermediate hosts; progenesis (early maturation) of larvae is widespread. (e.g., *Spathebothrium, Bothrimonus*)

ORDER TETRABOTHRIIDEA Intestinal parasites of marine homeotherms inhabiting pelagic ecosystems; body with well-defined strobilation; scolex with 4 muscular bothridia of variable form; rostellum lacking; eggs with 3 membranes; life cycles are unknown but are likely to involve crustaceans, cephalopods, and teleosts as intermediate hosts. (e.g., *Priapocephalus, Tetrabothrius, Trigonocotyle*)

ORDER TETRAPHYLLIDEA Intestinal parasites of elasmobranch fishes, rarely in holocephalan fishes; body strobilated with variable apolysis of proglottids; scolex often with 4 muscular bothridia that vary widely in form, often elongate, stalked and with hooks; life cycles are poorly known, but 3–5 hosts are likely and include molluscs, crustaceans, teleosts, and marine mammals; a recent molecular analysis has

for more ebooks/test bank/solution manuals requests Email 9601267344@qq.com

shown this order to be nonmonophyletic, and genera are being redistributed to other orders (Onchoproteocephalidea, Phyllobothriidea). (e.g., *Rhoptrobothrium*, *Dinobothrium*)

ORDER TRYPANORHYCHA Intestinal and stomach parasites of Chondrichthyes fishes; body strobilated with lateral genital pores; scolex with 4 eversible tentacles, each bearing a complex array of hooks; 2- to 3-host life cycles with crustaceans and teleosts and intermediate hosts. (e.g., *Dasyrhynchus*, *Halsiorhynchus*, *Otobothrium*)

The Platyhelminth Body Plan

The basics of a flatworm body plan can be appreciated by examining the rather complex structural features displayed by the free-living flatworms (Figure 17.2). The mesenchyme, derived from mesoderm, is fibrous and muscular, allowing for the formation of structural support and locomotion. Elaborate reproductive systems (male and female) provide for internal fertilization and enhance the production of yolky and encapsulated eggs. Most flatworms have abandoned free-swimming larval stages for mixed and direct life histories. Osmoregulatory structures in the form of protonephridia were most likely instrumental in the invasion of freshwater and later terrestrial environments.

The platyhelminth body plan has high energy demands for an active lifestyle. A major limiting factor for flatworms, functionally, is the absence of an efficient circulatory mechanism to move materials throughout the body. This problem is compounded by the lack of any special structures for gas exchange. These problems relate, of course, to the surface-to-volume dilemma discussed in Chapter 3. In the absence of circulatory and gas exchange structures, flatworms (particularly free-living ones) are constrained in terms of size and shape. They have remained relatively small and flat, with shapes that maintain short diffusion distances. The largest free-living flatworms have highly branched guts that assume much of the responsibility of internal transport.

Having a high surface-to-volume ratio and using the entire body surface for gas exchange create potential problems of ionic balance and osmoregulation in freshwater and terrestrial species, and of desiccation in intertidal and terrestrial habitats. The permeable body surface must be kept moist; thus, flatworms have invaded land rarely and mostly in very damp areas, although a few rhabdocoels and prorhynchids and several parasitic species have developed desiccation-resistant life stages. Flatworms have, however, exploited a variety of marine and freshwater habitats and are particularly successful as parasites and commensals, enjoying the benefits of living on or in their hosts.

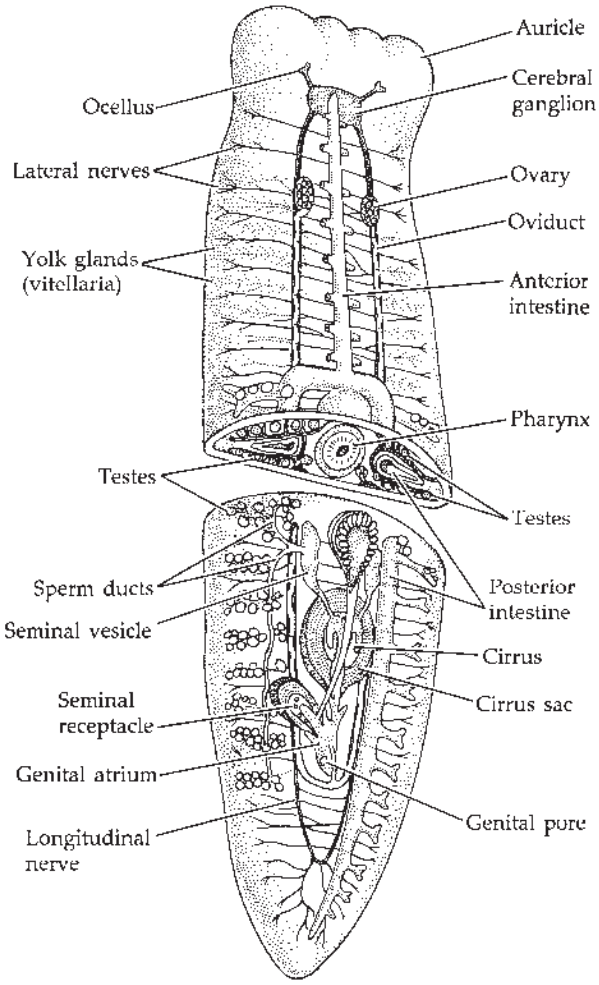

FIGURE 17.2 Anatomy of a generalized freshwater flatworm (order Tricladida).

The ancestral flatworm is thought to have been a free-living form, from which the present-day catenulids and rhabditophorans evolved and diversified. The flukes and tapeworms evolved from within the rhabditophoran assemblage (discussed in more detail later in this chapter). Thus, in each of the following sections we first examine the basic features of the free-living flatworms and set the stage for understanding not only the diversity within that body plan but the derivation of the specialized parasitic taxa as well.

Platyhelminths have become famous in biological lore for their unique totipotent stem cell system, the **neoblasts**, which can comprise around 20% or more of the cells in an adult animal. Neoblasts are thought to be competent for the renewal of all cell types, including germ cells, and they are presumed to be responsible for the maintenance of a healthy population of differentiated somatic cells. The power of neoblasts is what confers on flatworms their phenomenal regeneration powers.

The anatomy of free-living flatworms, flukes, and tapeworms is shown in Figures 17.2, 17.3, 17.4, and

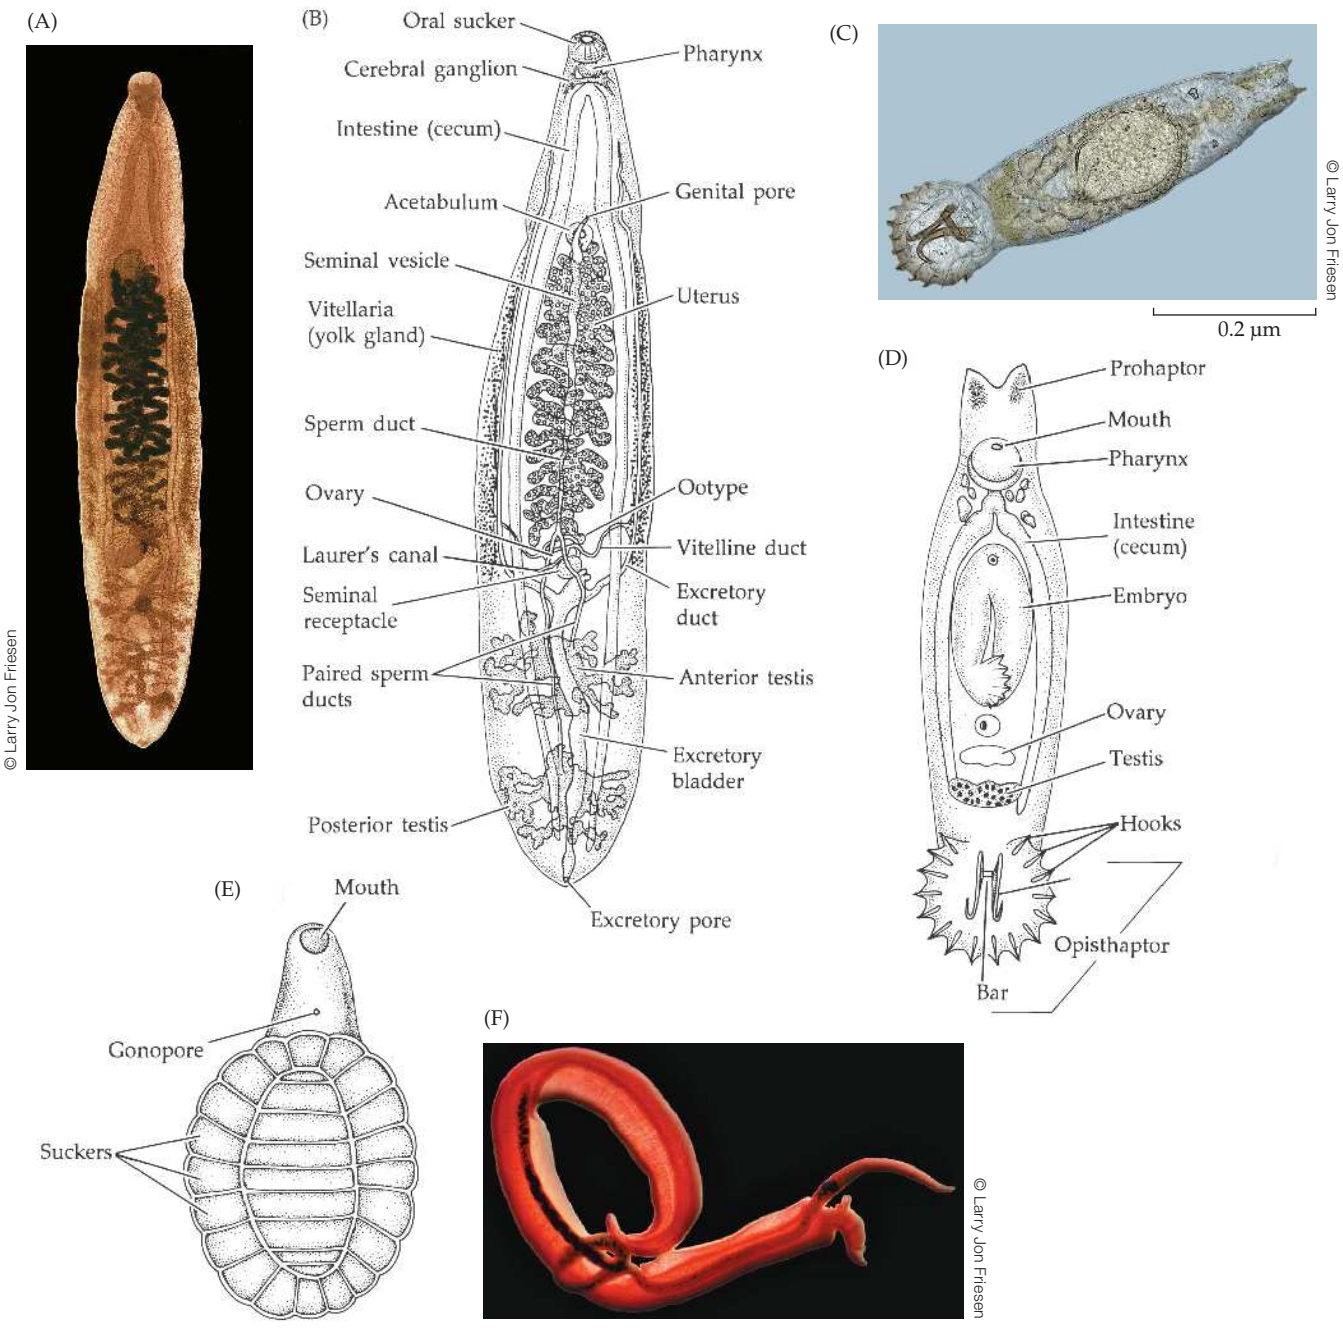

FIGURE 17.3 Representative flukes. (A,B) *Clonorchis sinensis*, a plagiorchiid trematode that inhabits human livers. (C,D) *Gyrodactylus* (Monogenea), an ectoparasite on fishes. (E) *Cotylaspis* (an aspidogastrid trematode). (F) The human blood fluke, *Schistosoma mansoni* (a copulating male and female), a diplostomidan fluke and one of the few gonochoristic flatworms.

17.6. Free-living flatworm species vary in shape from broadly oval to ribbonlike and are typically flattened dorsoventrally, although very small ones may be nearly cylindrical. The head is usually ill defined, except for the presence of sense organs. The mouth is often located ventrally, either near the middle of the body or more anteriorly, though again, there are exceptions (e.g., prorhynchids whose raptorial mouth is fully anterior; cestodes who have no mouth at all). Most flukes (Figure 17.3) are oval or leaf shaped and bear external attachment organs such as hooks and suckers. As their common name suggests, the tapeworms are typically elongate and ribbonlike (Figure 17.4). Their anterior end forms a tiny **scolex**, modified for attachment within the host; the rest of the body is essentially a reproductive machine.

Tapeworms live in the guts of vertebrates. Most species belong to the Cestoda and possess three distinguishable regions of the body. The **scolex** serves for attachment and is usually armed with hooks and suckers. Immediately behind the scolex is a short region called

for more books/test bank/solution manuals requests Email 9601267734@qq.com

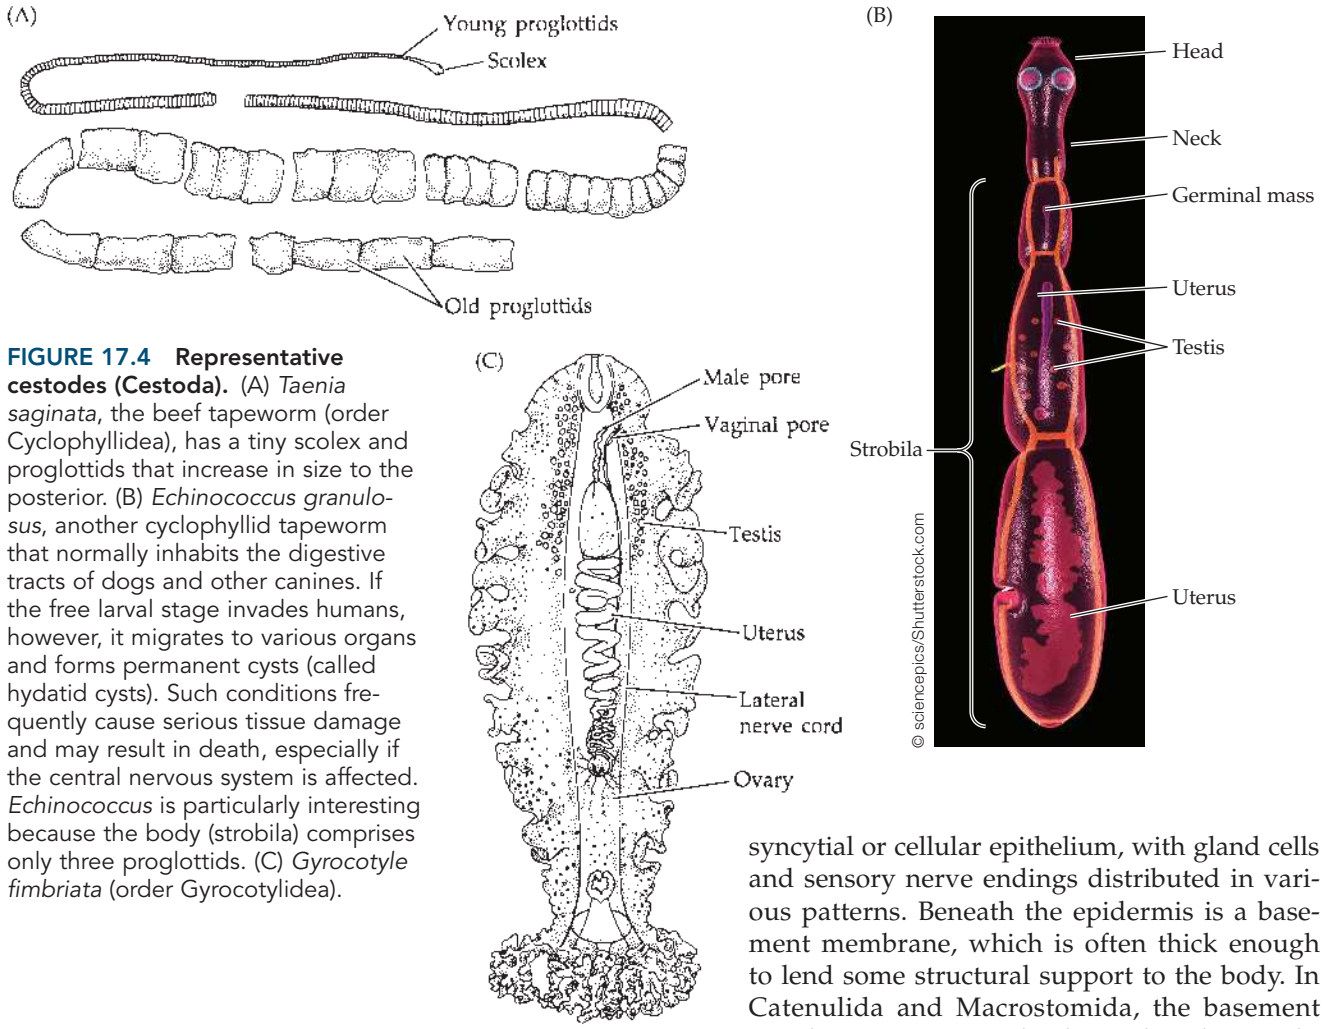

FIGURE 17.4 Representative cestodes (Cestoda). (A) *Taenia saginata*, the beef tapeworm (order Cyclophyllidea), has a tiny scolex and proglottids that increase in size to the posterior. (B) *Echinococcus granulosus*, another cyclophyllid tapeworm that normally inhabits the digestive tracts of dogs and other canines. If the free larval stage invades humans, however, it migrates to various organs and forms permanent cysts (called hydatid cysts). Such conditions frequently cause serious tissue damage and may result in death, especially if the central nervous system is affected. *Echinococcus* is particularly interesting because the body (strobila) comprises only three proglottids. (C) *Gyrocotyle fimbriata* (order Gyrocotylidea).

the **neck**, followed by an elongated, segmented trunk, or **strobila**, consisting of individual **proglottids**. The proglottids bud (strobilate) from a germinal zone in the neck (or at the base of the scolex when a neck is absent). As new proglottids arise at the base of the trunk, older ones mature, become inseminated, and fill with embryos. "Segmentation," or **strobilation**, in tapeworms is thus not by way of teloblastic growth (discussed in Chapters 15 and 20), and it is clearly not homologous to the segmentation seen in annelids and arthropods.

Tapeworms in the orders Amphilinidea and Gyrocotylidea are somewhat flukelike in appearance. They lack a scolex, and the body is not divided into proglottids. They are placed within the Cestoda because of the absence of a digestive tract and because of certain features of the life cycle. They may represent the primitive, prestrobilation body plan of the Cestoda.

Body Wall

Free-living flatworms The body wall of these species is multilayered and complex (Figure 17.5). The epidermis is composed of a wholly or partially ciliated, syncytial or cellular epithelium, with gland cells and sensory nerve endings distributed in various patterns. Beneath the epidermis is a basement membrane, which is often thick enough to lend some structural support to the body. In Catenulida and Macrostomida, the basement membrane is apparently absent, but this condition is viewed as secondarily derived. Internal to the basement membrane are smooth muscle cells, frequently arranged in rather loosely organized outer circular, middle diagonal, and inner longitudinal layers. The area between the body wall and the internal organs is usually filled with a mesenchyme (often called a parenchyme) that includes a variety of loose and fixed cells, muscle fibers, and connective tissue. Many macrostomorphans appear to lack a cellular mesenchyme.

The gland cells of the body wall are generally derived from ectoderm. When mature, many of these cells lie in the mesenchyme with a "neck" extending between epidermal cells to the body surface. These cells produce mucous secretions that serve a number of functions. In semiterrestrial and intertidal flatworms, the mucus forms a moist covering that provides protection from desiccation and aids in gas exchange. Most benthic flatworms possess a ventral concentration of mucous gland cells that secrete a slime that aids in locomotion. Mucous secretion around the mouth aids in prey capture and swallowing. Other gland cells or complexes of cells provide granules containing adhesives for temporary attachment, as well as granules that break the attachment, occurring several times per second. Such

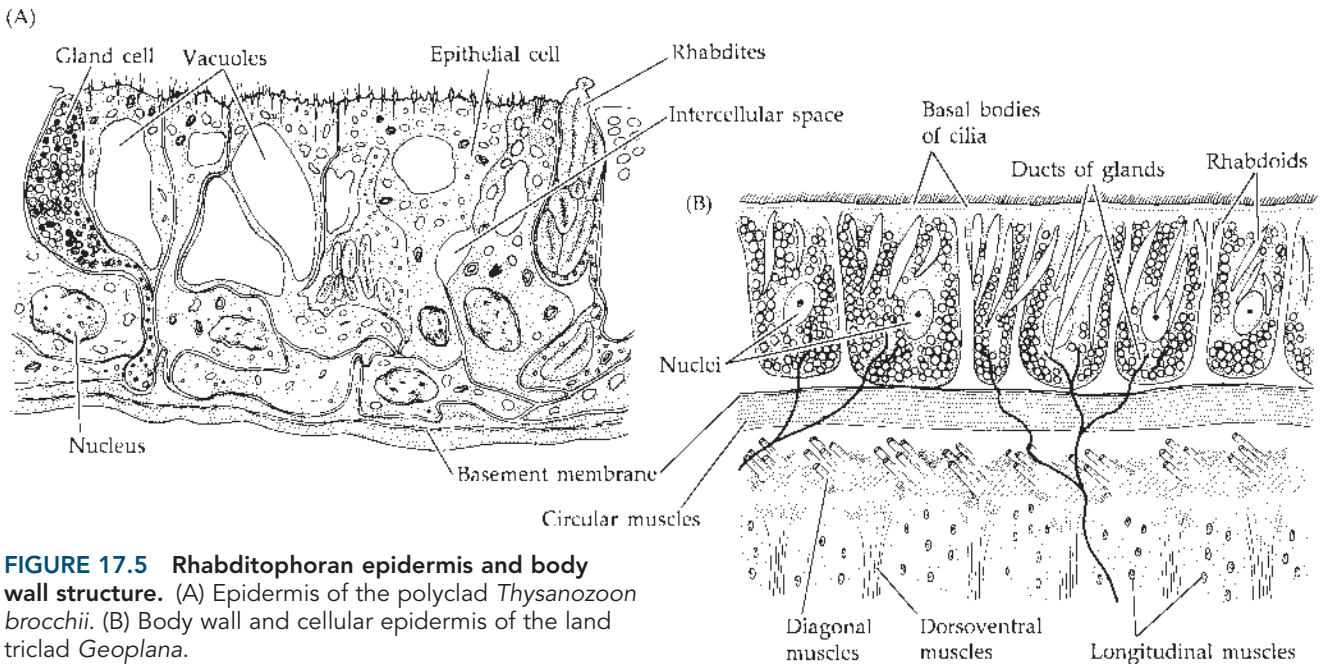

FIGURE 17.5 Rhabditophoran epidermis and body wall structure. (A) Epidermis of the polyclad *Thysanozoon brocchii*. (B) Body wall and cellular epidermis of the land triclad *Geoplana*.

duo-gland adhesion systems (often involving a third cell type that provides structural support) are widespread in free-living flatworms and other phyla with similar lifestyles. In some ectocommensal forms (e.g., *Bdelloura* triclads and various temnocephalid dalytyphloplanids; Figure 17.6) these adhesive glands are associated with special plates or suckers for attachment to the host.

In most free-living flatworms epidermal and subepidermal gland cells produce structures called **rhabdoids** (Figure 17.5B). These rod-shaped cellular inclusions produce mucus when moved to the surface of the epithelium. Some other phyla (e.g., Xenacoelomorpha, Gastrotricha, Nemertea, Annelida) have similar, but probably convergently evolved, secretory cellular bodies. The mucus aids in ciliary gliding and also may help protect animals from desiccation and from predators. Some rhabdoids that are produced by gland cells in the epidermis or mesenchyme have a distinct cortex (composed of concentrically arranged lamellae) and medulla, and these are called **rhabdites**. These structures

can reach the body surface through intercellular spaces in the epidermis (Figure 17.5A). They also contribute to mucus production and, in some species, release noxious chemicals for defense. Rhabdites are diagnostic of the huge flatworm clade (subphylum) Rhabditophora. Somewhat similar structures, called "false rhabdites," have been described from the other main flatworm clade (subphylum) Catenulidea, but they may not be homologous to those of Rhabditophora.

Some species of free-living flatworms (e.g., macrostomids, proseriates, polyclads) have prominent tubercles covering the dorsal surface, and these probably also have a defensive role. In some species, unfired nematocysts from hydroid prey are transported to the tubercles. In others, such as species of *Thysanozoon*, the tubercles appear to release a powerful acid that may deter would-be predators.

Flukes and tapeworms Modifications of the outer body covering are common among parasites, and platyhelminths are no exception. Unlike the free-living flatworms, flukes and tapeworms possess an external covering called a **tegument**, formed of nonciliated cytoplasmic extensions of large cells whose cell bodies actually lie in the mesenchyme (Figure 17.7). The extensions fuse their margins such that the outer surface of the worm forms a functional syncytium. The tegument not only provides some protection, but also is an important site of exchange between the body and the environment. Gases and nitrogenous wastes move across this surface by diffusion, and some nutrients, especially amino acids, are taken in by pinocytosis. In tapeworms, the uptake of nutrients occurs solely across the body wall, and the surface area of the tegument is greatly increased by many tiny folds called **microtriches** (Figure 17.7B). As one of nature's more remarkable adaptations, these folds may interdigitate with the intestinal microvilli of the host organism and aid in the absorption of nutrients.

The nature of the tegument in flukes and tapeworms is viewed by some zoologists as unique and of major phylogenetic importance. The larvae of these parasitic worms have a "normal" ciliated epidermis over at least part of their bodies. However, this epidermis is shed, and postlarval stages develop a new, syncytial body covering—the **neodermis**. This phenomenon appears to be a unique synapomorphy uniting the Monogenea, Trematoda, and Cestoda as a monophyletic taxon that Ehlers named Neodermata (in reference to the "new skin" of these animals), a hypothesis that is now substantiated by all molecular phylogenetic analyses.

The tegument/neodermis is underlain by a basement membrane, beneath which is the mesenchyme. Most flukes and tapeworms have circular and longitudinal muscles within the mesenchyme, and sometimes diagonal, transverse, and dorsoventral muscles as well. The mesenchyme varies from masses of densely packed cells to syncytial and fibrous networks with fluid-filled spaces. In some digenean flukes (Trematoda: orders Diplostomida and Plagiorchiida), spaces form vessels

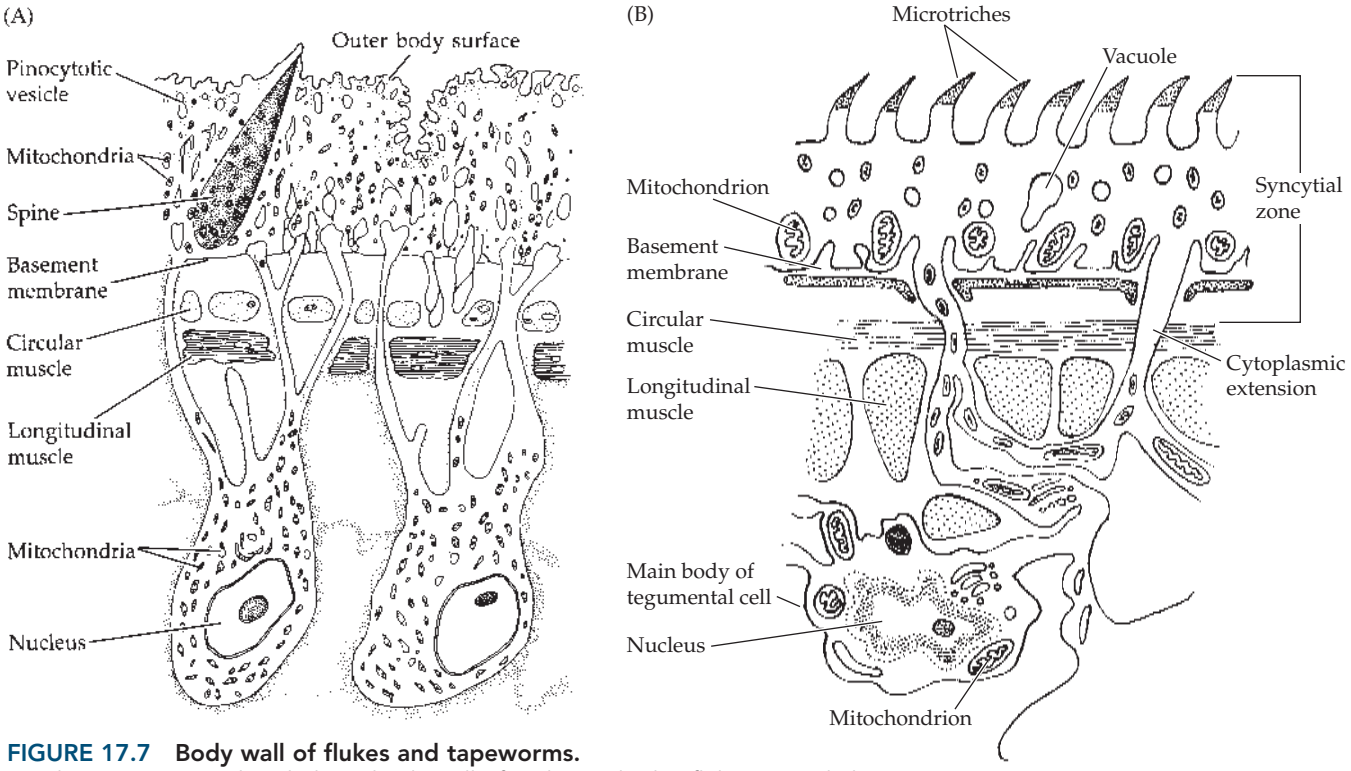

FIGURE 17.7 Body wall of flukes and tapeworms.

through the mesenchyme called **lymphatic channels**, which contain free cells that have been likened to lymphocytes. The mesenchyme also contains gland cells with connections to the surface of the body through the tegument. These gland cells are few in number compared with those of free-living flatworms, and they are primarily adhesive in nature and associated with certain organs of attachment.

One of the least explored yet most interesting attributes of tapeworms, and indeed of all intestinal parasites, is their ability to thrive in an environment of hydrolytic enzymes without being digested. In addition to constant replacement of the outer tegument by underlying cells, one popular hypothesis is that gut parasites produce enzyme inhibitors (sometimes called "antienzymes"). One study showed that *Hymenolepis diminuta* (a common tapeworm in rats and mice) releases proteins that appear to inhibit trypsin activity. This tapeworm can also regulate the pH of its immediate environment to about 5.0 by excreting organic acids; this acidic output may also inhibit the activity of trypsin.

Support, Locomotion, and Attachment

Only a very few flatworms possess any sort of special skeletal elements. In a few free-living species, tiny calcareous plates or spicules are embedded in the body wall (Figure 17.1L). Body support in all other flatworms is provided by the hydrostatic qualities of the mesenchyme, the elasticity of the body wall, and the general body musculature.

Most free-living, benthic species move on their ventral surface by cilia-powered gliding. Mucus provides lubrication as the animal moves and serves as a viscous medium against which the cilia act. Some of the larger or more elongate forms also use muscular contractions. The ventral surface of the body is thrown into a series of alternating transverse furrows and ridges that move as waves along the animal, propelling it forward. Muscular undulations of the lateral body margins allow some large polyclads to swim for brief periods of time. Muscular action allows the body to twist and turn, providing steerage. Some interstitial forms are highly elongate and use the body wall muscles to slither between sand grains. Many of these types of flatworms possess adhesive glands, the secretions of which provide temporary stickiness and enable the animals to gain purchase and leverage as they move.

Adult flukes lack external cilia, and their movement depends on their body wall muscles or on the body fluids of their host. Some move about slowly on or within their host by muscle action, and a few (e.g., blood flukes) are carried in the host's circulatory system. However, certain larval stages are highly motile and do swim using ciliary action. Once established within or on a host, it is usually advantageous for a fluke to stay more or less in one place. In that regard, nearly all of them are equipped with external organs for temporary or permanent attachment (Figures 17.3C and 17.8). Monogenean flukes typically have an anterior and a posterior adhesive organ called the **prohaptor** and the **opisthaptor**, respectively. The prohaptor consists of a pair of adhesive structures, one on each side of the mouth, bearing suckers or simple adhesive pads. The opisthaptor is usually the major organ of attachment and includes one or more well-developed suckers with hooks or claws.

The digenean flukes possess two hookless suckers. One, the **oral sucker**, surrounds the mouth, and the other, the **acetabulum**, is located elsewhere on the ventral surface (Figure 17.3B). These suckers are usually supplied with adhesive gland cells, although the well-developed ones operate mainly on suction produced by muscle action. The aspidogastrean flukes lack an oral sucker but have a large, subdivided ventral sucker (Figure 17.3E).

Adult tapeworms (Cestoda) do not move around much, but they are capable of muscular undulations of

the body. They remain fixed to the host's intestinal wall by the **scolex** (or, in the case of members of the cestode order Amphilinidea, by an anterior adhesive organ) and by the microtriches. The details of scolex anatomy (Figure 17.9) are extremely variable and have great importance in the taxonomy of tapeworms. The tip of the scolex in many cestodes (e.g., *Taenia*) is equipped with a movable hook-bearing **rostellum**, which is sometimes retractable into the scolex. In others (e.g., *Cephalobothrium*) the anterior end bears a protrusible sucker, or adhesive pad, called a **myzorhynchus**. The rest of the scolex bears various suckers or suckerlike structures and sometimes hooks or spines. There are three categories of adhesive suckers upon which ordinal and subordinal classification of cestodes is partially based. **Bothria** are elongate, longitudinal grooves on the scolex. They possess weak muscles but are capable of some sucking action. Bothria occur as a single pair and are typical of the orders Diphyllobothriidea (e.g., *Diphyllobothrium*) and Bothriocephalidea. Members of the nonmonophyletic order Tetraphyllidea (e.g., *Acanthobothrium*, *Phyllobothrium*) bear four symmetrically placed **bothridia** around the scolex. These foliose structures are often equipped with suckers at their anterior ends. The third and most familiar type of attachment structures on the scolex are true suckers, or **acetabula**. They are identical in structure and are probably homologous to the acetabula of digenean trematodes. There are usually four acetabula, placed symmetrically around the circumference of the scolex. They are characteristic of many members of the order Cyclophyllidea (e.g., *Dipylidium*, *Taenia*).

Feeding and Digestion

Free-living flatworms Most species are carnivorous predators or scavengers, feeding on nearly any available animal matter or, in the case of very small species, on bacteria or fungi in biofilms. A few are herbivorous on microalgae, and some species switch from herbivory to carnivory as they mature. Their prey include protists or almost any invertebrate small enough to be captured and ingested (e.g., small crustaceans, worms, tiny gastropods). Some species graze on sponges, ectoprocts,

and tunicates, and some consume the flesh of barnacles, leaving behind the empty shell. Most free-living flatworms locate food by chemoreception. Land planarians capture and consume earthworms, land snails, and insects. *Platydemus manokwari*, the 6.5 cm-long "New Guinea flatworm," is a highly invasive species that is a threat for endemic terrestrial molluscs; it has invaded throughout the Pacific, as well as in Europe, the Caribbean, and most recently Florida (USA). *Endeavouria septemlineata* is invasive in at least Hawaii and Brazil, where it feeds on a variety of invertebrates (e.g., isopods, millipedes, earwigs, gastropods). *Obama nungara*, a highly invasive South American species, has widely invaded Europe.

More than 100 species of free-living flatworms are known to be symbiotic with other invertebrates. Some of these are simply commensals that derive some protection from their associations, showing only physical modifications for temporary attachment. Others, however, feed upon their hosts, causing various degrees of damage and displaying true physiological dependency in the relationship. While we can devote space to mentioning only a few examples of symbiotic free-living flatworms, recognition of these situations is of considerable importance. First, it emphasizes the evolutionary adaptability of the flatworm body plan; second, it provides some essential foundation for our later discussion of the origins of the flukes and tapeworms.

Most of the symbiotic free-living flatworms belong to the class Rhabdocoela. Species in the family Temnocephalidae (Figure 17.6B) are ectocommensals within the branchial chambers of freshwater decapod crustaceans, where they feed on microorganisms in the host's gas exchange currents. Temnocephalids also occur on aquatic insects, molluscs, turtles, and a few other kinds of hosts. Several families of Dalytyphloplanida include symbiotic members. For example, *Syndesmis* live within the gut and coelomic fluid of echinoids, where they feed on protists and bacteria, and some may devour cells of their hosts (Figure 17.10). The genera *Graffilla* and *Paravortex* include several species of parasites in the digestive tracts of gastropod and bivalve molluscs, where they derive nutrients from the host tissues. Members of the family Fecampiidae (*Fecampia*, *Kronborgia*, *Glanduloderma*) are parasites in marine crustaceans and certain polychaete worms, where they reside in the host's body fluids and absorb soluble organic nutrients. Non-Rhabdocoela symbiotic species include the triclad *Bdelloura* (Figure 17.6A), an ectocommensal on the gills of *Limulus polyphemus*, the American horseshoe crab. At least two polyclads live and feed on coral (*Prosthiostomum montiporae* on Hawaiian *Montipora*; *Prosthiostomum acroporae* on Australian *Acropora*).

The digestive system of the free-living flatworms includes a mouth and a pharynx, which lead to an intestine, or **enteron**. Like that of cnidarians and Xenacoelomorpha, the free-living flatworm gut is incomplete, bearing a single opening, and thus may be called a **gastrovascular cavity**. The mouth varies in position from midventral to anterior. The pharynx is derived from embryonic ectoderm (i.e., it is stomodeal) and lined with epidermis. Epithelial **pharyngeal glands** are associated with the lumen of the pharynx; they produce mucus that aids in feeding and swallowing, and (in some species) they produce proteolytic enzymes that initiate digestion outside the body.

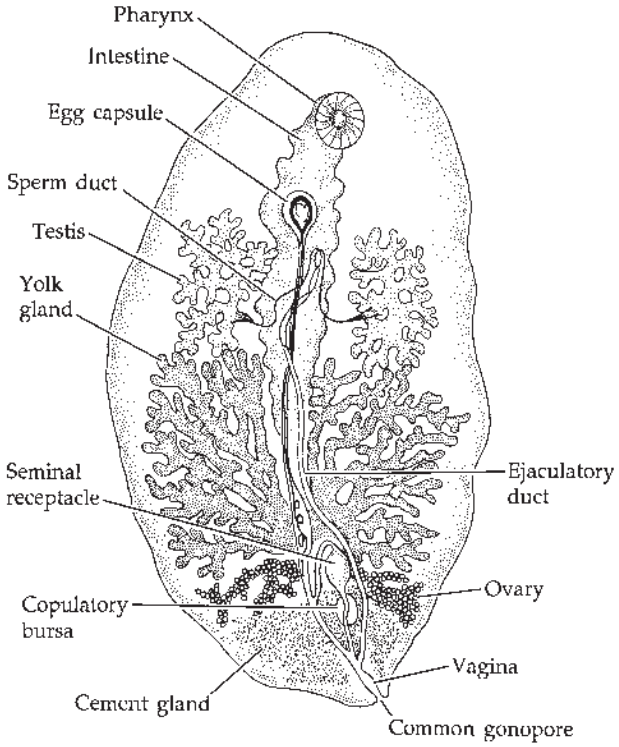

FIGURE 17.10 ***Syndesmis*, a symbiotic rhabdocoel from the gut of a sea urchin.**

The feeding methods of free-living flatworms vary with the size of the animal and the complexity of their food-gathering apparatus, especially the pharynx. As noted in the classification scheme, the nature of the pharynx varies greatly among taxa. There are three basic pharynx types among the free-living flatworms: simple, bulbous, and plicate (Figures 17.11 and 17.12).

A **pharynx simplex** (simple pharynx) is a short, ciliated tube connecting the mouth and intestine (Figure 17.12). This type of pharynx has been considered plesiomorphic within the phylum Platyhelminthes and is found in the orders Macrostomida and Catenulida. In all members of these orders, the pharynx leads to a simple saclike or elongate intestine generally lacking extensive diverticula. Free-living flatworms with a simple tubular pharynx are generally quite small, with the mouth located more or less midventrally. They usually feed by sweeping small organic particles and tiny prey into the pharynx by ciliary action.

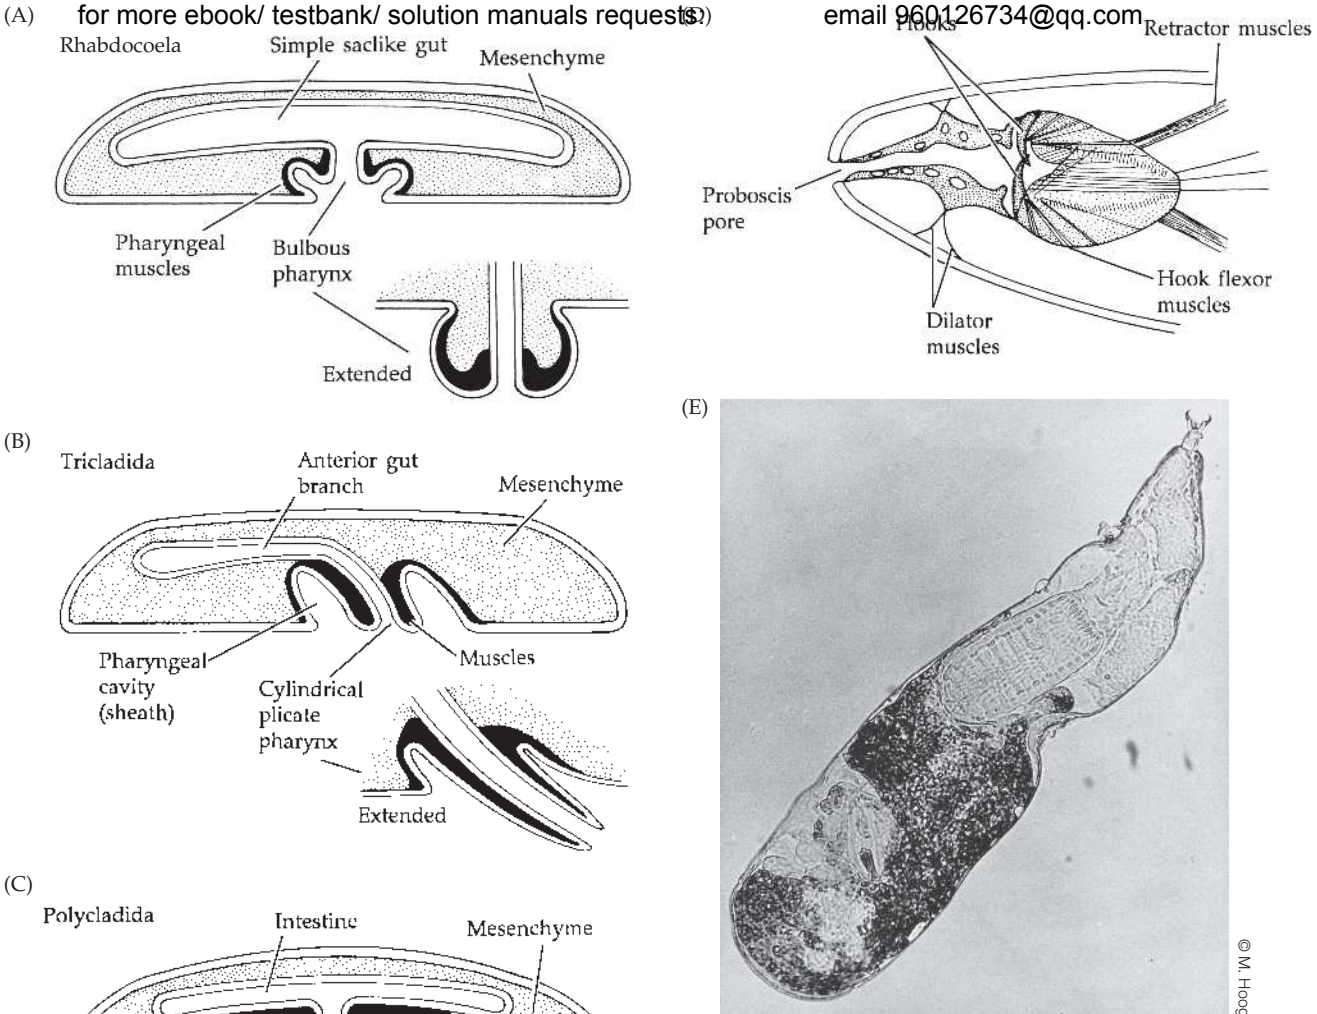

FIGURE 17.11 Pharynges of flatworms. (A–C) The pharynges of three free-living flatworms (sagittal sections). (D) The proboscis apparatus (sagittal section) of the rhabdocoel *Gnathorhynchus* (order Kalyptorhynchia). (E) *Cheliplana*, another rhabdocoel (order Kalyptorhynchia), with jawed proboscis extended (top right).

Those with an eversible pharynx usually fold their body around the prey or other food source and cover it with mucus from the epidermal glands. Then the pharynx is everted over or into the food item.

Some free-living flatworms, especially triclads, secrete digestive enzymes externally via special glands that empty through the pharyngeal lumen or from the tip of the pharynx. The food is partially digested and reduced to a soupy consistency prior to swallowing. Many other species swallow their food whole by the action of powerful pharyngeal muscles.

Rhabdocoels typically possess a slightly protractile, muscular, bulbous pharynx and a simple saclike gut (Figures 7.11A and 17.13A). Members of the Proseriata, Tricladida, and Polycladida have eversible plicate

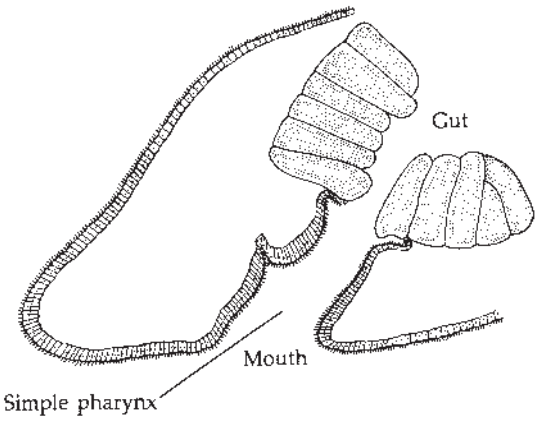

FIGURE 17.12 Sagittal section through anterior end of *Macrostomum* (Macrostomorpha), which has a simple tubular pharynx.

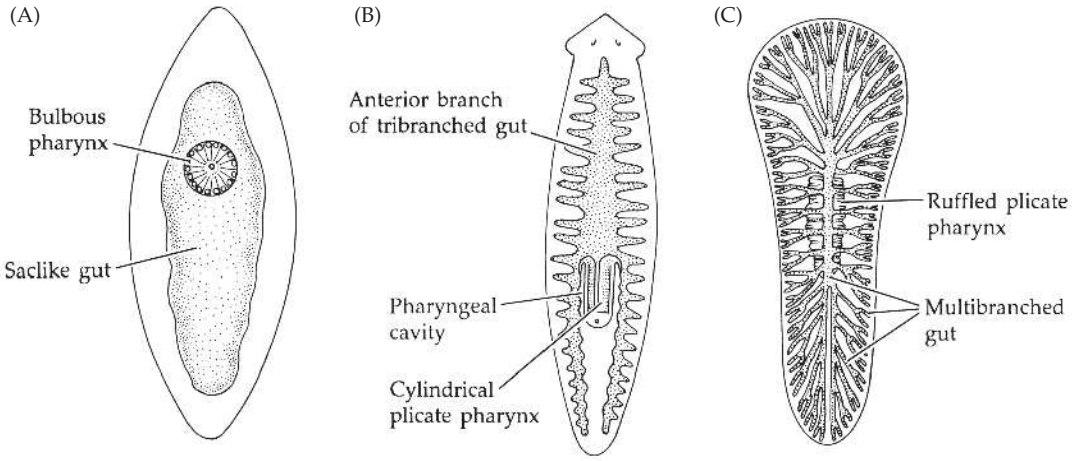

FIGURE 17.13 Pharynx type and gut shape combinations among free-living flatworms. (A) Rhabdocoela. (B) Tricladida. (C) Polycladida.

pharynges. The eversible portion of a plicate pharynx lies within a space called the pharyngeal cavity, which is produced by a muscular fold of the body wall (Figures 17.11 and 17.13).

Proseriates and triclads possess cylindrical plicate pharynges oriented along the body axis. Most polyclads have a ruffled, skirtlike plicate pharynx attached dorsally within the pharyngeal cavity. During feeding, a plicate pharynx is protruded by a squeezing action of extrinsic pharyngeal muscles. Once extended, the pharynx can be moved about by intrinsic muscles of its wall. Retractor muscles pull the pharynx back inside the cavity.

Active prey can be subdued in several ways. Some free-living flatworms produce mucus, which, in addition to entangling the prey, may contain narcotic or poisonous chemicals such as tetrodotoxin. A few flatworms use the sharp **stylet** of the copulatory organ to stab prey and even to introduce venom; one cannot help but concede the remarkable adaptive capacity of the flatworms. Members of the Kalyptorhynchia (Rhabdocoela) are unique among free-living flatworms in their possession of a muscular proboscis that is situated at the anterior end of the body and is separate from the mouth (Figure 17.11D,E); the proboscis, which in some species is armed with hooks, can be everted to grab prey.

Most of the free-living flatworms that possess a plicate pharynx are relatively large, especially the triclads and the polyclads. Associated with this large body size is an elaboration of the intestine. As the names imply, the triclad intestine comprises three main branches, one anterior and two posterior, each with numerous diverticula, whereas the intestine of polyclads is multibranched with diverticula (Figure 17.13B,C). These ramifications of the intestine not only provide an increased surface area for digestion and absorption, but also are a means of distributing the products of digestion through the relatively large body in the absence of a circulatory system. The lining of the intestine is a single cell layer of phagocytic nutritive cells and enzymatic gland cells (Figure 17.14). In some groups, the gastrodermis is ciliated.

In most free-living flatworms, initial digestion is extracellular, mediated by endopeptidases secreted from the pharyngeal glands or from enzymatic gland cells within the intestine. The partially digested material is distributed throughout the gut, then phagocytized by the intestinal cells, wherein final (intracellular) digestion occurs. There are, however, some notable exceptions to this sequence. Bowen (1980) described an interesting phagocytic process in the freshwater triclad *Polycelis tenuis*. Following the ingestion of tiny food particles or the preliminary extracellular digestion of larger food, the intestinal phagocytic cells extend processes into the gut lumen, nearly occluding the digestive cavity. These processes interdigitate to form

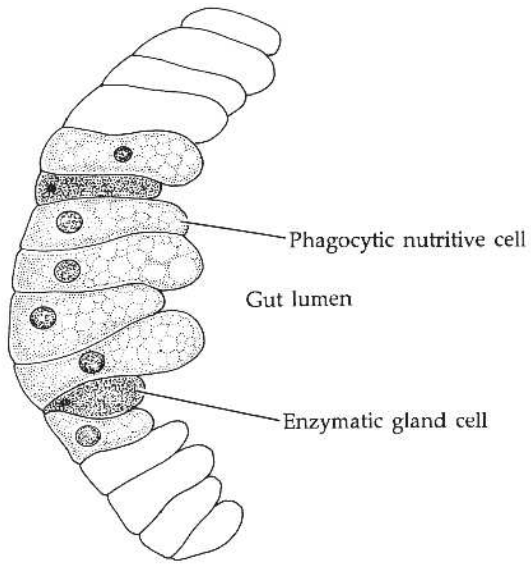

FIGURE 17.14 The gut lining (partial cross section) of a freshwater triclad contains enzymatic gland cells and phagocytic nutritive cells.

for more ebooks/test bank/solution manuals requests Email 9601267734@qq.com

a complex web, forcing food material into the phagocytes, where digestion is completed.

Since flatworms generally lack a through gut, any undigested material must be expelled through the mouth. As discussed in Chapter 3, a major limitation of single-opening guts is the restriction on regional specialization. However, an incipient anus occurs in several flatworms; but does this represent an "experiment" with through gut in this group, or does it represent vestiges of a through gut they once had and have lost? One macrostomorphan, *Haplopharynx rostratus*, possesses a minute anal pore, some polyclads have pores at the ends of gut branches, and some proseriates (e.g., *Tabaota*) may form a temporary anus.

Flukes and tapeworms Adult flukes feed on host tissues and fluids or, in some cases, material within the host's gut. Most of the food is taken in through the mouth by a pumping action of the muscular pharynx, but some organic molecules are picked up across the tegument by pinocytosis. The anterior part of the digestive system includes a mouth, a muscular pharynx, and a short esophagus. The esophagus leads to a pair of intestinal **ceca** (occasionally, a single cecum), which extend(s) posteriorly in the body (Figures 17.3 and 17.15). The lining of the ceca includes absorptive nutritive cells and enzymatic gland cells. Digestion is at least partly extracellular. Some flukes secrete enzymes from the gut out the mouth, or from the suckers, to partially digest host tissue prior to ingestion.

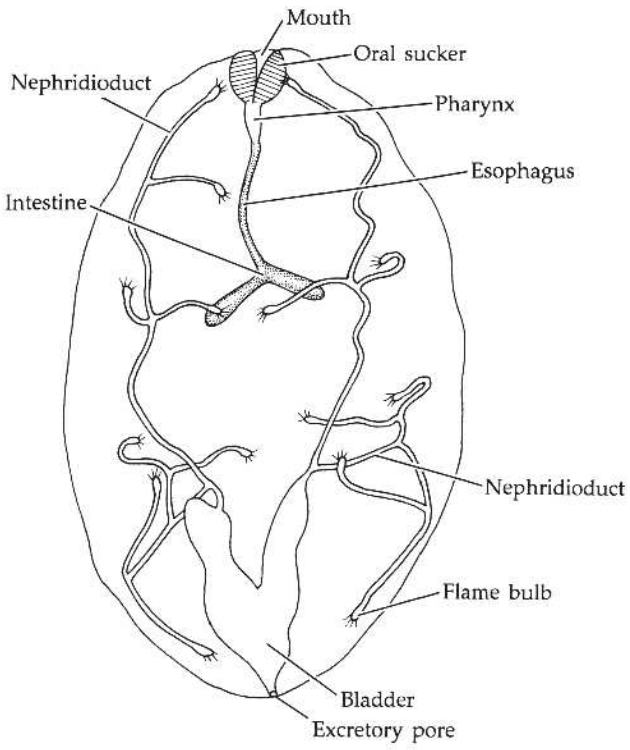

FIGURE 17.15 Gut and protonephridial system of *Microphallus* (order Plagiorchiida; see also Figure 17.3). In most monogenean flukes, the protonephridial ducts are separate and terminate anteriorly in separate pores.

Cestodes lack any vestige of a mouth or digestive tract. All nutrients must be taken into the body across the tegument. Uptake probably occurs by pinocytosis and by diffusion across the increased surface area of the microtriches. Some work suggests that tapeworms are unable to take in large molecules and thus rely to a considerable extent on the digestive processes of their hosts and the secretion of enzymes outside their bodies to chemically reduce the size of potential nutrient material. It has also been proposed that the surface of the scolex may absorb host tissue fluids through the site of attachment to the gut wall.

Many parasites, in numerous phyla, have been shown to alter the behavior of their hosts in ways that are beneficial to themselves, usually by causing the host to position itself such that the odds of success in the next stage in the parasite's life cycle are improved. Parasitic platyhelminths are no exception. For example, larvae of the digenean *Microphallus papillorobustus* encyst in the nervous systems of two species of amphipods (*Gammarus* spp.). There, they induce photophilia in animals that are usually photophobic. Consequently, infected amphipods are more likely than uninfected animals to be eaten by seagulls (a potential final host). When the cestode *Eubothrium salvelini* reaches the developmental stage where it is infective to the final host (brook trout, *Salvelinus fontinalis*), its intermediate host—the copepod *Acanthocyclops vernalis*—begins to swim more often than normal, making it more likely to be eaten by the fish. The beetle *Tribolium confusum* is an intermediate host to the tapeworm *Hymenolepis diminuta*. Evidence suggests the beetle might be more attracted to rat feces that contain the cestode's eggs than to uninfected feces. The same may be true of cockroaches (*Periplaneta americana*) confronted with the feces of rats parasitized by the acanthocephalan *Moniliformis moniliformis*. Infection by the digenetic trematode *Parorchis acanthus* reduces feeding by more than 80% in marsh snails (*Littoraria irrorata*).

Circulation and Gas Exchange

As mentioned earlier, except for the lymphatic channels in some flukes, flatworms lack special circulatory or gas exchange structures. This condition imposes restrictions on size and shape. The key to survival with such limitations and a generally solid mesenchyme is the maintenance of small diffusion distances. Thus, the flatness of their bodies facilitates gas exchange across the body wall, between the tissues and the environment; nutrients are distributed internally by the digestive system and by diffusion, which is aided by general body movements.

The endoparasitic flatworms are capable of surviving in areas of their host where oxygen is absent. In such cases, they rely on anaerobic metabolism, producing a variety of reduced end products (e.g., lactate,

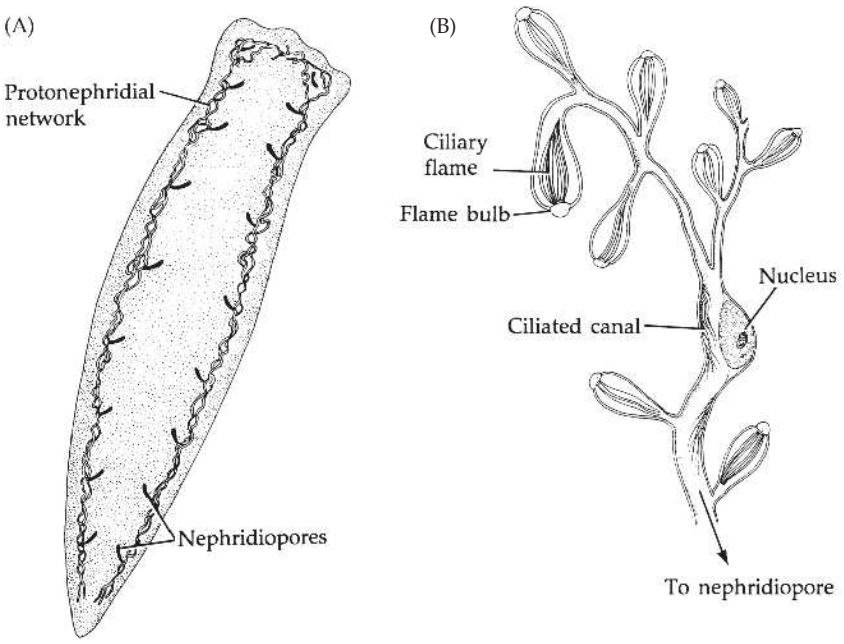

FIGURE 17.16 Nephridia of euneoophoran flatworms. (A) The protonephridial system in a freshwater triclad. (B) The nephridial arrangement in a rhabdocoel that has anucleate flame bulbs attached to collecting tubules.

succinate, alanine, and long-chain fatty acids). Most of these adaptable animals also possess the appropriate enzymes for and are capable of aerobic respiration in the presence of oxygen.

Excretion and Osmoregulation

Protonephridia seem to occur in all free-living flatworms (except some marine catenulids) and consist of flame bulbs that may occur singly (as they do in some catenulids) or in pairs (from one to many pairs in different taxa). The protonephridia connect to networks of collecting tubules that coalesce as nephridioducts (sometimes called excretory ducts), and then to one or more nephridiopores (Figure 17.3B, 17.15, and 17.16). Protonephridia in free-living flatworms function primarily as osmoregulatory structures. Freshwater species tend to have more protonephridia and more complex tubule systems than do their marine counterparts. Although some ammonia is released via the protonephridia, most metabolic wastes (including ammonia) are lost by diffusion across the body wall. Typically, two nephridioducts drain the nephridia. In some cases there is a storage area, or bladder, that connects with a posterior nephridiopore, such as in digenean flukes, or to a pair of anterior pores in the monogenean types (Figure 17.15). As in free-living flatworms, the protonephridia of flukes are primarily osmoregulatory.

Tapeworms possess numerous flame bulb protonephridia throughout the body. The flame bulbs drain to pairs of dorsolateral and ventrolateral nephridioducts that run the length of the body (Figure 17.17). Although some variation in plumbing occurs, the ventral ducts are typically connected to one another by transverse tubules near the posterior end of each proglottid. In relatively young worms that have not lost any proglottids (see the section on Reproduction and Development), the excretory ducts lead to a collecting bladder in the most posterior proglottid. Once this terminal proglottid is lost, the nephridioducts open separately to the outside on the posterior margin of the remaining hindmost proglottid. There is still much to be learned about the protonephridia of cestodes. They probably function both in excretion and osmoregulation. They may also serve to eliminate certain organic acid products of anaerobic cellular

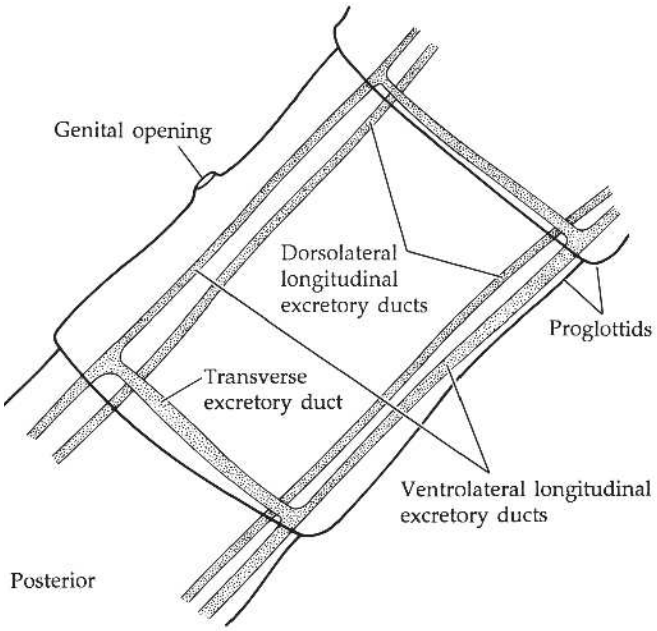

FIGURE 17.17 The arrangement of major protonephridial ducts in a cestode proglottid (ventral view).

for more books/tests/answer keys/solution manuals requests email 9601267734@qq.com

metabolism. Some experimental work indicates that tapeworms are capable of precipitating and storing some waste products within their proglottids.

Nervous System and Sense Organs

Free-living flatworms The nervous systems of these species vary from a simple netlike nerve plexus with only a minor concentration of neurons in the head (similar to that seen in the phylum Xenacoelomorpha), to a distinctly bilateral arrangement with a well-developed cerebral ganglion and longitudinal nerve cords connected by transverse commissures (Figure 17.18). The more advanced condition is referred to as a ladderlike nervous system. Even many of those species that possess distinctly centralized nervous systems have a plexus formed by the repeated branching of nerve endings (e.g., polyclads). In general, larger flatworms show an increasing concentration of the peripheral nerves into fewer and fewer longitudinal cords and an accumulation of neurons in the head as an associative center or cerebral ganglion. Furthermore, they show a tendency to separate the elements of the nervous system into distinct sensory and motor pathways and to develop a circuitry that operates primarily on unidirectional impulse transmission.

Free-living flatworms have a general concentration of sense organs at the anterior end of the body and an elaboration of receptor types that are compatible with their lifestyle. Tactile receptors are abundant over much of the body surface as sensory bristles projecting from the epidermis, but they tend to concentrate at the anterior end and around the pharynx. Benthic free-living flatworms orient to the substratum by touch; they are positively thigmotactic ventrally and negatively thigmotactic dorsally.

Most free-living flatworms are equipped with chemoreceptors that aid in food location. Although sensitive over most of the body, free-living flatworms have distinct concentrations of chemoreceptors anteriorly, particularly on the sides of the head. Some forms, such as the familiar freshwater planarians and the prorhynchidans, have the chemoreceptors located in flaplike processes called **auricles** on the head (Figures 17.2 and 17.18C), whereas others have these sense organs in ciliated pits, on tentacles, or distributed over much of the anterior end of the body. The epithelium bearing the chemoreceptors is usually ciliated and frequently forms depressions or grooves. The cilia are the receptor organelles, but they also circulate water, thus facilitating sensory input from the environment.

The utilization of chemoreception in locating food has been demonstrated in many free-living flatworms. Some are known to home in on concentrations of dissolved chemicals associated with potential food. Others, such as *Dugesia*, hunt by waving the head back and forth as they crawl forward, exposing the auricles to any chemical stimulus in their path. When exposed to diffuse chemical attractants, some free-living flatworms begin a trial-and-error behavior pattern. If unable to determine the direction of the attractant, the worm begins moving in a straight line. If the stimulus weakens, the animal makes apparently random turns until it encounters sufficient stimulus, then moves toward it. This behavior can eventually bring the animal near enough to the food source to home in on it directly. Some species orient to water movements by rheoreceptors located on the sides of the head (Figure 17.18D).

Statocysts are common in certain flatworms, notably in members of the Catenulida and Proseriata. These groups include mostly swimming and interstitial forms in which orientation to gravity cannot be accomplished by touch. When present, the statocyst is usually located on or near the cerebral ganglion. Ehlers (1991) presents details on the ultrastructure of some flatworm statocysts.

Most free-living flatworms possess photoreceptors in the form of inverted pigment-cup ocelli (Figure 17.18E). A few macrostomids possess simple pigment-spot ocelli, which are presumed to be primitive within the flatworms. Many species bear a single pair of ocelli on the head, but some, such as certain polyclads and terrestrial triclads, may have many pairs of eyes. In a few terrestrial forms (e.g., *Parakontikia ventrolineata*) and many of the large tropical polyclads, numerous eyes extend along the edges of the body. Most free-living species are negatively phototactic. The dorsal placement of the eyes and the orientation of the pigment cups facilitate the detection of light direction as well as intensity. Larvae of the polyclad flatworm *Pseudoceros canadensis* possess two dissimilar kinds of eyes. The right eye appears to be microvillar (i.e., rhabdomeric), but the left one has components of both microvillar and ciliary origin (Eakin and Brandenberger 1980). The nature of these two eye types was noted in Chapter 3.

Neurosecretory cells have been known in free-living flatworms for more than three decades, and work continues on exploring their functions. These special cells are generally located in the cerebral ganglion, but they also occur along major nerve cords in at least some species. Neurosecretions play important roles in regeneration, asexual reproduction, and gonad maturation in free-living species that could serve as models for understanding similar functions in parasitic species.

Flukes and tapeworms The nervous system of flukes is distinctly ladderlike and very similar to that in many free-living flatworms (Figure 17.19). The cerebral ganglion comprises two well-defined lobes connected by a dorsal transverse commissure. Nerves from the cerebral ganglion extend anteriorly to supply the area of the mouth, adhesive organs, and any cephalic sense organs.

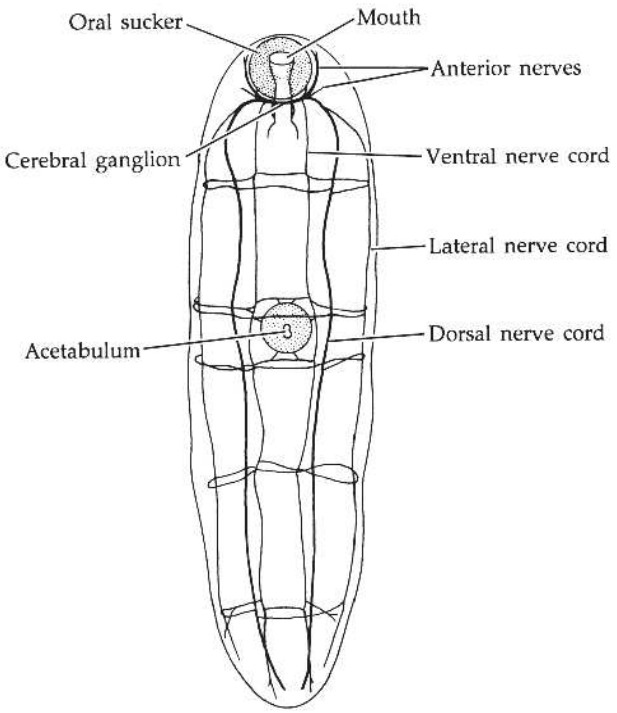

FIGURE 17.19 A generalized ladderlike nervous system of a trematode (ventral view).

Extending posteriorly from the cerebral ganglion are up to three pairs of longitudinal nerve cords with transverse connectives. A pair of ventral cords is usually most well developed, and dorsal cords are present in the digenean flukes. Most flukes also have a pair of lateral nerve cords. The suckers of flukes bear tactile receptors in the form of bristles and small spines. There is also some evidence of reduced chemoreceptors. Nearly all monogenean flukes possess a pair of rudimentary pigment-cup ocelli near the cerebral ganglion.

The cerebral ganglion of cestodes is usually a complex nerve ring located in the scolex (Figure 17.20). The ring bears ganglionic swellings and gives rise to a number of nerves. Anterior nerves, in the form of a ring or plexus, serve the rostellum (when present) and other attachment organs. Lateral cerebral ganglionic swellings give rise to a pair of major lateral longitudinal nerves, which extend the length of the animal. In each proglottid, these nerves bear additional ganglia from which transverse commissures arise and connect the two longitudinal cords. Additional longitudinal nerves are often present; the most typical pattern includes two pairs of accessory lateral cords—a pair of dorsal cords and a pair of ventral cords. As might be expected, sense organs are greatly reduced in cestodes and are limited to abundant tactile receptors in the scolex.

Reproduction and Development

Asexual processes Asexual reproduction is common among freshwater and terrestrial free-living flatworms, and it generally occurs by transverse fission. In the catenulids and macrostomorphans, an odd sort of multiple transverse fission occurs wherein the individuals thus produced remain attached to one another in a chain until they mature enough to survive alone (Figure 17.21A). Some freshwater triclads (e.g., *Dugesia*, *Schmidtea*) split in half behind the pharynx, and each half goes its own way, eventually regenerating the lost parts. A few (e.g., *Phagocata*) reproduce by fragmentation, each part encysting until the new worm forms.

The remarkable regenerative abilities of free-living flatworms have been studied intensely for many years. Much of this experimental work has been conducted on triclads. Underlying all of the bizarre results of various surgeries performed on these animals (Figure 17.21B,C) is the fact that the cells of organisms like *Dugesia* are not totipotent; an anterior–posterior body polarity exists in terms of the regenerative capabilities of the cells. However, the cells in the midbody region are less fixed in their potential to produce other parts of the body than are those toward the anterior or posterior ends. Thus, if the flatworm is cut through the middle of the body (as occurs in natural transverse fission), each half will regenerate the corresponding lost part. However, if the animal is cut transversely near one end—say, separating a small piece of the tail from the rest of the body—the larger piece will grow a new posterior end, but the piece of tail lacks the capability to produce an entire new anterior end. This gradient of cell potency has been of particular interest to cell biologists and medical researchers because of its relevance to healing and regeneration potential in higher animals.

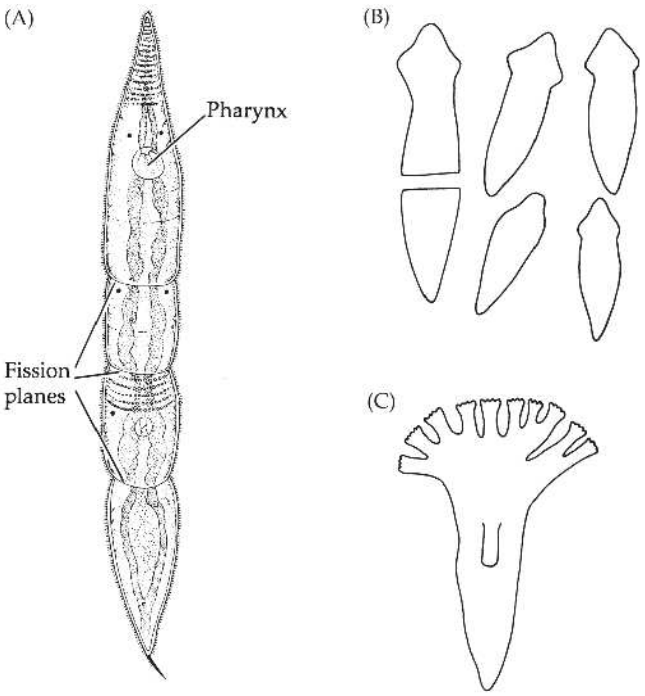

FIGURE 17.21 Asexual reproduction. (A) Asexual reproduction by transverse fission in a macrostomorphan flatworm, *Alaurina*. (B,C) Regeneration after experimental injuries in planarians.

Asexual reproduction is an important feature of the life cycle of flukes, where the ability to reproduce asexually helps ensure survival, particularly when potential mates may not be nearby.

Sexual reproduction: Free-living flatworms Most free-living flatworms are hermaphroditic and possess complex and highly diverse reproductive systems (Figure 17.22). The male system includes single (e.g., Macrostomorpha), paired (e.g., many Rhabdocoela), or multiple (e.g., Polycladida) testes. The testes are generally drained by collecting tubules that unite to form one or two sperm ducts, which often lead to a precopulatory storage area or seminal vesicle. Prostatic glands, which supply seminal fluid to the sperm, are often associated with and empty into the seminal vesicle. The seminal vesicle is typically part of a muscular chamber called the **male atrium**, which houses the copulatory organ. The actual organ of sperm transfer may be a papilla-like penis or an eversible cirrus, through which sperm are forced out by muscular action of the atrium.

The female reproductive system is more variable than that of the male. Much of the variation is related to whether the flatworm in question produces **endolecithal** or **ectolecithal** ova—that is, whether the worm is described as **archoöphoran** or **neoöphoran**. The archoöphorans (e.g., Macrostomida, Polycladida) typically possess an organ that produces both eggs and yolk. The final product is endolecithal ova. Such an organ is called a **germovitellarium,** and it may occur either singly or paired. In the neoöphorans (e.g., the order Prolecithophora and the entire superclass Euneoophora), the ovary (**germarium**) is separate from the yolk gland (**vitellarium**). Yolk-free eggs are produced by the ovary and then cellular yolk is transported through a vitelline duct and deposited alongside the ova inside the eggshell, a process resulting in ectolecithal ova.

In both cases, the eggs are typically moved via an oviduct toward the female atrium, which often bears special chambers for storage of sperm (i.e., seminal receptacle and copulatory bursa). Associated with this arrangement may be a variety of accessory glands, such as **cement glands**, for the production of shells and egg cases.

The male and female gonopores are often separate, the female opening usually located posterior to the male pore. In some species, however, the two systems share a common genital opening, and in a few the male atrium curiously opens just inside the mouth. In the latter case, the mouth is referred to as an **orogenital pore**.

Mating is usually by mutual cross-fertilization. The two mates align themselves so that the male gonopore of each is pressed against the female gonopore of the mate (Figure 17.23A). The male copulatory organ, or **stylet** (or penis or cirrus), is everted by hydrostatic pressure caused by the muscles surrounding the atrium and is inserted into the mate's female atrium, where sperm are deposited. The mates then separate, each going its own way and carrying foreign sperm. Fertilization usually occurs as the eggs pass into the female atrium or within the oviduct itself. The zygotes are frequently stored for a period of time in special parts of the female system or in enlarged oviducts; any such storage area is called a **uterus**.

Some macrostomorph and polyclad flatworms exhibit hypodermic insemination, whereby the male stylet is thrust through the body wall of the mate and sperm are forcibly injected into the mesenchyme. In other polyclads, individuals receive spermatophores from partners on their dorsal surface. Whereas most flatworms mate in pairs, such dermal impregnation may occur in groups. By a method not yet understood, after mating, the sperm find their way to the female system and fertilize the eggs.

In the genus *Macrostomum*, a close correspondence exists between the morphology of sperm, the morphology of the male stylet, and whether insemination is hypodermic or occurs by copulation (Figure 17.23C,D). Sperm in all *Macrostomum* have "feelers," anterior projections that embed themselves into the wall of the female reproductive tract in position to allow fertilization. However, depending on the species, sperm may also possess backwardly directed bristles. Species in which the stylet is hooked engage

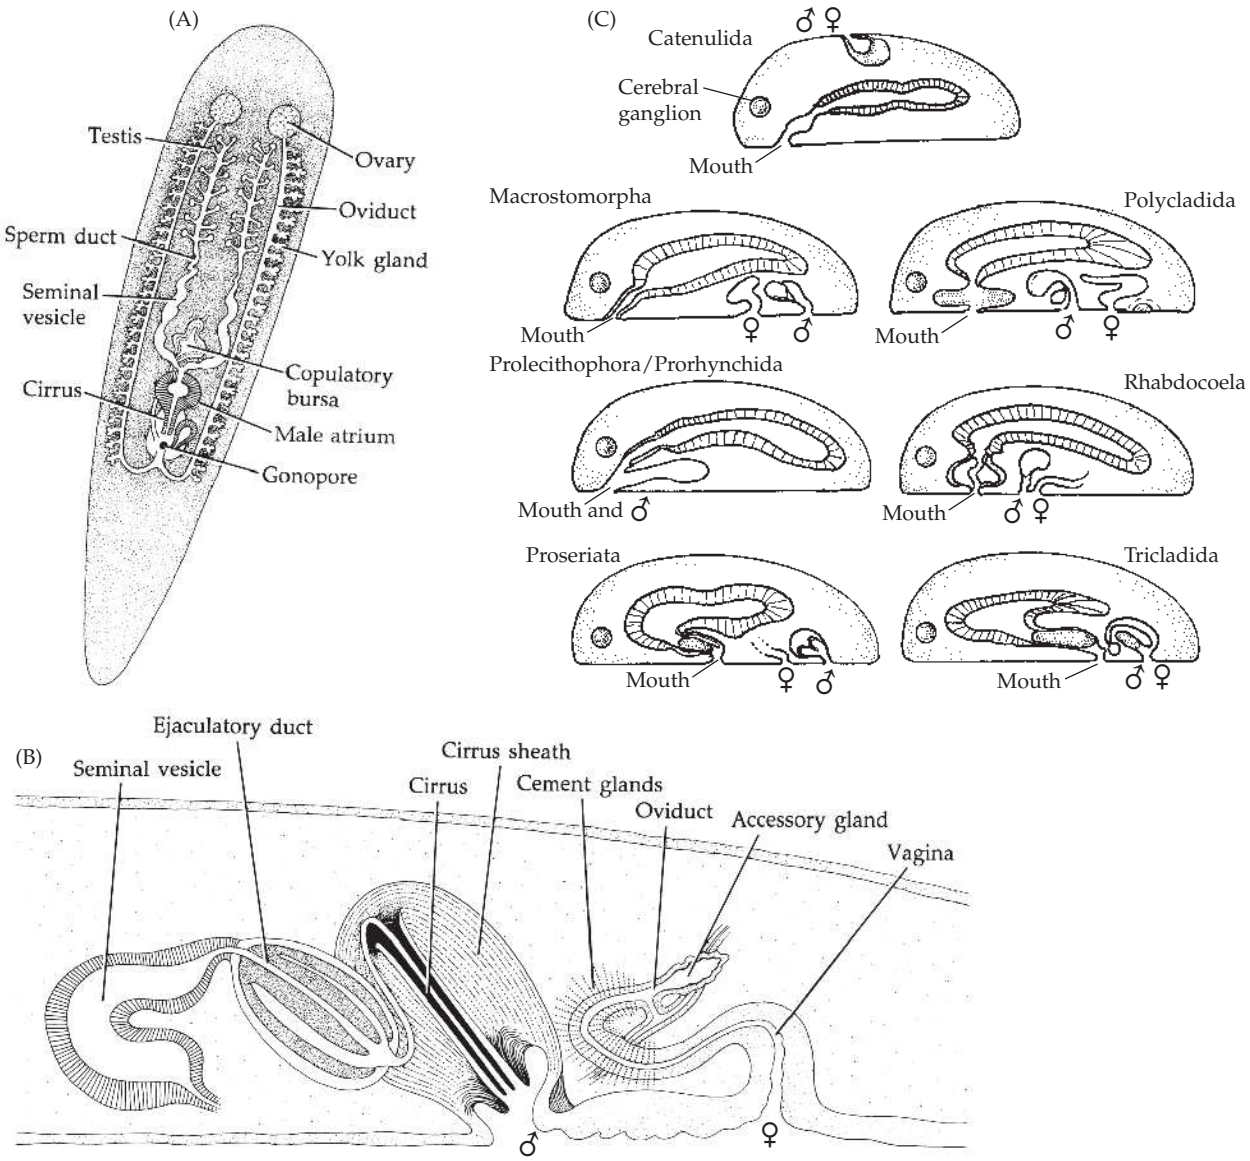

FIGURE 17.22 Reproductive systems of free-living flatworms. (A) Generalized triclad condition with separate ovaries and yolk glands (neoöphoran condition). (B) The copulatory structures of a triclad (sagittal section). (C) Generalized scheme of the relative position of male (♂) and female (♀) reproductive structures with respect to the location of the mouth in seven taxa.

in hypodermic insemination, and sperm lack bristles. In contrast, species in which the stylet is not hooked tend to copulate, and sperm do possess bristles. Bristles appear to maintain sperm in position within the female reproductive tract after mutual insemination by mating pairs. After pairs separate, each individual applies its mouth to its own vagina and "sucks," evidently removing unattached sperm. The sperm that have imbedded their feelers into the female reproductive tract are in position for fertilization, and bristles appear to assist in this process. Unattached sperm removed from the vagina are apparently eaten.

Ingestion of sperm from mating partners may in fact be widespread. In other free-living flatworms from several taxa, the presence of **Lang's vesicle** is associated with species that engage in copulation. Although this structure is thought to be a sperm storage organ, its significance is still in doubt. The structure is usually attached to the digestive system, suggesting that it may be involved in sperm digestion.

Once fertilization is accomplished, the zygotes are either retained by the parent within the uteri of the female reproductive tract or laid in various sorts of gelatinous or encapsulated egg masses (Figure 17.23B). Thus, most maternal free-living flatworms are obliged to contribute substantially toward the care of their embryos; they may be described as oviparous or ovoviviparous. Some freshwater triclads produce special overwintering zygotes, which are encapsulated and retained within the female reproductive tract until spring.

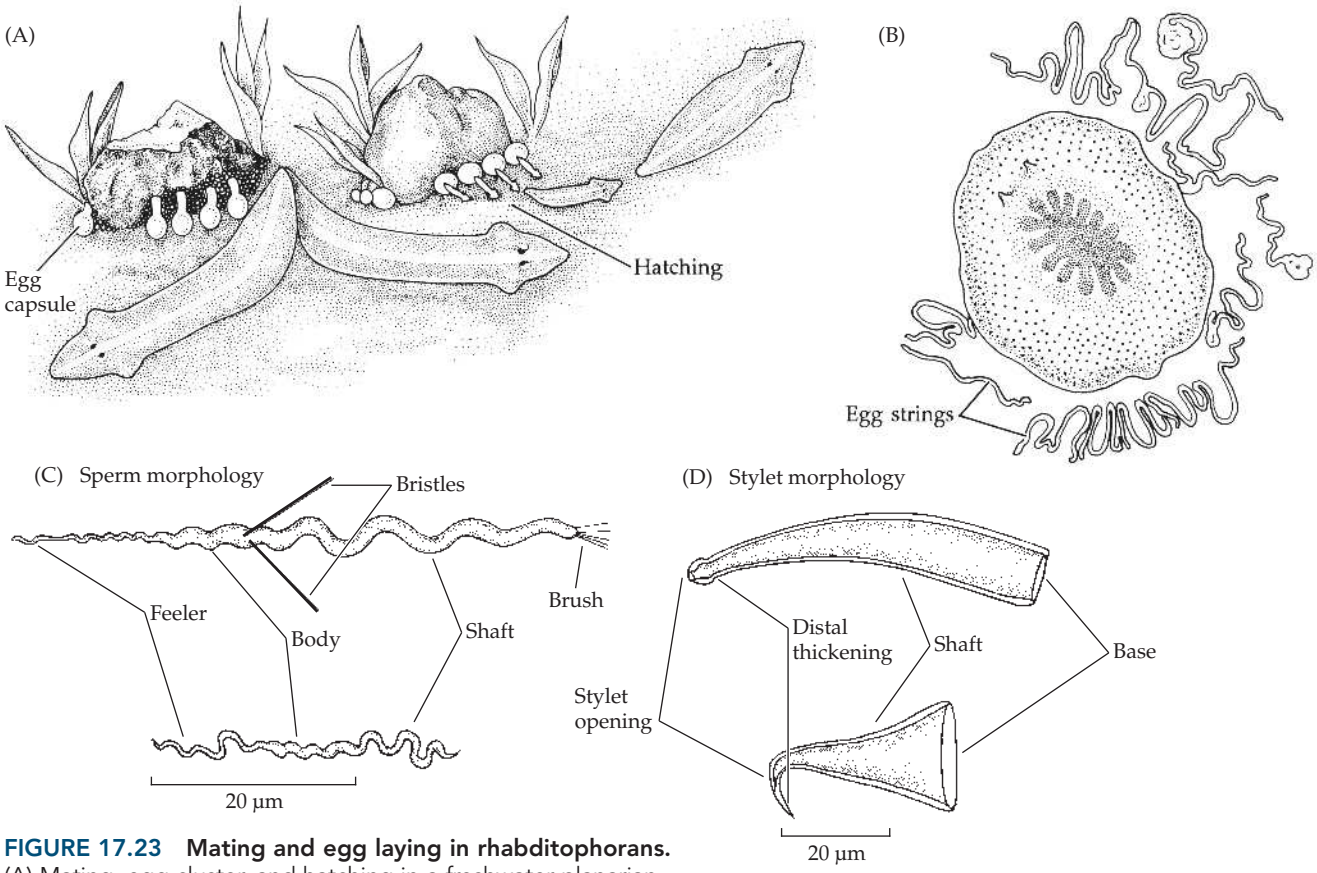

FIGURE 17.23 Mating and egg laying in rhabditophorans. (A) Mating, egg cluster, and hatching in a freshwater planarian. (B) Egg laying by the polyclad *Stylochus*. (C,D) Sperm and stylet morphology in two species of *Macrostomum*. Upper figures are *M. lignano*, a species in which individuals reciprocally copulate when mating. Lower figures are *M. hystrix*, a species in which hypodermic insemination occurs.

The general strategy of the vast majority of free-living flatworms is to produce relatively few zygotes, which are protected by brooding or encapsulation and undergo direct development. A few polyclads produce a **Müller's larva**, which swim about for a few days prior to settling and metamorphosing (Figures 17.24 and 17.25). This type of larva is equipped with eight ventrally directed ciliated lobes, by means of which it swims. A few species of parasitic polyclads of the genus *Stylochus* produce a **Götte's larva**, which bears four rather than eight lobes; and members of the freshwater catenulid genus *Rhynchoscolex* pass through a vermiform stage in their development that has been referred to as a larval form.

Early embryogeny differs greatly between the archoöphoran and neoöphoran flatworms. The endolecithal ova of the archoöphorans undergo some form of spiral cleavage (although some authors question the details of this process). The pattern and cell fates in many of these archoöphoran embryos are distinctly protostome-like, and this spiral cleavage has been well studied (especially in polyclads). Quartets of cells are produced, the fates of which may be described using Wilson's coding system (Chapter 4). By the end of spiral cleavage, the embryo is considered a stereoblastula, oriented with the derivatives of the first micromere quartet at the animal pole and the macromeres at the vegetal pole. The lq cells become the anterior ectoderm, cerebral ganglion, and most of the rest of the nervous system. The 2q derivatives contribute to

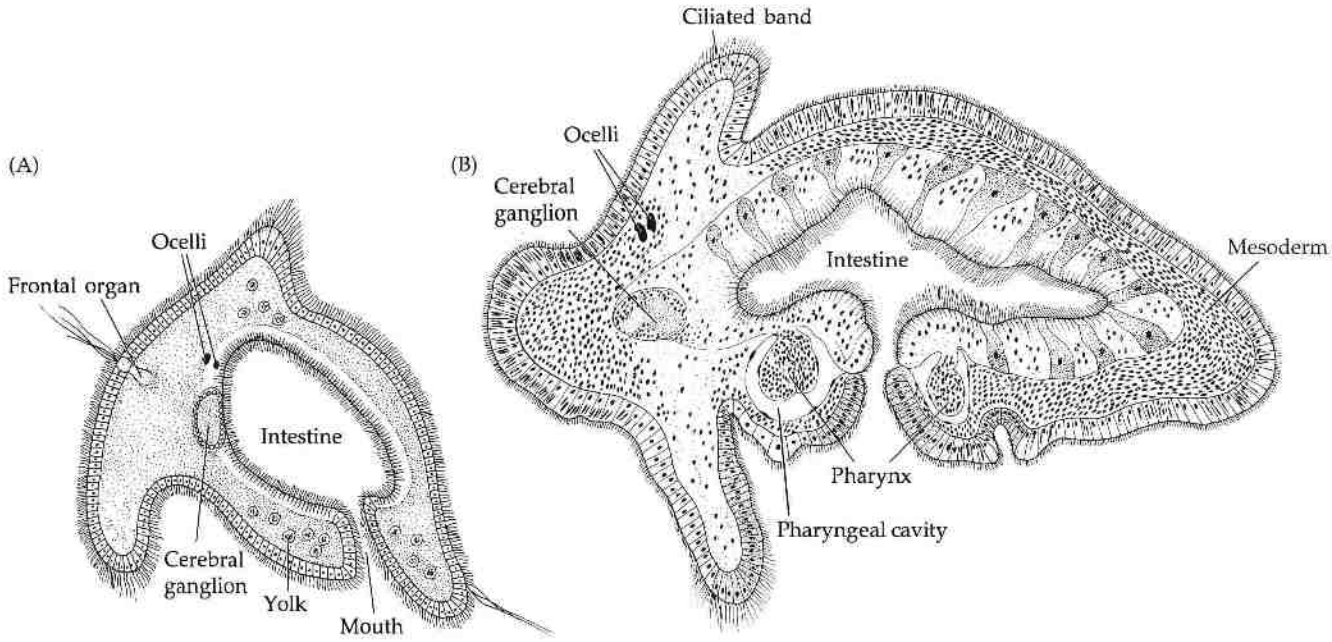

FIGURE 17.25 Polyclad development. (A) A Müller's larva (sagittal section). (B) A later larval stage, showing formation of the pharyngeal apparatus (sagittal section).

ectoderm and ectomesoderm, particularly that of the pharyngeal apparatus and its associated musculature. The remainder of the ectoderm and probably some ectomesoderm are formed from the derivatives of the third micromere quartet. The 4d cell, normally associated solely with endomesoderm in typical protostomes, divides to produce a $4d^1$ and $4d^2$ cell in polyclads. The $4d^1$ gives rise to endoderm and thus to the intestine; the $4d^2$ produces the endomesoderm from which the body wall and mesenchymal muscles, much of the mesenchymal mass, and most of the reproductive system are derived. The remaining cells (4a, 4b, 4c, and the 4Q) include most of the yolk and are incorporated into the developing archenteron as embryonic food.

Gastrulation is by epiboly of the presumptive ectoderm derived from some of the cells of the first three micromere quartets. The ectoderm grows from the animal pole to the vegetal pole, surrounding the 4q and 4Q cells. At the vegetal pole the ectoderm turns inward as a stomodeal invagination, which later elaborates as the pharynx and connects with the developing intestine (Figure 17.25). As development proceeds, the embryo flattens, with the mouth directed ventrally, and hatches as a tiny flatworm. If development is indirect, the larva emerges about the time the intestine is hollowing.

Because of the deposition of extracellular yolk with ectolecithal ova, the development of neoöphoran species is highly modified from the plan just described. Certain species of rhabdocoels and triclads have been most extensively studied, and the two groups differ—especially in the early stages. In both cases, cleavage is so distorted that cell fates and germ layer formation cannot easily be compared with the typical spiralian pattern. In the rhabdocoels, early cleavage leads to the formation of three masses of cells positioned along the presumptive ventral surface of the embryo beneath the mass of yolk (Figure 17.26A). The cell masses then produce a layer of cells that extends around to enclose the yolk. This covering thickens to several cell layers, the innermost eventually becoming the intestinal lining (and enclosing the yolk), the outermost becoming the epidermis. The anterior cell mass produces the nervous system; the middle cell mass produces the pharynx and associated muscles; the posterior cell mass forms the rear portion of the worm and the reproductive system.

Early development in triclads differs from that of other neoöphorans. During early cleavage, the blastomeres are loose within a surrounding mass of fluid yolk, a condition described as "blastomere anarchy." A few of the blastomeres migrate away from the others and flatten to produce a thin membrane enclosing a packet of the yolk including the remaining blastomeres (Figure 17.26B,C). These migrating blastomeres are often called **hull cells**, but the yolk-enclosing **hull membrane** they create can be variable and may not be homologous among flatworm taxa. Additional yolk cells are produced as a syncytial mass around a group of developing embryos and encapsulated, as many as 40 per capsule. Through migration and differentiation of various blastomeres, each embryo forms a temporary intestine, pharynx, and mouth, through which it ingests the yolky syncytium. The embryonic mouth eventually closes and the wall of the embryo thickens to form anterior, middle, and posterior cell masses, whose fates are similar to those in rhabdocoels.

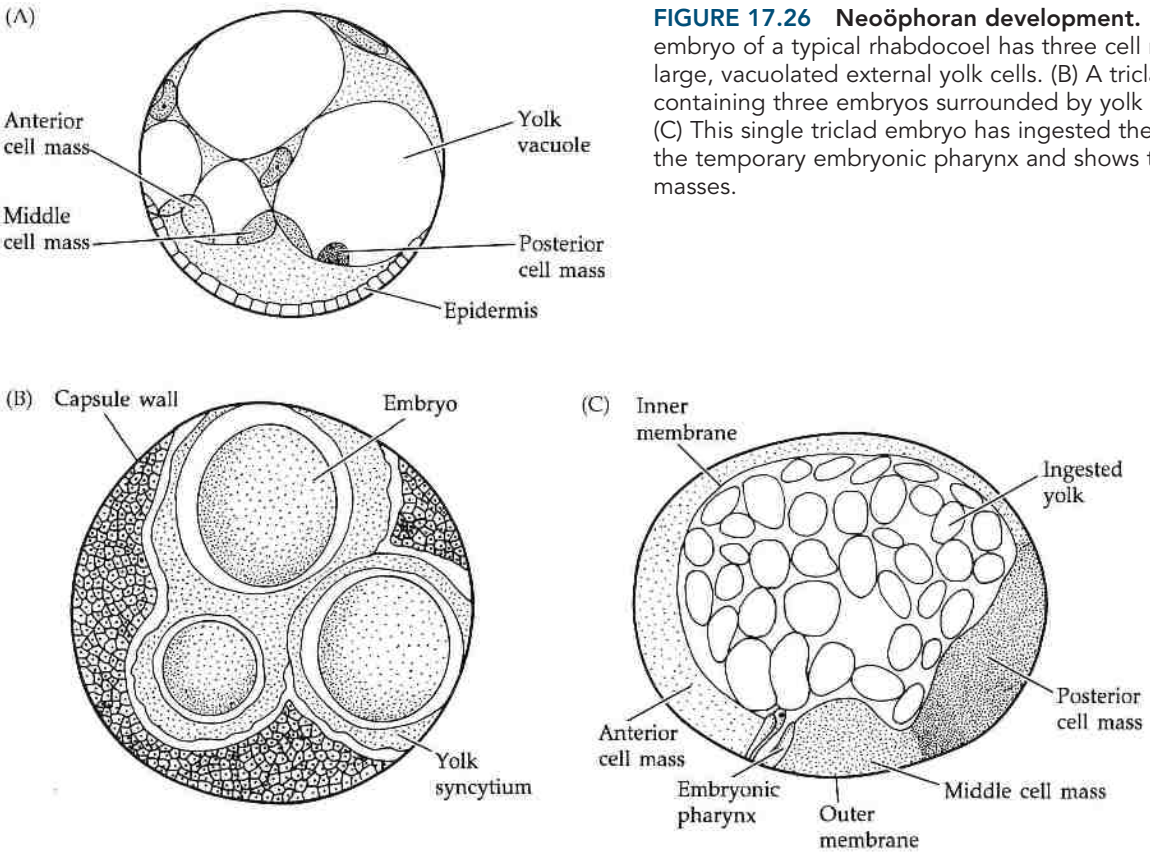

FIGURE 17.26 Neoöphoran development. (A) The embryo of a typical rhabdocoel has three cell masses with large, vacuolated external yolk cells. (B) A triclad egg capsule containing three embryos surrounded by yolk syncytium. (C) This single triclad embryo has ingested the yolk through the temporary embryonic pharynx and shows the three cell masses.

Sexual reproduction: Flukes Like the free-living flatworms, flukes are hermaphroditic and typically engage in mutual cross-fertilization. Self-fertilization occurs only in rare cases. There is a great deal of variation in the details of the reproductive systems among flukes, but most are built around a common plan similar to that in certain free-living flatworms (Figure 17.27). The male system includes a variable number of testes (usually many in the monogenean flukes and two in the digenean flukes), all of which drain to a common sperm duct that leads to a copulatory apparatus, usually an eversible cirrus. The sperm duct–cirrus junction is frequently enlarged as a seminal vesicle. Prostatic glands are commonly present, opening into the cirrus lumen near the seminal vesicle. All of these terminal structures are housed within a muscular **cirrus sac**, the contraction of which causes eversion of the cirrus as an intromittent organ (Figure 17.27C). There is usually a common genital pore that opens ventrally near the anterior end of the animal and leads to a shallow atrium, shared by both the male and female systems. Many monogenean flukes have simpler male systems than that just described, often lacking much elaboration of the terminal structures and possessing a simple **penis papilla** rather than an eversible cirrus.

The female reproductive system (Figure 17.27B) usually bears a single ovary connected by a short oviduct to a region known as the **ootype**. The oviduct is joined by a yolk duct (= vitelline duct) formed by the union of paired ducts, which carry yolk from the multiple laterally placed yolk glands. A seminal receptacle is usually present as a blind pouch off the oviduct. Extending anteriorly to the genital atrium is a single uterus, which is sometimes modified as a **vagina** near the female gonopore.

Sperm are produced in the testes and stored prior to copulation in the seminal vesicle (Figure 17.27C). During mating, two flukes align themselves such that the cirrus of each can be inserted into the female orifice of the other. Sperm, along with semen from the prostatic glands, are ejaculated into the female system by muscular contractions. The sperm move to, and are stored within, the seminal receptacle, and the mates separate. As eggs pass through the oviduct to the ootype, they are fertilized by sperm released from the seminal receptacle into the oviduct.

Flukes produce ectolecithal ova. The yolk glands produce yolk, which is deposited outside the eggs along with secretions that form a tough shell around the zygote. Thus encapsulated, the zygotes move from the ootype into the uterus, probably aided by secretions from clusters of unicellular **Mehlis's glands**. The zygotes may be stored within the uterus for various lengths of time prior to release through the female gonopore.

Some flukes possess an additional canal that arises from the oviduct and serves as a special copulatory duct.

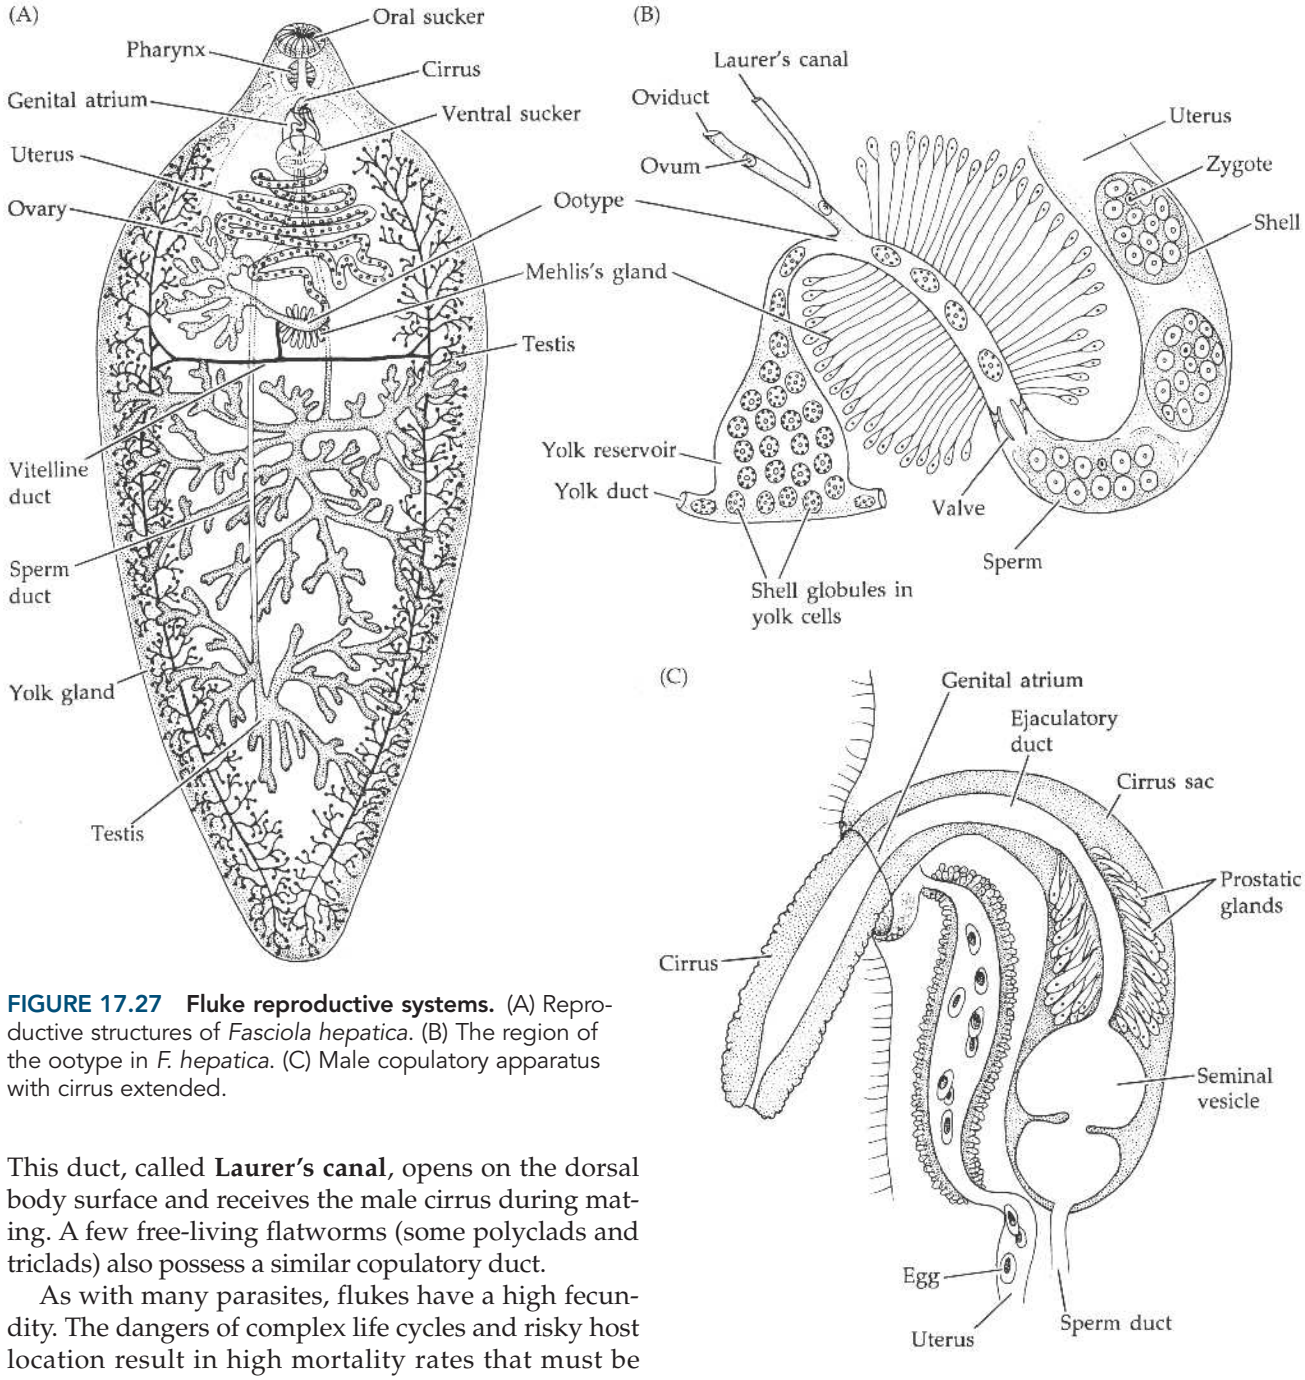

FIGURE 17.27 Fluke reproductive systems. (A) Reproductive structures of *Fasciola hepatica*. (B) The region of the ootype in *F. hepatica*. (C) Male copulatory apparatus with cirrus extended.

This duct, called **Laurer's canal**, opens on the dorsal body surface and receives the male cirrus during mating. A few free-living flatworms (some polyclads and triclads) also possess a similar copulatory duct.

As with many parasites, flukes have a high fecundity. The dangers of complex life cycles and risky host location result in high mortality rates that must be offset by increased zygote production or asexual processes. Flukes may produce as many as 100,000 times as many eggs as free-living species.

The early stages of development in flukes are usually highly modified because of the ectolecithal nature of the ova. In species where little yolk is present, cleavage is holoblastic, and cell fates and germ layer formation have been traced accurately. Development is virtually always mixed, involving one or more independent larval stages.

The life cycles of monogenean flukes are relatively simple and involve only a single host, hence the name. Most of the adults are ectoparasites on fishes, although some attach to turtles, various amphibians, and even some invertebrates. A few members of the Monogenea have taken up a mesoparasitic life style and reside in host body chambers that open to the environment (e.g., gill chambers, mouth, bladder, cloacal cavity). When the embryos are released from the uterus, they often attach to the host tissue by means of special adhesive threads on the shell. Upon hatching, a larval stage called an **oncomiracidium** is released to the environment (Figure 17.28). The oncomiracidium is densely ciliated and swims about until it encounters another appropriate host. The cues larvae use to locate particular hosts may be tactile or chemical and may vary depending on local densities of hosts and other larvae.

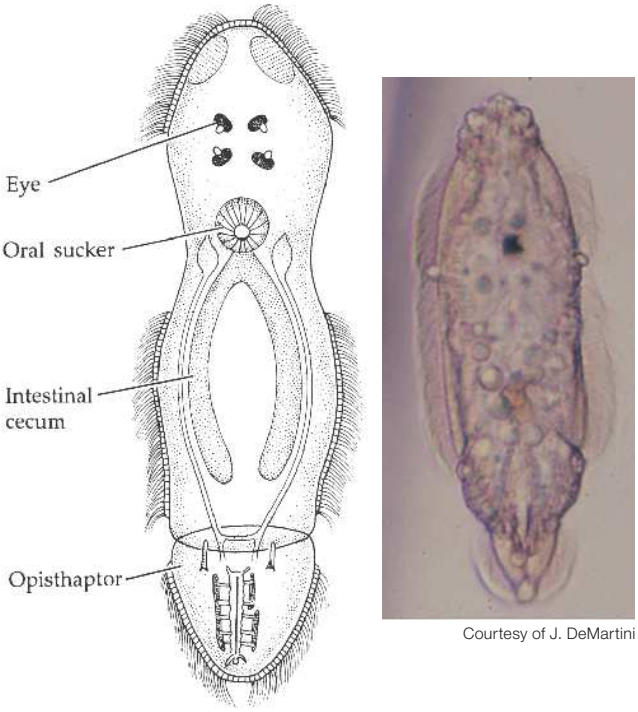

FIGURE 17.28 Drawing and photograph of an oncomiracidium larva of a monogenean fluke.

The prohaptor and especially the opisthaptor develop during the larval stage and facilitate attachment to the new host, whereupon the larva metamorphoses to a juvenile fluke. It is about this time that the ciliated larval skin is shed and the tegument (= neodermis) forms. There are many variations on this basic life cycle among members of the class Monogenea; we present two in outline form in Figure 17.29.

Digenean flukes (orders Diplostomida and Plagiorchiida) include some of the most successful parasites known. A good deal of variation exists, not only in adult morphology, but also in life cycles (Figure 17.30). In general, eggs are produced by adult worms in their definitive host. After fertilization, the zygotes are eventually discharged via the host's feces, urine, or sputum. Upon reaching water, they either are eaten by an intermediate host or hatch as free-swimming ciliated larvae called **miracidia**, which actively penetrate an intermediate host. Several asexual generations of larval forms occur in the intermediate host, eventually producing free-swimming forms called **cercaria**. The cercaria usually encyst within a second intermediate host, becoming **metacercaria**. Infection of the definitive host occurs when the metacercaria are eaten or, if there is no second intermediate host, when the cercaria penetrate directly. The larval skin is lost in the definitive host, and the syncytial tegument develops.

In their adult stages, nearly all of the digenean flukes are endoparasites of vertebrates. They are known to inhabit nearly every organ of the body, and many are serious pathogens of humans and livestock. The intermediate hosts of trematode flukes are gastropods, although some are known to use other invertebrates or even certain vertebrates. Most species of snails host one or more species of digenean flukes; the common California tidal flat gastropod *Cerithideopsis californica* serves as intermediate host to nearly two dozen species of digenean flukes, most of which ultimately infect shore birds. Almost all of the trematodes that infect *C. californica* castrate the snail, thus, theoretically, freeing up the host's energy reserves for their own purposes as they live out their lives producing their own offspring. Diplostomid flukes in the genus *Tylodelphys* usually parasitize the eyes and central nervous system of freshwater fishes. Swimmer's itch is a reemerging human disease caused by bird schistosome cercariae (e.g., *Trichobilharzia*), which can infect people in water bodies; the cercariae typically fail after penetrating human skin, but they can still cause dangerous symptoms. Space does not permit an account of more than a few of the life cycles of these worms. We begin with a general case, using the Chinese liver fluke *Clonorchis sinensis* (order Plagiorchiida) as an example. This trematode is widespread in the Far East. It displays all the common stages found in the life cycles of most digenetic flukes. In northern Thailand a related fluke, *Opisthorchis viverrini,* has a similar life cycle and pathology.

The adult Chinese liver fluke usually lives within the branches of the bile duct in humans. This animal may reach several centimeters in length and in high numbers causes serious problems, including cholangiocarcinoma, a rare but aggressive cancer of the

FIGURE 17.29 Life cycles of two monogenean trematodes. (A) The life cycle of *Dactylogyrus vastator*, a parasite of freshwater cyprinodont fishes. (B) The life cycle of *Polystoma integerrimum*, a parasite in the urinary bladders of frogs. This fascinating life history demonstrates the dramatic influences exerted by the developmental stage of the host on the development of the parasite. Under normal conditions, the adult fluke resides in the bladder of adult frogs. The fluke releases fertilized eggs into the water, where they hatch as oncomiracidia. These in turn become so-called gyrodactylid larvae, which attack the tadpole larval stages of the host. If the tadpole is very young, the fluke larvae attach to the external gills of the host and undergo precocious sexual maturation (progenesis) to produce more zygotes; these flukes die upon metamorphosis of the host. However, if the fluke larvae encounter more advanced tadpoles, they enter the branchial chambers and attach to the host's gills, where they reside until the host undergoes metamorphosis. At that time, the flukes leave the branchial chamber, migrate to the cloacal pore, and enter the host's bladder. Here the flukes live and grow, but they do not become sexually active until they are influenced by the host's sex hormones. Thus, sexual reproduction of the host and of its parasites are synchronized—a pattern that guarantees availability of larval hosts for larval parasites!

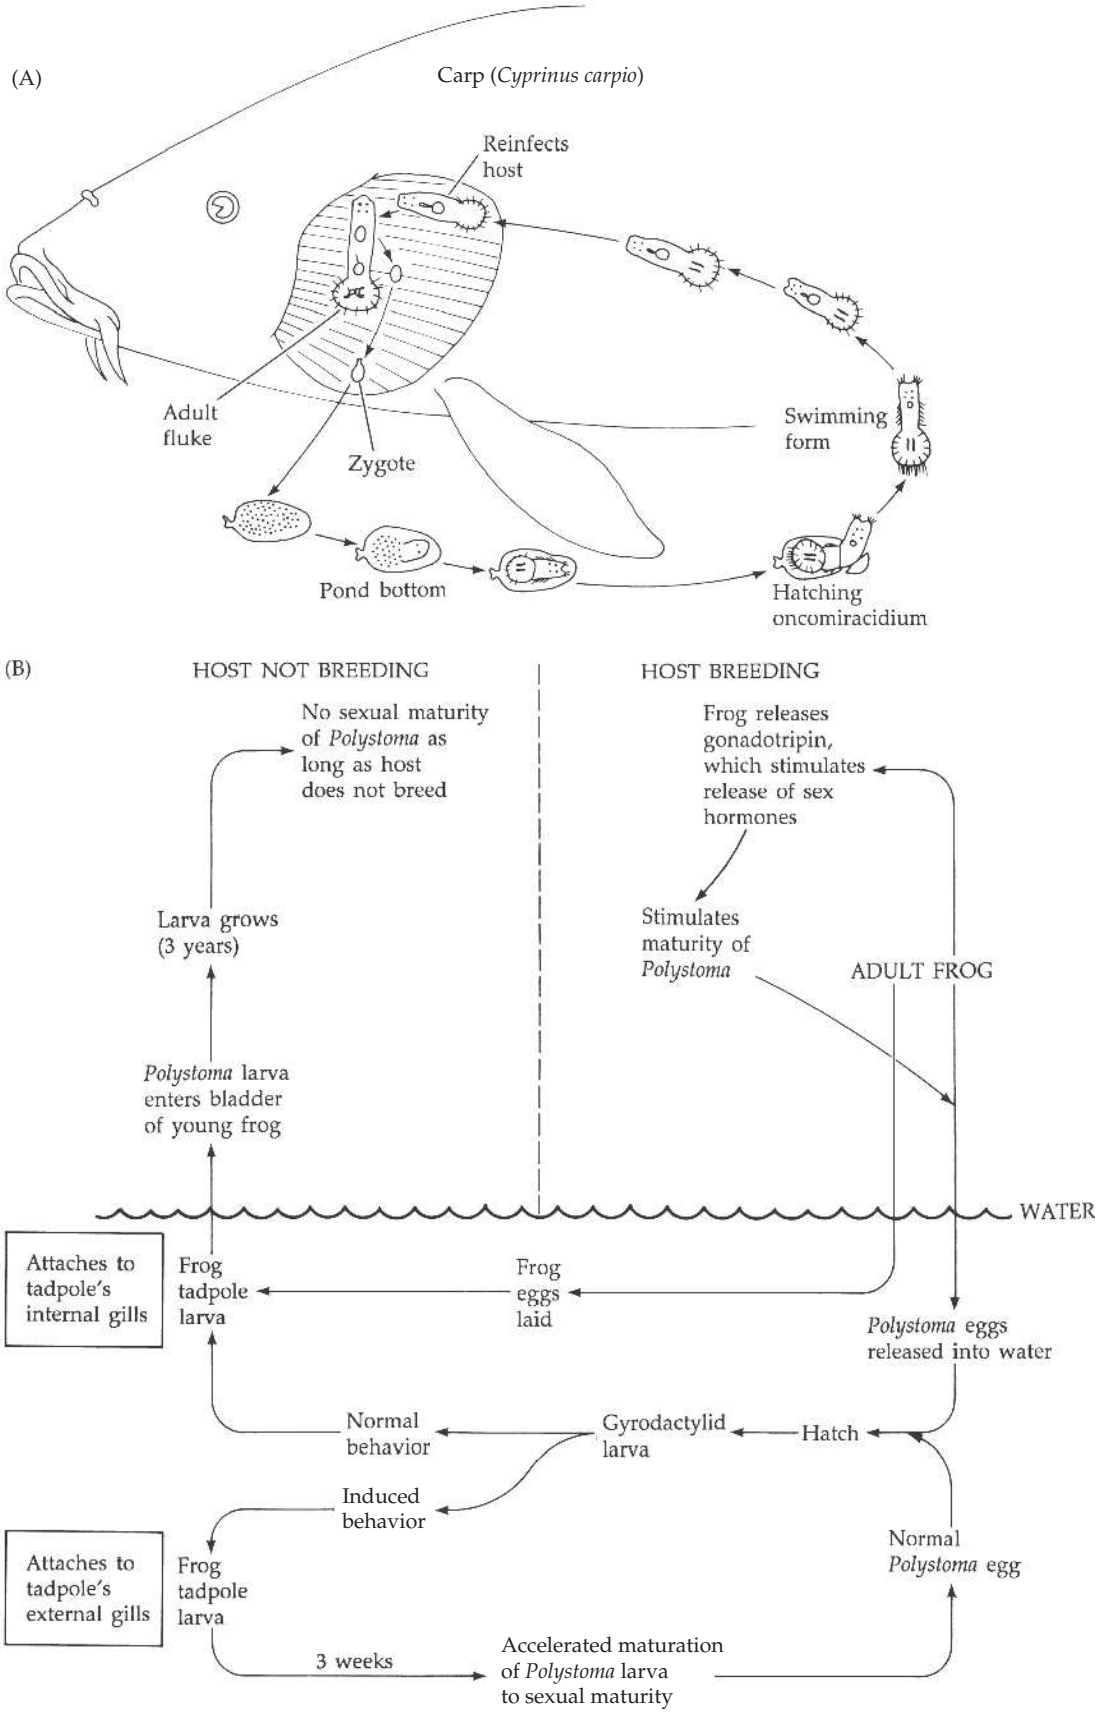

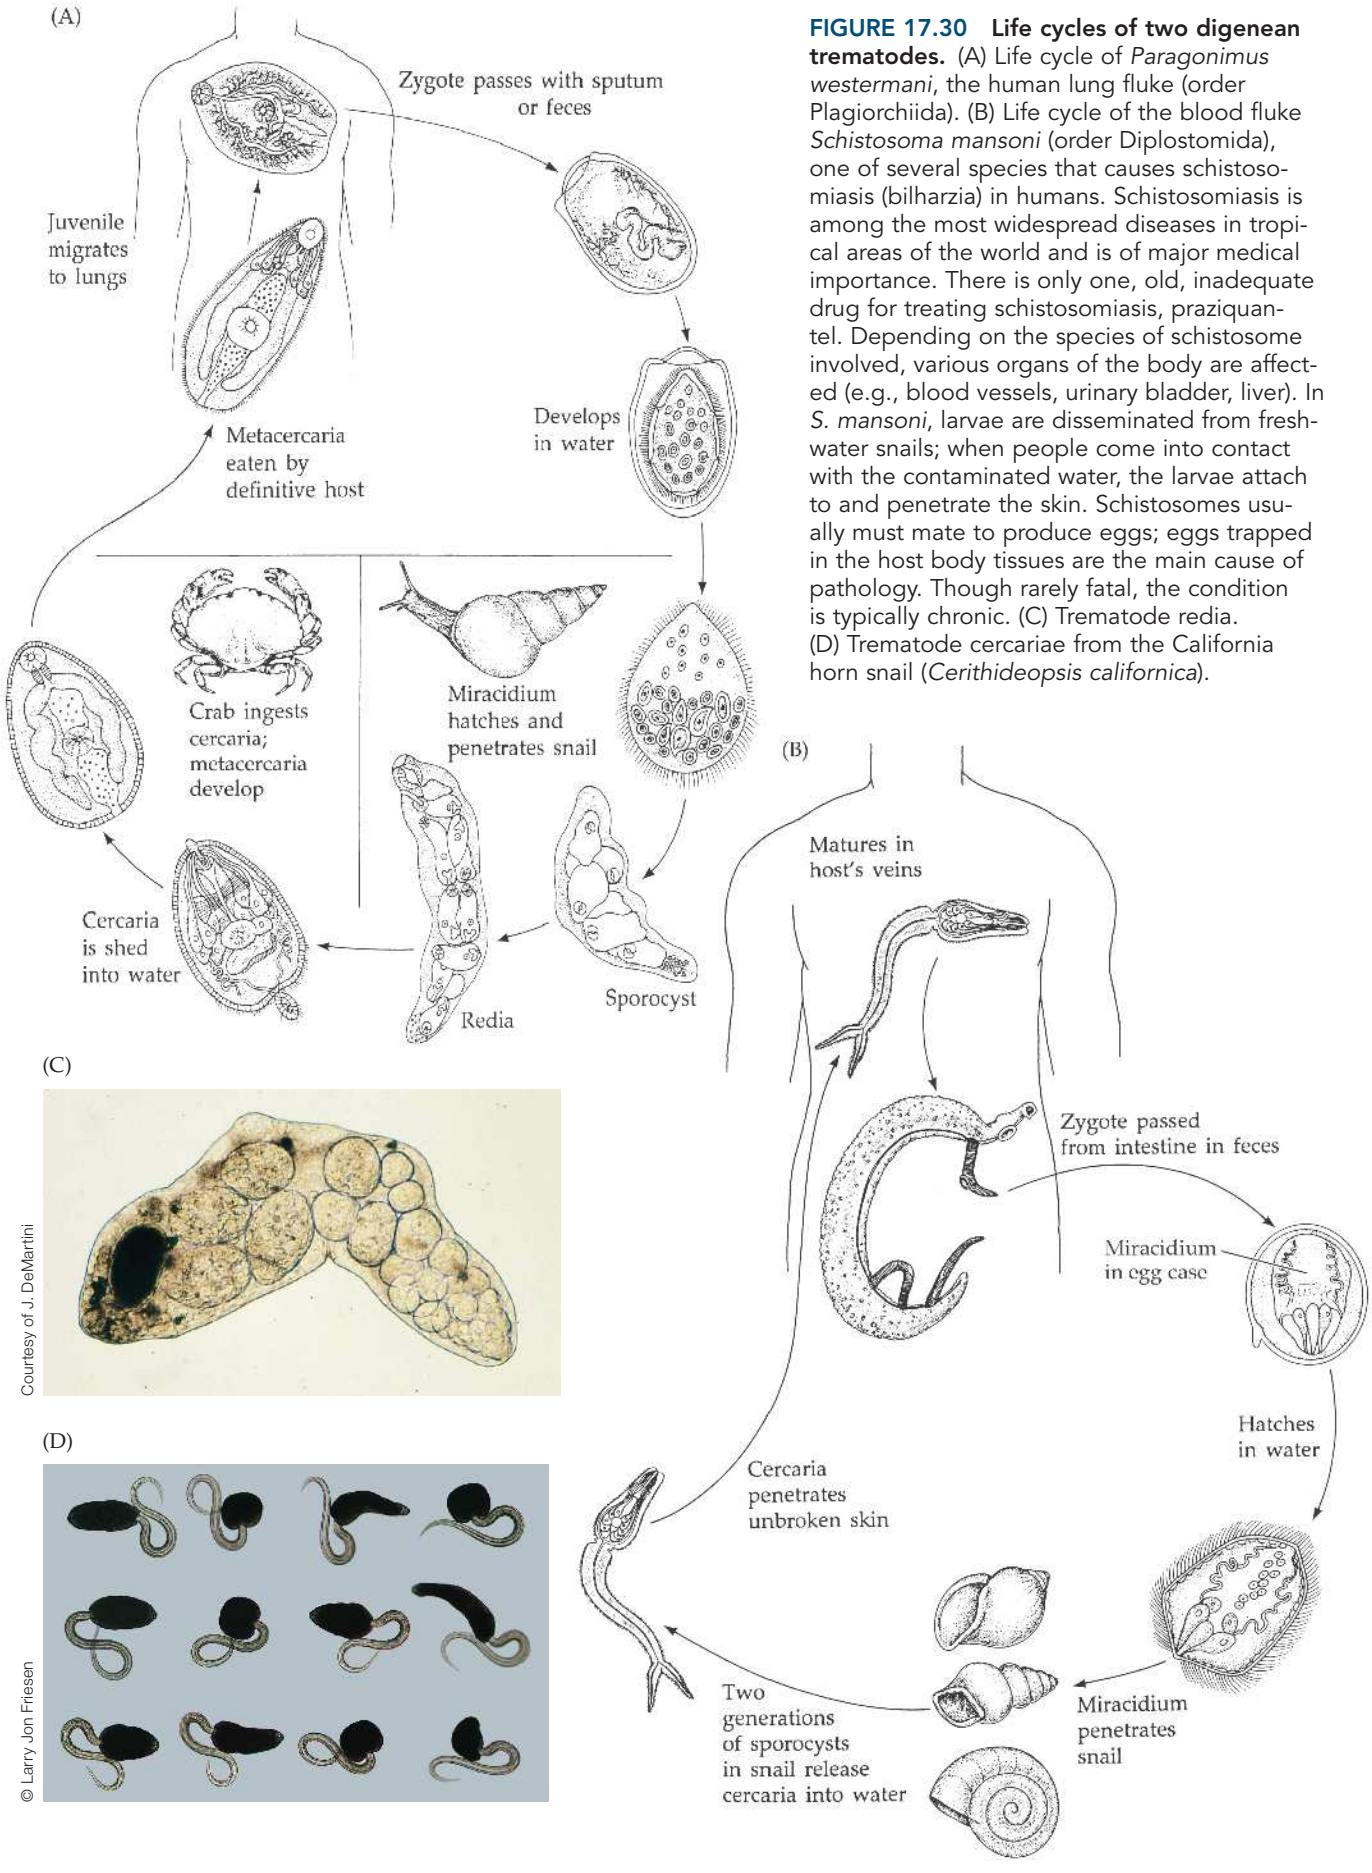

FIGURE 17.30 Life cycles of two digenean trematodes. (A) Life cycle of *Paragonimus westermani*, the human lung fluke (order Plagiorchiida). (B) Life cycle of the blood fluke *Schistosoma mansoni* (order Diplostomida), one of several species that causes schistosomiasis (bilharzia) in humans. Schistosomiasis is among the most widespread diseases in tropical areas of the world and is of major medical importance. There is only one, old, inadequate drug for treating schistosomiasis, praziquantel. Depending on the species of schistosome involved, various organs of the body are affected (e.g., blood vessels, urinary bladder, liver). In *S. mansoni*, larvae are disseminated from freshwater snails; when people come into contact with the contaminated water, the larvae attach to and penetrate the skin. Schistosomes usually must mate to produce eggs; eggs trapped in the host body tissues are the main cause of pathology. Though rarely fatal, the condition is typically chronic. (C) Trematode redia. (D) Trematode cercariae from the California horn snail (*Cerithideopsis californica*).

for more ebooks/test bank/solution manuals requests Email 9601267346@qq.com

bile duct. While still in the uterus of the female reproductive tract, the zygotes develop to miracidia, each housed within its original egg case. Once released from the female system and passed out of the host with the feces, the miracidia are eaten by the first intermediate host, a snail of the genus *Parafossarulus*. The ciliated, swimming miracidium hatches from its egg case in the gut of the snail and migrates into the digestive gland. Here each miracidium becomes an asexually active form called a **sporocyst**, within which germinal cells become yet another larval form called a **redia**. Subsequently, germinal cells within the redia produce the cercaria larvae. This double sequence of rapid asexual reproduction results in perhaps 250,000 cercariae from each original miracidium!

The cercariae leave the snail, swim about, and enter the second intermediate host, the Chinese golden carp (*Macropodus opercularis*). The cercariae of *C. sinensis* burrow through the skin of the fish and encyst in the muscle tissue as metacercaria. If the fish is insufficiently cooked and then eaten by a human, the metacercaria survive and are released from their cysts by the action of the host's digestive enzymes. Once freed, they migrate into the bile duct, metamorphose into juvenile worms, mature, and complete the cycle. Adult flukes can inhabit their hosts for many years, causing irritation and blockages. With this general life cycle in mind, we refer you to Figure 17.30 for a brief overview of two additional examples.

A critical point here are the strategies for survival displayed by these parasites. There is, of course, no assurance of finding the proper hosts at the proper times, and mortality is extremely high. The advantages of high specialization could be efficiency and reduced competition with other species, once established in a proper host. However, multiple infections and within-host competition can be intense, favoring a wide range of competitive adaptations among species, including in at least one trematode species (*Himasthla elongata*), soldier and reproductive castes within molluscan hosts, similar to those observed in social insects. Such adaptations imply the existence of strong selection, acting on larval as well as adult life stages. As we have emphasized earlier, the compensation for such high mortality is high fecundity coupled with asexual reproduction—and therein lies the expense. Another question is how so many different body plans can be produced by a single animal, but stem cell heterogeneity has an important role in driving the propagation of these complex life cycles.

Sexual reproduction: Tapeworms That the "business of animals is to reproduce themselves" is a lesson the cestodes demonstrate well. Most of their time, energy, and body mass are devoted to the production of more tapeworms. Like other flatworms, cestodes are hermaphroditic and practice mutual cross-fertilization when mates are available. However, some cestodes are known to self-fertilize. The orders Amphilinidea and Gyrocotylidea possess a single male and a single female reproductive system, whereas the remaining cestodes, which constitute a clade named Eucestoda (see the Classification section), contain complete systems repeated within each proglottid. There is a good deal of variation in the details of these systems; the following is a generalized description of the male and female systems as they occur in a single proglottid of a cestode (Figure 17.31).

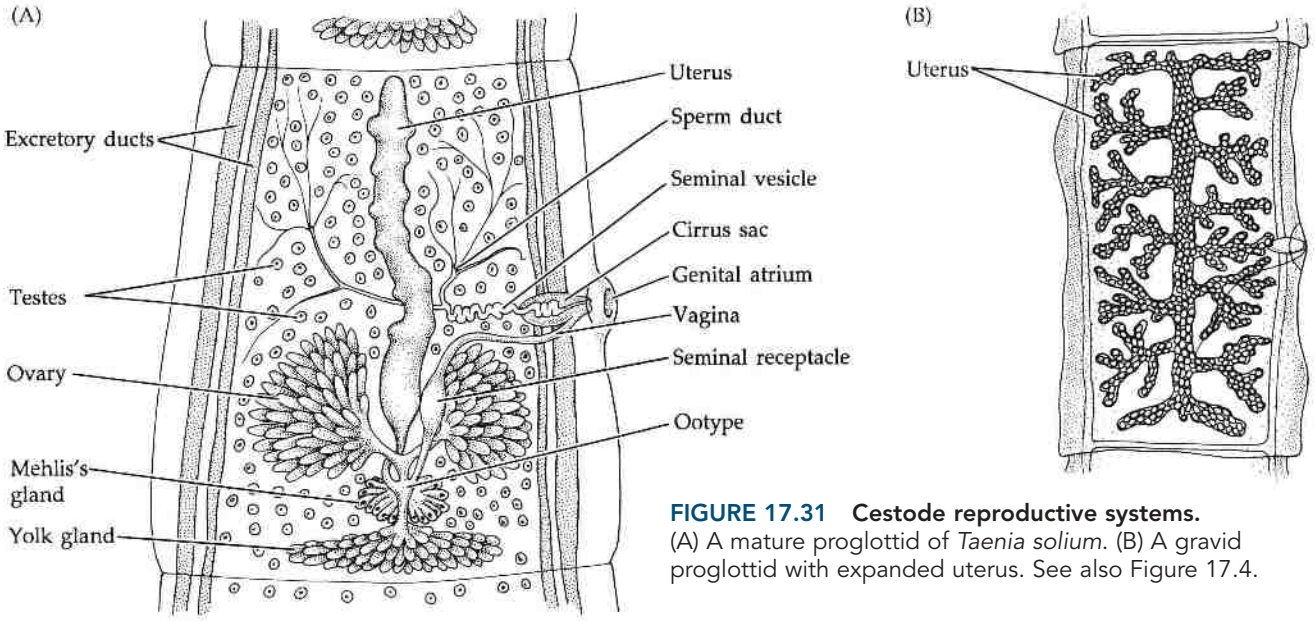

FIGURE 17.31 Cestode reproductive systems. (A) A mature proglottid of *Taenia solium*. (B) A gravid proglottid with expanded uterus. See also Figure 17.4.

The testes are numerous. Some are scattered throughout the mesenchyme, but most are concentrated along the lateral margins. Collecting tubules lead from the testes to a single coiled sperm duct, which extends laterally (as a seminal vesicle) to a cirrus housed within a muscular cirrus sac. The male system empties into a common genital atrium.

The female system usually includes two ovaries from which an oviduct extends to an ootype surrounded by shell glands. The uterus is a branched blind sac extending from the ootype. A duct extends from the female gonopore in the genital atrium to the oviduct; its junction with the oviduct, near the tube, is swollen as a seminal receptacle. The portion of the duct near the genital atrium is called the vagina. A diffuse yolk gland empties via a vitelline duct into the oviduct.

During mutual cross-fertilization the cirrus of each mate is inserted into the vagina of the other. Many tapeworms double back on themselves so that two proglottids of the same worm cross-fertilize; in some species, self-fertilization is known to occur within a single proglottid. Sperm are injected into the vaginal duct and are stored in the seminal receptacle. Eggs are fertilized as they move through the oviduct from the ovaries to the ootype. Capsule material and yolk cells are deposited around each zygote, and the zygotes are moved into the uterus for temporary storage.

The reproductive system of each proglottid matures and becomes functional with age as they are moved more posteriorly along the body by the production of new proglottids. If mating has occurred, the proglottids toward the posterior end become filled with an expanded uterus engorged with developing embryos (Figure 17.31B). These proglottids eventually break free from the body and are lost from the host with the feces, although in some cases the proglottids release embryos inside the host and the embryos pass out with the feces. Early development of tapeworm embryos is drastically modified from the pattern seen in free-living flatworms and varies somewhat among different groups. However, like all Neodermata, after fertilization the ectolecithal ova of cestodes show no vestiges of spiral cleavage, and even germ layer formation is often difficult or impossible to trace.

Most adult tapeworms live in the digestive tracts of vertebrates and usually require one or more intermediate hosts to complete their life cycles. A few can complete their life cycle in a single host. Depending on the number of hosts and other factors, tapeworm life cycles are quite variable, and we describe only two examples.

Taenia saginata (order Cyclophyllidea) is known as the beef tapeworm, since cattle are the intermediate hosts. The adults, which may exceed 1 m in length, reside in human small intestines (Figure 17.32A). As proglottids mature, they are released in the host's feces. The fertilized eggs break free into the environment as the proglottids disintegrate. By this time each zygote has developed to a stage called an **oncosphere**, surrounded by a resistant coat called an **embryophore**, which allows the embryo to remain in the environment for two or three months. Usually six tiny hooks are evident in the embryo; thus, the oncosphere is sometimes called a **hexacanth larva**.

If grazing cattle ingest the oncosphere, it is released from its covering, the hexacanth larva penetrates the intestinal wall using its hooks, and it is carried by the circulatory system to the cow's skeletal muscle. Here the hexacanth develops into a stage called the **cysticercus**, or bladder worm, which encysts in the connective tissue within the muscle of the intermediate host. Each cysticercus contains an invaginated developing scolex. If humans eat raw or poorly cooked infected beef, the scolex evaginates and attaches to the lining of the new host's small intestine, where the adult worm grows and matures. (Another tapeworm, *Taenia solium*, utilizes pigs as its intermediate host and follows a similar life cycle.)

The life cycles of some cestodes involve two or more hosts. An example is *Diphyllobothrium latum*, the so-called broad fish tapeworm (order Diphyllobothriidea) (Figure 17.32B). Nearly any fish-eating mammal, including humans, can serve as the definitive host for this tapeworm. Encapsulated zygotes are released from mature proglottids and shed in the host's feces. After one or two weeks in water, the embryos develop to the oncosphere (hexacanth) stage. At this time, each oncosphere is encased in a ciliated embryophore, and it hatches as a free-swimming larva called a **coracidium**. To successfully continue the life cycle, the coracidium must be eaten by the first intermediate host, a copepod (Crustacea). The cilia are shed and the released hexacanth larva bores through the gut wall into the host's body cavity, where it develops into a **procercoid** stage. Certain species of freshwater fish can serve as the second intermediate host. The fish eats the copepod, the procercoid bores through the gut and into the fish's muscle tissue, and there it grows into a segmented **plerocercoid** stage, complete with a tiny scolex. When a human consumes raw or undercooked infected fish, the plerocercoid attaches to the intestinal wall and matures.

Life cycles of parasitic flatworms can be a fascinating topic, and this lifestyle has resulted in great evolutionary success. Because of health and food industry implications, many life cycles are well studied and broadly available in public internet sites, such as the U.S. Centers for Disease Control and Prevention (CDC). We address the reader to these sites when they are interested in exploring the life cycles of many parasitic flatworms and other invertebrates.

Platyhelminth Phylogeny

Ideas about the origin of flatworms, their relationships to other phyla, and evolution within the group have been debated for a very long time. The lack of a robust fossil record and the relative anatomical simplicity of flatworms have made morphology-based phylogenetic analysis difficult—there is a paucity of reliable characters that might identify and differentiate clades. In fact, unambiguous synapomorphies that define the phylum Platyhelminthes itself have yet to be clearly identified. Platyhelminth fossils consist mainly of structures left on hosts by parasitic species, or occasional evidence from host coprolites, although some trace fossils from the early Paleozoic have been assigned to this phylum.

For most of the twentieth century, flatworms were considered to be very primitive bilaterians, perhaps even the sister group to the rest of Bilateria. However, in 1963, the German zoologist Peter Ax suggested that flatworms might actually be more highly derived (in the protostome line) than previously thought and that they might represent a series of reductions from a vermiform coelomate ancestor—a case of extreme reduction by paedomorphosis (the retention by adult individuals of traits seen in young), perhaps through neoteny, wherein the somatic development of adults is slowed or delayed. The idea had some support, especially with regard to the acoelomorphs (then included in Platyhelminthes). There was also an idea that platyhelminths arose through progenesis (a type of paedomorphosis in which sexual development of larvae or young is accelerated), from developmental stages of early protostomes prior to the embryonic appearance of the coelomic cavities—that is, rapid maturation of larval or other stages that had solid bodies or still contained the blastocoel. By the 1990s other researchers, such as the Danish zoologist Claus Nielsen, also began to argue that Platyhelminthes were nested higher in the spiralian protostome line. And in the late twentieth century and early in this century, phylogenetic studies based on gene sequence data clearly supported the idea that flatworms are not at the base of the bilaterian clade, but indeed nested higher in the Spiralia as a likely sister group of Gastrotricha. Thus, the anatomical simplicity of these animals, such as lack of a circulatory system and through gut, appears to be the result of secondary reductions, not primitiveness.

We can safely assume that the original flatworm was free-living, although not necessarily assignable to any extant order. Peter Ax, Tor Karling, and Ulrich Ehlers have presented various versions of this "turbellarian archetype." These hypothetical ancestral flatworms are envisioned as having had a simple pharynx and a saclike gut without diverticula, such as seen in modern Catenulidea and Macrostomorpha (Figure 17.33A,B). There is also general agreement that the primitive flatworm was probably an

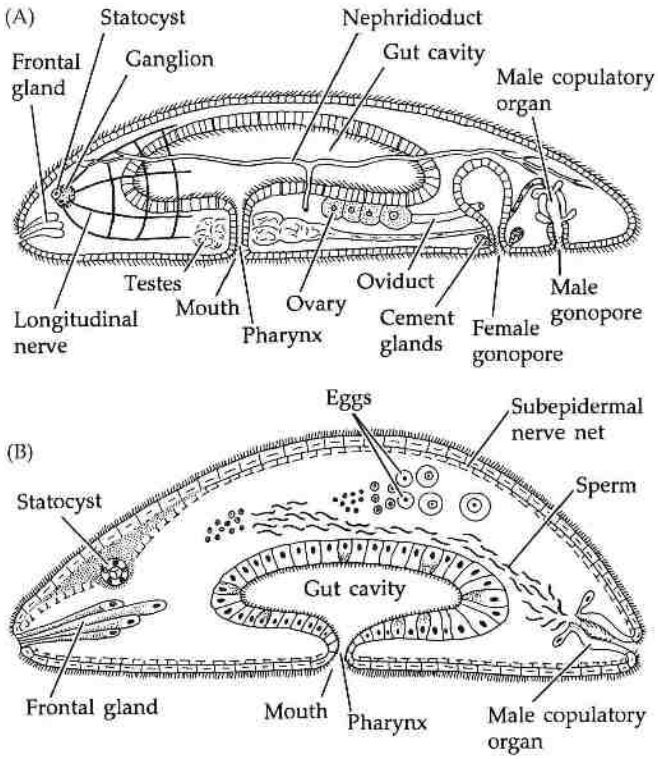

FIGURE 17.33 Two examples of hypothetical "turbellarian" archetypes. (A) Macrostomid-like archetype suggested by Peter Ax. (B) Archetype proposed by Tor Karling.

archoöphoran with endolecithal ova, spiral cleavage, and a single-layered, completely ciliated epidermis.

Fortunately, modern gene sequence analyses have begun to shed new light on the phylogeny of flatworms, including the removal of the Acoelomorpha (now in the phylum Xenacoelomorpha) and broad acceptance that platyhelminths comprise two major clades, Catenulidea and Rhabditophora. Molecular phylogenies also support the monophyly of Neodermata and also of its three major clades—Trematoda, Monogenea, and Cestoda (Figure 17.34).

The availability of genomic data sets for platyhelminths is uneven, clearly biased toward those of medical and veterinary importance. High-quality reference genomes exist for dozens of parasites, including the first platyhelminth genomes of *Schistosoma mansoni* and *Echinococcus multilocularis*, and detailed analyses of *S. haematobium* and *Taenia solium* as well as partial genomes of a couple dozen tapeworms, and about the same number for flukes, now exist. However, few free-living platyhelminths have been fully sequenced. These include *Macrostomum lignano* and the triclad *Schmidtea mediterranea*. In the fluke *Schistosoma*, two distinct mitochondrial gene orders have been found. The gene orders in free-living groups are often quite different from one another (and from the gene order of parasitic species). The use of transcriptomic data since 2015 has resulted in a number of

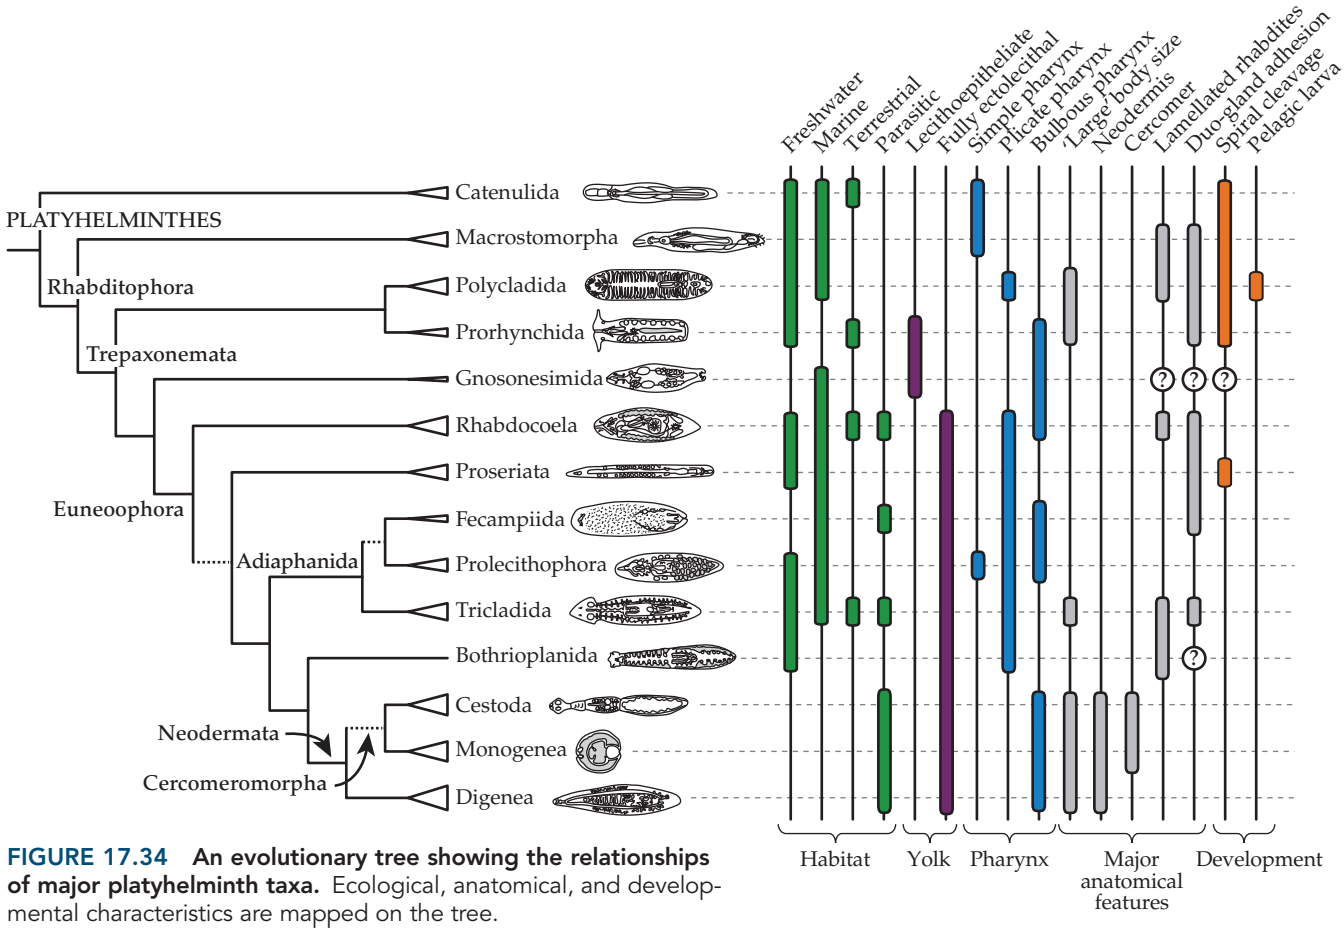

FIGURE 17.34 An evolutionary tree showing the relationships of major platyhelminth taxa. Ecological, anatomical, and developmental characteristics are mapped on the tree.

highly congruent hypotheses of relationships among the major platyhelminth lineages.

The phylogeny of Platyhelminthes shown in Figure 17.34 is based primarily on two simultaneous genomic studies (Laumer et al. 2015, Egger et al. 2015). Although many internal relationships remain enigmatic, the order Catenulida is now widely viewed to be the most basal of the platyhelminths and the sister group to Rhabditophora (containing the remaining platyhelminths). Catenulids are anatomically simple flatworms, with an unbranched pharynx and gut and a single biflagellate protonephridium. And they retain the spiral cleavage and endolecithal ova that characterize most phyla in the clade Spiralia. Rhabditophora comprises two clades, Macrostomorpha and Trepaxonemata, the latter being home to the majority of species in the phylum and including some of the best known free-living groups as well as the flukes and tapeworms.

All of the earliest-branching clades of flatworms, Catenulida, Macrostomorpha, and Polycladida share spiral cleavage and endolecithal eggs with other spriralian protostomes. The terrestrial/freshwater group Prorhynchida, a proposed sister group to the mainly marine, diverse, and well-known polyclad flatworms (Polycladida), retains spiral cleavage but has shifted to ectolecithal eggs. Molecular evidence strongly supports the sister-group relationship between the endolecithal polyclads and the ectolecithal Prorhynchida (a clade known as Amplimatricata), suggesting that prorhynchids independently evolved ectolecithal ova. The discovery of this likely evolution led to abandonment of the old taxon "Neoophora," which had held *all* the ectolecithal taxa (i.e., Prorhynchida, Rhabdocoela, Proseriata, and Acentrosomata). The last three groups now comprise the Euneoophora, the most highly derived flatworm lineage. These patterns confirm the basal nature of the archoöphoran plan. Gnosonesimora is likely the sister group to the Euneoophora. Recall that in the neoöphoran plan (seen in the order Prorhynchida and the superclass Euneoophora) there is an ovarian specialization into germinal and vitelline cell producing regions. It has been suggested that this separation of germ-line and yolk-line cells might allow these ectolecithal species to synthesize yolk at a higher rate than their endolecithal ancestors, thereby enhancing fecundity, and possibly allowing multiple embryos to develop within the same egg capsule, also enhancing fecundity by allowing conservation of resources for larval nutrition.

Phylogenetic relationships within the huge and complex Euneoophora lineage are still somewhat unsettled. The Rhabdocoela and Proseriata retain elements of spiral cleavage, suggesting their basal placement within this clade. Molecular analyses also suggest that rhabdocoels could be the sister group to the Proseriata +

Acentrosomata. Acentrosomata is notable for its loss of spiral cleavage. This is thought to be due to the evolutionary loss of the centrosome (and redirection of centriole formation) due to loss of three particular genes in species of Adiaphanida, Bothrioplanida, and Neodermata. It is this feature that led to their grouping under the name Acentrosomata. Centrioles, of course, play a critical role in the development of spindle fibers during cell division. In some cases, early embryogenesis in acentrosomate species is so chaotic that the blastomeres undergo what has been called dispersive cleavage, wherein they temporarily lose physical contact with one another and "drift" in a matrix of yolk. This process has been given the colorful name blastomere anarchy, and it characterizes Adiaphanida (triclads, prolecithophorans, and fecampiids) and Bothrioplanida. In these groups, centrioles are assembled in terminally differentiating ciliated cells through a so-called acentriolar pathway that triggers their assembly. This is the only known case of centrosome loss in the animal kingdom. Tricladida has been shown to be a monophyletic group. Bothrioplanids appear to be the last free-living ancestor to the Neodermata. There is no trace of spiral cleavage in neodermatans either, although they are not generally characterized by blastomere anarchy. There seems to be no question about the monophyly of the Neodermata, all of which are ectolecithal, lack spiral cleavage, and have larvae that shed their cilia early in their life cycle. However, there is still debate over relationships among the Monogenea, Cestoda, and Trematoda, as reflected in our phylogeny.

Phylum Gastrotricha: The Gastrotrichs, or Hairy-Bellied Worms

The phylum Gastrotricha (Greek *gasteros*, "stomach"; *trichos*, "hair") comprises about 860 species of marine, brackish, and freshwater protostomes. Most species are less than 1 mm long, although a few are only 60 μm in length while some reach 3.5 mm. Many gastrotrichs bear a superficial resemblance to flatworms and rotifers, but they are easily distinguished by their adhesive tubes and cilia restricted to the ventral surface. Under high magnification, tiny gastrotrichs appear as very charismatic invertebrates, with their "whiskered" faces and spiny or scaled, often bowling-pin-shaped bodies. Figure 17.35 illustrates some of the body forms within this phylum and some features of their external anatomy, and Box 17B lists the distinguishing features of the group. Marine gastrotrichs are meiofaunal and live in the interstitial spaces between sand grains, from the intertidal zone to abyssal depths (5,700 m). Freshwater species are found in surface detritus or among the filaments of aquatic plants and plantlike protists and sometimes form large blooms with densities of 2.6 million individuals per square meter; a few are semiplanktonic.

The gastrotrich body is typically divisible into a head and a trunk (Figures 17.35B,C and 17.36A), though many species lack such an obvious distinction. Externally, gastrotrichs possess a cuticle that surrounds all aspects of the body and is often smooth in appearance but may be elaborated into spines, bristles, scales, and/or plates (Figure 17.35). **Adhesive tubes**, a diagnostic character of most gastrotrichs, are also derived from the cuticle and generally contain a pair of glands that secrete adhesive and releaser substances (the **duo-gland adhesive system**). These tubes may be abundant (Macrodasyida) or sparse to absent (most Chaetonotida).

The gastrotrich head bears a terminal or subterminal mouth with stiff cilia or other cuticular elaborations. A ring of motile cilia often encompasses the head dorsally while other ciliary elaborations such as pits and tentacles are present on the sides (Figure 17.35F). A necklike constriction behind the head is present in many but not all gastrotrichs. The gastrotrich trunk (the main part of the body) is generally vermiform (Macrodasyida, *Neodasys*) or bowling-pin-shaped (Chaetonotida), and it contains most of the organ systems. The trunk terminates in a rounded, bilobed, tailed, or forked caudum that bears adhesive tubes.

The most recent molecular phylogenetic studies place gastrotrichs squarely within the protostome bilaterians and close to the base of the Spiralia, where they seem to arise near the Platyhelminthes or the Gnathifera (Gnathostomulida, Micrognathozoa, and Rotifera). Anatomically, however, gastrotrichs are more similar to the members of the Nematoida and Scalidophora clades because of their circumpharyngeal brain, bilayered cuticle, and myoepithelial pharynx.

GASTROTRICH CLASSIFICATION

ORDER CHAETONOTIDA (Figure 17.35A–C). Primarily freshwater, but also some marine, estuarine, and semiterrestrial (freshwater microhabitat) species; body usually bowling-pin-shaped, smooth or complex cuticle with a variable number of adhesive tubes (most with only 2 on caudal furca); pharynx with Y-shaped lumen, pharyngeal pores absent; 1 or more pairs of protonephridia present; hermaphroditic, parthenogenetic, or a combination of hermaphroditic and parthenogenetic.

SUBORDER MULTITUBULATINA Marine; strap-shaped body with smooth cuticle and anterior, posterior, ventral, and lateral adhesive tubes; hermaphroditic with complex reproductive organs. Monogeneric: *Neodasys*, with two known species.

SUBORDER PAUCITUBULATINA Mostly freshwater species but with many marine representatives;

The section on Gastrotricha was revised by Rick Hochberg.

bowling-pin-shaped body often covered by elaborate cuticle, usually with 2 terminal adhesive tubes on caudal furca, though some with 4 (e.g., *Diuronotus*) and others with no tubes (e.g., *Neogossea*, *Kijanebalola*); hermaphroditic, parthenogenetic, or both (e.g., *Aspidiophorus, Chaetonotus, Dasydytes, Lepidodermella*).

ORDER MACRODASYIDA (Figures 17.35D–F). Mostly marine and estuarine gastrotrichs with only a single freshwater genus (*Redudasys*); body usually strap shaped, with smooth or elaborately sculptured cuticle, usually bearing numerous adhesive tubes along the head (ventral) and trunk (lateral, ventral, posterior, sometimes dorsal); pharynx with inverted Y-shaped lumen, pharyngeal pores present in all except species of *Lepidodasys*; usually with several pairs of protonephridia; hermaphroditic with complex reproductive organs; some may be parthenogenetic (e.g., Redudasyidae, some *Macrodasys, Turbanella, Urodasys*).

BOX 17B Characteristics of the Phylum Gastrotricha

1. Triploblastic, bilateral, unsegmented, acoelomate
2. Microscopic, body elongate or bowling-pin-shaped
3. Bilayered cuticle, smooth or with scales or spinelike elaborations; with exocuticle covering entire body including all cilia; cuticle not molted
4. Duo-gland adhesive tubes
5. Epidermis cellular or partly syncytial; epidermal cells monociliate or multiciliate; locomotory cilia on ventral surface only
6. Myoepithelial pharynx with triradiate lumen; complete gut
7. One pair or more of protonephridia, without special circulatory or gas exchange structures
8. Hermaphroditic, parthenogenetic, or hermaphroditic and parthenogenetic
9. Complex reproductive organs
10. Embryonic development poorly studied
11. Direct development

The Gastrotrich Body Plan

Body Wall

A gastrotrich's body is encased in a multilayered cuticle of varying thickness and complexity. It is never molted. The outer portion, or exocuticle (also called epicuticle), contains one or more lamellae that cover all external surfaces, including locomotory and sensory cilia (Figure 17.36E); the inner portion, or endocuticle, is thick and fibrous and produces the spines, scales, and adhesive tubes (Figure 17.35). The epidermis may be cellular as in Macrodasyida or partly syncytial as in most Chaetonotida; only ventral epidermal cells bear locomotory cilia (thus the derivation of the phylum name: "hairy belly"). Most species possess multiciliate epidermal cells; however, some species possess monociliate cells in some parts of their body. **Duo-gland adhesive organs**, consisting of at least one adhesive gland and one releaser gland (which are critical for rapid grip and release from sand grains in the interstitial environment), are present in most species and form cuticle-covered necklike tubes to the outside (Figure 17.36F). A similar system also occurs in some Platyhelminthes. Species of *Neodasys* lack the releaser gland, and neither gland is present in some semiplanktonic species (e.g., Neogosseidae). An epidermal gland system consisting of multiple, independent, unicellular exocrine glands is present in most species of Macrodasyida and hypothesized to secrete compounds that function as repellents against predators.

Internal to the epidermis are connective tissues such as a basal lamina (absent in many species) or in some cases large vacuolar **Y-cells** (some Macrodasyida and *Neodasys*) that function in hydrostatic support. Hemoglobin has been detected in the Y-cells of *Neodasys* and may be present in others. Muscles are present as circular, helicoidal, and longitudinal bands that insert on the cuticle via an intervening epithelial cell; dorsoventral and other muscle orientations may also be present.

Support and Locomotion

The cuticle and compact (acoelomate) body plan provide hydrostatic support while the complex array of muscles produces the bending and twisting movements that are characteristic of gastrotrich locomotion and essential for life between sand grains (which are "boulder size" for millimeters-long gastrotrichs). Most animals are highly flexible and in some genera such as *Megadasys* (Figure 17.35D) can stretch their already elongate bodies to nearly twice gliding length or contract into a tight ball. The adhesive tubes play a significant role during these activities. Some semiplanktonic freshwater gastrotrichs, such as species of Dasydytidae (Chaetonotida), have movable spines that permit a form of saltatory swimming.

Feeding and Digestion

Most gastrotrichs feed by pumping small food items into the gut by action of the pharynx, a myoepithelial tube that is surrounded by complex layered muscles. The pharyngeal lumen is either Y-shaped (Chaetonotida) or inverted Y-shaped (Macrodasyida) (Figures 17.36B,D). In most macrodasyidans, a pair of pharyngeal pores connects the pharyngeal lumen to the outside, thereby permitting the release of excess water imbibed with the food (Figure 17.36C). Gastrotrichs feed on nearly any organic material, alive or dead, of appropriately small size (bacteria, detritus, protists, unicellular algae).

The mouth is terminal or subterminal and often surrounded by a ring of stiff cilia or cuticular spines that may aid in food capture. A short buccal cavity connects the mouth to the elongate muscular pharynx lined with cuticle (a stomodaeum) (Figure 17.36). In species of Chaetonotida, a pharyngeal "valve" may be present at the junction of the pharynx and intestine (midgut). The endodermally derived portion of the gut is a straight tube that narrows posteriorly and leads to a ventral anus. The anus is preceded by a cuticle-lined hindgut in Chaetonotida, while in most Macrodasyida a hindgut is absent and the anus is presumably permanent or temporary. Digestion and absorption occur in the intestine, which is composed of cuboidal cells with a brush border; motile cilia may be present in some species and aid in food passage.

Circulation, Gas Exchange, Excretion, and Osmoregulation

Circulation and gas exchange occur by diffusion through the body wall. Some gastrotrichs are capable of anaerobic respiration when environmental conditions require it. Protonephridia are the primary excretory organs in gastrotrichs. Marine species such as most macrodasyidans and *Neodasys* possess multiple pairs of protonephridia that function solely in the removal of metabolic wastes. Their protonephridia are generally mono- or bicellular filtration organs, each with a single flagellum; they connect to the outside by way of a single ciliary canal cell and nephridiopore cell. In species that live in a hypo-osmotic environment, like most freshwater chaetonotidans, the single pair of protonephridia also function in osmoregulation. Their protonephridia are bicellular organs that lead to an elongate and convoluted canal cell (Figure 17.36A). The extra length of the canal cell in freshwater species is hypothesized to function for increased reabsorption of necessary salts and minerals from the primary urine before elimination.

Nervous System and Sense Organs

The central nervous system consists of a dorsal brain and one or more pairs of longitudinal nerve cords. The

for more ebooks/test bank/solution manuals requests Email 9601267344@qq.com

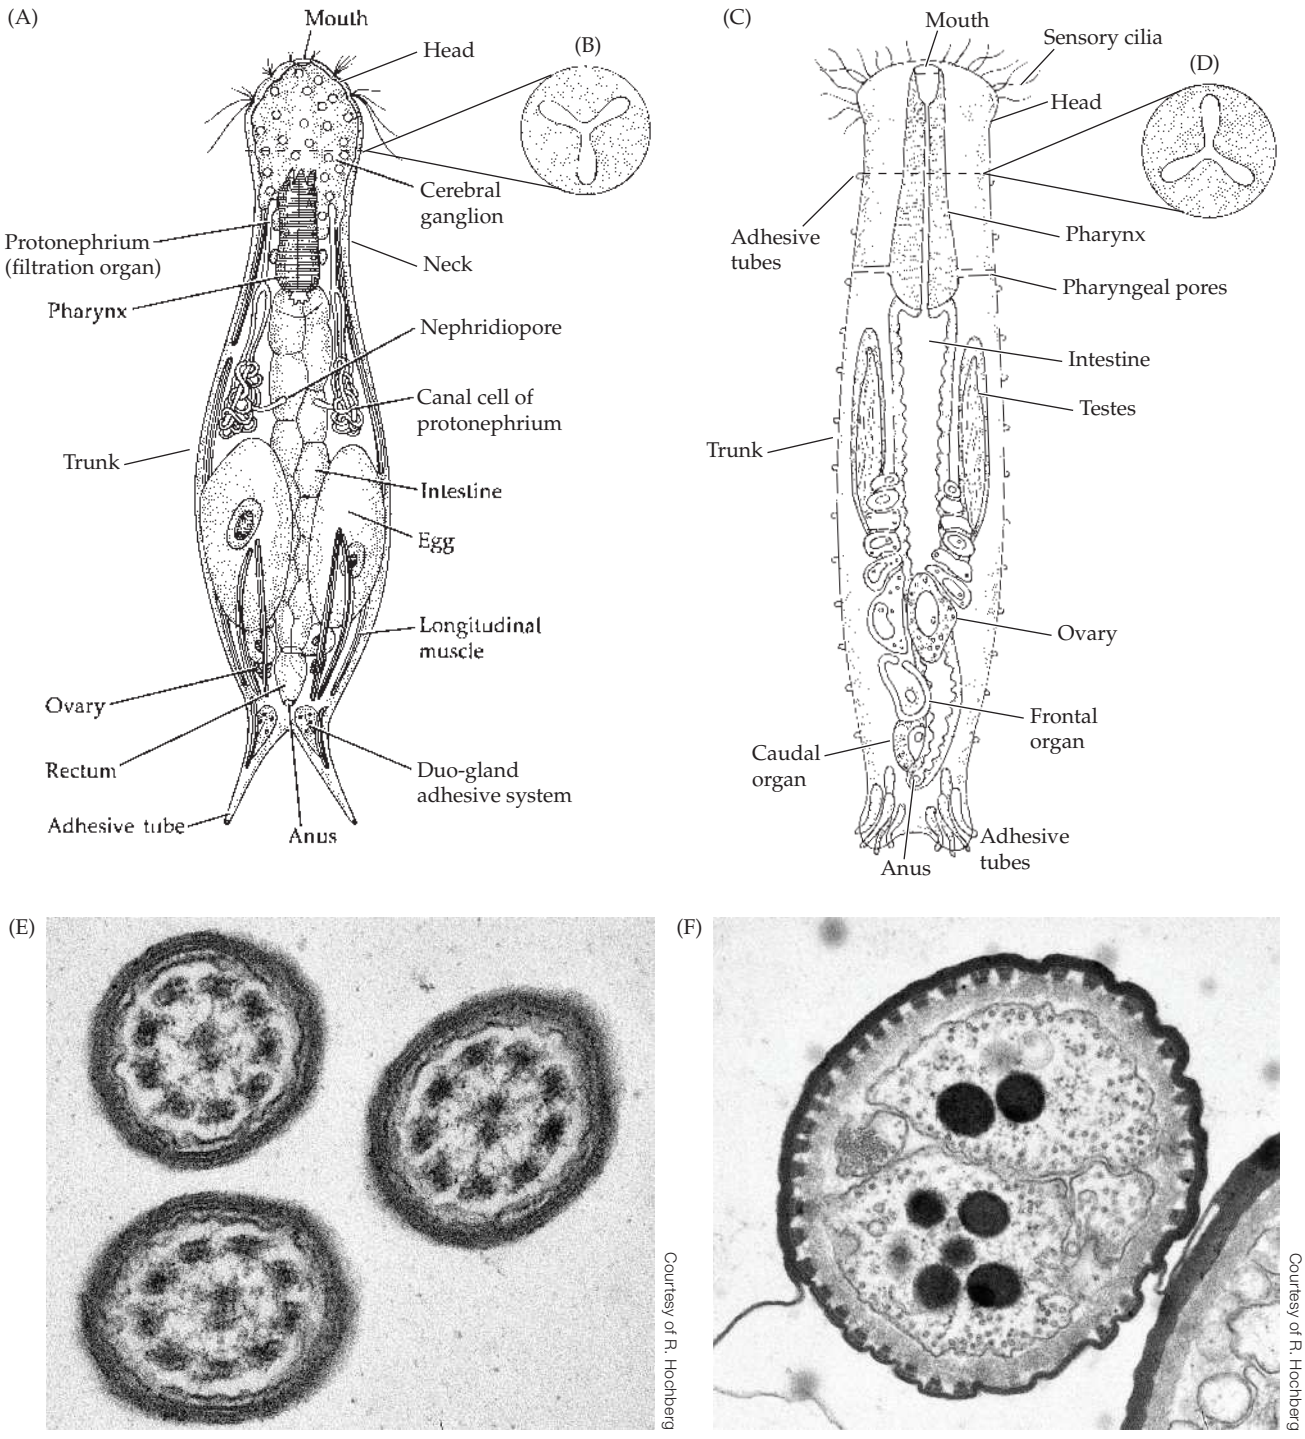

FIGURE 17.36 Anatomy of gastrotrichs. (A) Representative of Chaetonotida, *Paucitubulatina*. (B) Cross section through pharynx showing Y-shaped pharyngeal lumen. (C) Representative of Macrodasyida and (D) cross section through pharynx showing inverted Y-shaped pharyngeal lumen. (E–F) Transmission electron micrographs of (E) a cross section through locomotory cilia and (F) an adhesive tube.

brain consists of numerous cells that sit atop a ringlike commissure around the anterior region of the pharynx (Figure 17.36A). Cerebral neurons innervate the head and pharynx. The nonganglionated nerve cords arise from the brain and are interconnected by thin commissures; they unite at the posterior end.

Sensory receptors are ciliary in structure and concentrated in the head region but may be distributed over the entire body. Ciliary pits and tentacles on the heads of some species are likely chemosensory, while stiff, bristlelike cilia on the head and trunk probably have a tactile function. Several species possess

pigmented (red) ocelli that indicate probable photoreceptive capabilities; experiments have shown that species lacking ocelli still have spectral sensitivity. One species, *Pleurodasys helgolandicus*, possesses an unusual pair of drumstick-like organs that are hypothesized to function as gravity receptors.

Reproduction and Development

Most species of gastrotrichs are hermaphroditic or a combination of hermaphroditic and parthenogenetic. Strict parthenogenesis is rare and known from only a few species. The hermaphroditic reproductive system is best studied in Macrodasyida and often contains gametes and organs of sperm transfer and storage (Figure 17.36C). The male system comprises one or two testes with associated sperm ducts that lead to a single or paired ventral gonopores. A **caudal organ** that presumably functions in the transfer of sperm is present in most species, but in Hummondasyidae, and in some Macrodasyidae and Thaumastodermatidae, is it directly connected to the sperm ducts. Some species bear a sclerotized stylet within the caudal organ.

The female system includes one or two ovaries in the posterior body region. Other reproductive organs may include a **frontal organ** (seminal receptacle), as in Macrodasyida and *Neodasys*, or an **X-organ**, as in most Chaetonotida. The ovaries are generally compact or somewhat diffuse. Oocytes mature anteriorly in most species and become positioned above the intestine and in proximity to the frontal organ when present; oviducts are rare, but some species do have a distinct uterus. Yolk is produced within the oocyte itself. Mutual cross-fertilization leads to the direct exchange of sperm or spermatophores (via hypodermic impregnation or some other mechanism) in all species, but sperm is stored in the frontal organ of most macrodasyidans. The X-organ in chaetonotidans is a bilobed syncytial organ in the posterior trunk that develops during the sexual phase and is thought to play a role in reproduction, although its function has never been demonstrated. Fertilization is always internal and precedes the production of an eggshell by the egg itself. Oviposition is through the body wall of most species, and it might occur through a temporary or perhaps permanent pore, or in some cases via rupture of the body wall.

Historically, most freshwater chaetonotidans were assumed to be strict parthenogens until small packets of rodlike sperm were discovered next to their midgut. The sperm develop after the production of the parthenogenetic ova and in synchrony with the meiotic (sexual) ova, suggesting they are not vestigial male gametes; such a condition is referred to as **postparthenogenetic hermaphroditism**. Cross-fertilization has never been observed in these species. Two forms of parthenogenetic eggs are produced: the first few eggs (tachyblastic) hatch quickly and are important for rapid population growth, while the last egg (opsiblastic) may overwinter before hatching. A third and more rare type of egg, called the plaque-bearing egg, is thought to be the result of sexual reproduction, but its development has never been followed.

Few embryological studies have been conducted on gastrotrichs, and those few have shown that the main cleavage events are somewhat contradictory. In general, cleavage is holoblastic and subequal (i.e., the blastomeres are of approximately equal size); however, after the initial equatorial division, there is an apparent divergence in cleavage patterns between the two orders. The second cleavage plane of the posterior blastomere is meridional in macrodasyidans but equatorial in chaetonotidans, which leads to different fates for the developing tissues. In neither case is a spiral-like cleavage pattern evident. By the fifth division, a bilaterally symmetric embryo has developed. Gastrulation occurs by invagination followed by epiboly of the secondary ectoderm over presumptive mesoderm. A stomodaeum forms in both orders, but a proctodeum has been noted only for chaetonotidans. The U-shaped embryo continues to grow and elongate in the eggshell for several hours (to several days) prior to hatching.

Development is direct, juveniles being small versions of adults, though without noticeable reproductive organs and with fewer adhesive tubes (in Macrodasyida). Maturation is rapid and the animals usually are sexually mature within a few days after hatching. Individuals of most species probably live only a few weeks.

Chapter Summary

This chapter introduced you to the recently recognized clade Rouphozoa, a lineage of spiralian protostomes that includes two phyla: Platyhelminthes (flatworms) and Gastrotricha (hairy-bellied worms). For many years, flatworms had been regarded as basal bilaterians because of their seemingly simplified anatomy and lack of a through gut (absence of an anus). By the 2010s, however, phylogenomic analyses were indicating that platyhelminths and gastrotrichs comprise a sister group embedded well within the spiralian clade. Few anatomical apomorphies have been identified that define Rouphozoa, and both phyla seem to be characterized by features that are plesiomorphic for the Spiralia in general (dense body ciliation, protonephridia, etc.). One putative synapomorphy of Rouphozoa is the presence of duo-gland adhesive organs, although similar organs also exist in other groups as well (e.g., annelids, nematodes). Both

for more ebooks/test bank/solution manuals requests Email 960126734@qq.com

phyla are acoelomate, and their precise placement among the spiralian protostomes remains unresolved.

Nearly 30,000 species of platyhelminths have been described, including free-living, commensal, and parasitic forms from marine, freshwater, and terrestrial environments. Most are dorsoventrally flattened and all lack discrete circulatory or gas exchange structures and an anus. They possess a unique system of neoblast cells and produce mucus with specialized rhabdoids/rhabdites. Most are hermaphroditic, with complex reproductive systems and biflagellate sperm. Development is direct or indirect, with unique larvae in the large order Polycladida (Götte's and Müller's larvae). Platyhelminthes include many important parasitic species, including the flukes and tapeworms. About 860 species of marine, brackish-water, and freshwater gastrotrichs have been described, all being microscopic (60 μm to 3.5 mm). The cuticle is well developed, smooth or with scales or spines, and the epidermis is cellular or partly syncytial. The pharynx has a distinctive triradiate lumen, and the gut is complete.

CHAPTER 18

Introduction to Ecdysozoa

Scalidophora (Phyla Kinorhyncha, Priapula, Loricifera)

This chapter is the first of seven that describe animals belonging to the large protostome clade Ecdysozoa, first introduced in Chapter 8. Unlike the Spiralia, Ecdysozoa can be defined by clear morphological synapomorphies, including their three-layered cuticle that is molted, a process regulated by ecdysteroid hormones (where known). The cuticle consists of a proteinaceous exocuticle and an endocuticle with chitin or collagen, with the epicuticle forming from the apical zone of the epidermal microvilli. The cuticle contains chitin in all ecdysozoans, at least in some stages of the life cycle or in particular regions of their body. Ecdysozoans do not have external epithelial cilia, nor a ciliated larva with an apical organ, and they never undergo spiral cleavage. Cilia may be present, however, in association with certain cuticular structures, such as the scalids and buccal papillae of priapulans, the clavoscalids of loricriferans, and sensory spots on kinorhynchs.

Introduction to Ecdysozoa

Ecdysozoa contains eight phyla (and about 83% of known animal diversity), commonly organized into three subclades: Scalidophora, Nematoida (see Chapter 19), and Panarthropoda (see Chapter 20). The latter two subclades have robust morphological and sometimes molecular support, but while Scalidophora has strong morphological support, it is not always recovered as a clade in molecular analyses. The relationships of the three ecdysozoan clades have not been firmly determined, and they appear as an unresolved trichotomy in our tree of the Metazoa (see Chapter 28). Some evidence suggests

The sections on Kinorhyncha and Priapula were revised by Martin Vinther Sørensen. The section on Loricifera was revised by Katrine Worsaae and Reinhardt Møbjerg Kristensen.

** Molecular phylogenetic support for a monophyletic Scalidophora is ambivalent

*** Paraphyletic (excludes Hexapoda)

that Nematoida and Scalidophora might comprise a sister group, and they do share a number of morphological similarities, though nothing that is fully unique to the two groups. This putative clade has been given the name Cycloneuralia. However, most molecular phylogenetic analyses have failed to find support for Cycloneuralia, often placing Nematoida as a sister group to Panarthropoda, and Priapula sometimes as a sister group to all other ecdysozoans, a hypothesis that is in part supported by the large diversity of priapulan-like forms in the Cambrian, some of which may be stem-group priapulans or stem-group ecdysozoans.

The Scalidophora

The clade Scalidophora includes three phyla of marine infaunal animals, two exclusively meiofaunal (Kinorhyncha and Loricifera) and Priapula, which can be megainfaunal or meiofaunal as juveniles or even as adults. These three phyla may seem to have little in common, given the variation in body plans: the segmented trunk of kinorhynchs, the wormlike body of priapulans, and the loricated trunk (i.e., covered by a hard protective shell) of loriciferans. However, Scalidophora has been supported by a series of morphological characters. The name of the clade derives from the presence of scalids on the introvert—short spines, triradiate in cross section (at some ontogenetic stage), with ciliary receptors from one or more monociliated sensory cells. Another proposed synapomorphy uniting the three phyla is the presence of inner and outer retractor muscles in the introvert, the muscles attaching via **tanycytes**—extremely elongated epidermal cells with intermediate filaments. The protonephridia of scalidophorans are also unique, with a compound filter built by two or more terminal cells. And finally, scalidophorans are also characterized by the presence of **flosculi**, special sensory spots with external cuticular micropapillae surrounding a central pore and a few ciliary receptors. However, despite these seemingly strong synapomorphies, some morphologists have questioned Scalidophora based on similarities of the loriciferan larva to that of nematomorphs, including hexaradial symmetry in their internal armature as well as musculature (hexaradial symmetry is also found in some cephalic structures in nematodes).

While the clade Scalidophora has been largely endorsed by morphologists, the monophyly of this grouping has not been thoroughly tested with molecular data, and when tested, it has not been supported. Earlier molecular results, based on one or two genes, did not find a consistent placement for Loricifera. The first phylogenomic analysis including data for Loricifera recovered a sister-group relationship between Loricifera and Priapula, although without significant support, but the analysis did not include Kinorhyncha or Nematomorpha. A more recent phylogenomic analysis, with a data set designed to resolve ecdysozoan relationships, failed to recognize Scalidophora. For those molecular studies including at least Kinorhyncha and Priapula, many recovered their sister-group relationship with variable support, although other recent ones have suggested that Priapula is the sister group to all other ecdysozoans. Mitochondrial gene data fail to recognize Scalidophora, instead resolving Kinorhyncha and Priapula as a grade toward the stem of Ecdysozoa. So, although we continue to use Scalidophora in this edition of our text, we recognize that this clade still needs further testing.

The oldest suspected scalidophoran fossils are treptichnid burrows dating to the base of the Cambrian, thought to have been produced by a priapulan-like creature, and the annulated, introvert-bearing, lower Cambrian *Markuelia*. The latter includes several described fossil species that are among the earliest known ecdysozoans in the fossil record. Likewise, a series of articulated priapulan-like fossils, in addition to scalids, teeth, and hooks preserved as small carbonaceous fossils, are known since the Fortunian stage of the earliest Cambrian. However, positive identifications are difficult to make without being able to provide a clear morphological definition of Scalidophora that can be recognized in fossils. Several other, younger fossils have been assigned to Scalidophora or one of its constituent phyla, especially Priapula and Loricifera (see the Phylum Priapula and Phylum Loricifera sections).

Phylum Kinorhyncha: The Kinorhynchs, or Mud Dragons

Among the most intriguing of ecdysozoans are members of the phylum Kinorhyncha (Greek *kineo*, "movable"; *rhynchos*, "snout"), sometimes called "mud dragons." Since their discovery in 1841 on the northern coast of France, about 300 species of kinorhynchs have been described from around the world, nearly all of which are less than 1 mm in length. Most live in marine sands or muds, from the intertidal zone to a depth of 9,500 m. However, specimens have also been recorded from algal mats and kelp holdfasts, sandy beaches, and brackish estuaries; others live on hydroids, bryozoans, sponges, or sediment aggregations in polychaete tubes or on shells of molluscs.

The body of a kinorhynch is composed of three regions: a head, a short neck region, and a segmented trunk (Figure 18.1). Families and genera are often diagnosed by the composition of the segments, whereas species differences often relate to distribution of spines and setae. Kinorhynchs are one of three truly segmented metazoan clades (the other two being Annelida and the Panarthropoda), although the genetic developmental process of segment formation in kinorhynchs is not yet understood. The major characteristics of kinorhynchs are given in Box 18A.

(C) A trunk segment (cross section) of a kinorhynch; note the arrangement of the body wall structures and the organs within the blastocoelom. (D) *Echinoderes* sp., a meiofaunal species, with head extended.

The kinorhynch head is formed by a retractable mouth cone with nine outer **oral styles**, and an introvert with numerous appendages called **spinoscalids** (Figures 18.1 and 18.2A). By using the ten anterior-most primary spinoscalids as markers, the remaining spinoscalids on the introvert can be divided into ten sectors, where the spinoscalids follow either a bilateral or pentaradial symmetry pattern. Functionally, the two units can be distinguished by the way they move when the head is retracted into the trunk. The mouth cone can be withdrawn by simple retraction in which muscles attached to its proximal base drag it into the introvert. When the head retraction continues into the trunk, the introvert is inverted, meaning that the anterior-most spinoscalids and the part of the introvert that joins the mouth cone are the first to retract.

The kinorhynch neck is composed of a number of plates, called **placids**, and when the head is retracted, the placids act as a closing apparatus (Figure 18.2B). In some genera the placids are hard structures that are

BOX 18A Characteristics of the Phylum Kinorhyncha

1. Triploblastic, bilaterally symmetrical, body segmented (both externally and internally)
2. Blastocoelomate or, in some species, acoelomate
3. Body divided into head, neck, and 11-segmented trunk
4. Head divided into mouth cone and introvert with scalids
5. Segments formed by complete cuticular rings, or composed of tergal and sternal plates
6. Epidermis cellular without locomotory cilia
7. Gut complete
8. With one pair of protonephridia in segment 8, nephridiopores opening on segment 9; without special circulatory or gas exchange structures
9. Direct development through six juvenile stages; juveniles molting their cuticle at the transition between each stage
10. Gonochoristic
11. Embryonic development and cleavage patterns not well understood
12. Found in marine and brackish benthic habitats; most common in mud, but also found in sand or inhabiting epizoic or epiphytic habitats

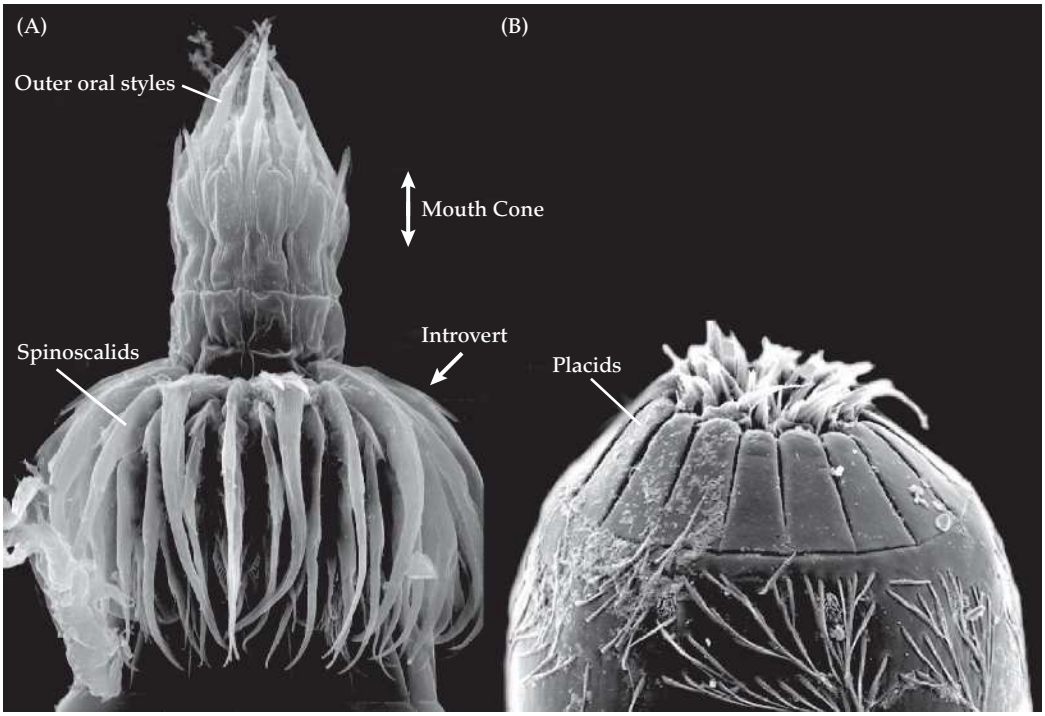

FIGURE 18.2 Scanning electron microscopy showing extended and retracted head of a kinorhynch. (A) Extended head, showing the external morphology of the mouth cone and introvert. (B) Retracted head, with the placids of the neck acting as closing apparatus.

easily recognized, whereas in other genera they are thinner and softer, and more difficult to see. Within the genus *Cateria*, the placids are extremely soft and in one species completely lost, whereas they are fused into a neck ring in the genus *Franciscideres*. The number of placids differs among genera and ranges from 4 to 16.

The kinorhynch trunk consists of 11 segments in all adults. Most trunk segments are made up of a dorsal (tergal) plate and a pair of ventral (sternal) plates (Figures 18.1A and 18.3). The anus is located on the last segment and is usually flanked by strong lateral terminal spines. The segmented body plan is reflected internally by the epidermal glands, nervous system, and muscles.

During juvenile development, and in some species during adult life as well, kinorhynchs shed their cuticle. This supports their position among the ecdysozoan protostomes, even though it is still uncertain whether molting is mediated by the hormone ecdysone.

CLASSIFICATION OF KINORHYNCHA

CLASS CYCLORHAGIDA Neck usually with 14–16 placids that work as a closing apparatus, although in one group a clamshell-like first trunk segment may assist;

trunk oval, inverted heart-shaped, or slightly triangular in cross section; numerous cuticular trunk spines and tubes present; trunk segments usually with dense covering of cuticular hairs or denticles. The class includes genera such as *Centroderes* (Figure 18.3B), *Echinoderes* (Figure 18.1D), *Meristoderes* (Figure 18.3C), and *Semnoderes*.

CLASS ALLOMALORHAGIDA Neck with 9 or fewer placids. Trunk either triangular or completely round in cross section. Midterminal spine never present in adults. The class includes genera such as *Paracentrophyes*, *Neocentrophyes*, *Pycnophyes*, *Dracoderes*, and *Franciscideres* (Figure 18.3A).

The Kinorhynch Body Plan

Body Wall

Beneath the thick, well-developed, chitinous cuticle is a nonciliated epidermis (Figure 18.1C) that contains elements of the nervous system. Largely internal to the epidermis but still attached to the cuticle are bands of cross-striated dorsal and ventral longitudinal muscles. All ventral muscles, and most dorsal ones, attach to cuticular thickenings at the anterior segment margins and run to the anterior margin of the following segment. Other dorsal muscles run throughout the trunk. The head is retracted by introvert and mouth cone retractor muscles that have anterior attachment points in the most anterior part of the introvert and have posterior attachments between trunk segments 3 to 6. A series of segmentally arranged dorsoventral muscles creates the increased hydrostatic pressure that protracts the introvert and **mouth cone** when the retractor muscles relax, and diagonal muscles contribute to lateral movement of the trunk (Figure 18.4).

Support and Locomotion

Body shape in kinorhynchs is more or less fixed by the rigid plates of the supportive cuticular exoskeleton, but the animals are able to flex and even twist at the points of articulation between adjacent segments. Segmented trunk musculature facilitates movements of the articulated cuticular plates. Intersegmental muscle fibers assist with dorsoventral and lateral trunk movements. In the absence of external cilia, burrowing is accomplished by extending the head into the substratum, anchoring the anterior spines, and then pulling the rest of the body forward. It has also been suggested that the numerous glandular cells that open along the trunk may be involved in locomotion, that is, by creating a push in a forward direction when mucus is released from the glands.

Feeding and Digestion

Kinorhynchs are probably direct deposit feeders, ingesting the substratum and digesting unicellular algae and/or other organic material therein; they have been found with their guts full of benthic diatoms. However, the details of feeding and the exact nature of their food are not known.

The digestive system is remarkably arthropodlike. The mouth leads into a buccal cavity located within the mouth cone and subsequently to a muscular pharynx (Figure 18.5). The buccal cavity, pharynx, and esophagus are lined with cuticle. Protractors, retractors, and circular muscles coordinate eversion and retraction of the introvert and mouth cone. Various paired glands are often associated with the esophagus, but their functions are uncertain. The esophagus connects with an elongate, straight midgut, which leads to a short, cuticle-lined proctodeal hindgut (rectum) and the anus on the last segment. So-called "digestive glands" often arise from the midgut.

Circulation, Gas Exchange, Excretion, and Osmoregulation

Gas exchange takes place by diffusion across the body wall, and circulation and internal transport are accomplished

primarily by body movements. Kinorhynchs possess one pair of solenocyte protonephridia in segment 8, each with a short nephridioduct that opens laterally through a nephridiopore on segment 9 (Figure 18.5B). Excretory and osmoregulatory physiology is likely interesting, although largely unstudied; some estuarine and intertidal species can tolerate large fluctuations in salinity, and some live in salinities as low as 3.5 parts per thousand in the Gulf of Finland.

Nervous System and Sense Organs

The central nervous system of kinorhynchs is relatively simple and is intimately associated with the epidermis. The brain is arranged in a ringlike manner around the pharynx (Figure 18.5A) and is composed of anterior and posterior aggregations of somata and a neuropil. Ten radially arranged longitudinal nerves arise from the neuropil. The two midventral longitudinal nerves converge in the trunk region forming the ventral nerve cord that has ganglia in each segment in most species. Sensory receptors include introvert spinoscalids and mouth cone styles (in the head region) and sensory spots and spines (on the trunk). Some species have pigmented eyespots in the anterior region of the introvert.

Reproduction and Development

Kinorhynchs are gonochoristic and possess relatively simple reproductive systems. External morphological differences between males and females are usually restricted to the most posterior segments. In both sexes, paired saclike gonads lead to short gonoducts that open separately on the terminal segment. In the males, the gonopore may be associated with two or three cuticular, hollow, penile spines that presumably aid in copulation, although their precise function is uncertain. The female gonads comprise both germ cells and nutritive (yolk-producing) cells. Each oviduct bears a diverticulum that forms as a seminal receptacle prior to ending at a gonopore between segments 10 and 11 (Figure 18.5C).

Mating has never been observed in kinorhynchs, and egg laying and early development (e.g., cleavage patterns) have not been adequately studied. Fertilized eggs are coated with a protective envelope of silt and detritus and then deposited in sediment. Embryos develop directly and hatch as juveniles with 9 segments. The juvenile reaches maturity after six molts and gradually changes into the adult morphology during these molts. New segments are added by elongation and by subsequent subdivision of the terminal segment. The mature condition with 11 trunk segments is often reached in juvenile stage 5. Molting among adults has been reported as well.

Phylum Priapula: The Priapulans, or Penis Worms

Twenty-two extant species (and several fossil species) are assigned to the phylum Priapula (from *Priapus*, the Greek god of reproduction, symbolized by his enormous penis). These odd creatures were recorded in Linnaeus's *Systema Naturae*, where he mentioned the species *Priapus humanus* (literally, "human penis"). Since that time priapulans have been associated with several different invertebrate phyla, but today morphological evidence supports their alliance with the other scalidophoran ecdysozoans, perhaps most closely related to the kinorhynchs. Molecular evidence is currently less conclusive, but some recent analyses also support the scalidophoran affinity. The major characteristics of priapulans are given in Box 18B.

Three genera (*Tubiluchus*, *Meiopriapulus*, and *Maccabeus*) comprise meiofaunal species that measure 1.5 mm to about 5 mm (Figure 18.6), whereas the remaining four genera (*Acanthopriapulus*, *Halicryptus*, *Priapulopsis*, and *Priapulus*) are macrofaunal, with the largest species, the Alaskan *Halicryptus higginsi*, reaching a length

Courtesy of G. Giribet

FIGURE 18.6 **The meiofaunal priapulan *Tubiluchus corallicola*.**

of almost 40 cm. Priapulans are cylindrical vermiform creatures. The body comprises an introvert, sometimes a neck region, a trunk, and sometimes a "tail" or **caudal appendage** (Figure 18.7). The whole introvert can be inverted, and it is equipped with short, hook-shaped scalids that are considered homologous with the spinoscalids of loriciferans and kinorhynchs. When present, the caudal appendage varies in shape and function among species.

Large priapulans are active infaunal burrowers in relatively fine marine sediments and occur primarily in boreal and cold temperate seas. A few species construct tubes. Adults of one species, *Halicryptus spinulosus*, lives in anoxic, sulfide-rich sediments in the Baltic Sea and shows remarkable abilities to both tolerate and detoxify high sulfide levels in its body. In contrast, the

BOX 18B Characteristics of the Phylum Priapula

1. Triploblastic, bilaterally symmetrical, unsegmented (may be superficially annulated), and vermiform
2. Body cavity lining probably not peritoneal; presumably blastocoelomate; one species coelomate
3. Introvert with hooked spines
4. Nervous system radially arranged and largely intraepidermal
5. Gut complete
6. With (often multicellular) protonephridia associated with the gonads as a urogenital system
7. Many with unique caudal appendage (in adults) that may serve for gas exchange
8. No circulatory system
9. Thin cuticle that is periodically shed; without epidermal cilia
10. With unique loricate larva, with cuticular lorica that is shed at metamorphosis to adult stage
11. Gonochoristic
12. Cleavage radial-like; the blastopore giving rise to the anus
13. Marine and benthic; mostly burrowers

small meiofaunal forms burrow or live interstitially among sediment particles, and they appear to be most diverse in subtropical and tropical waters.

Fossil stem- and crown-group priapulans are, so far, known only from the Cambrian record, where they are rather common. They may have been one of the major predator groups in the Cambrian seas, and they were almost certainly more diverse in Paleozoic times than they are today. The most abundant fossil species, *Ottoia prolifica*, resembles the extant *Halicryptus spinulosus*. Recent work confirms that *O. prolifica* and the closely related *O. tricuspida*, which date from the middle Cambrian, were serious carnivores, their introvert being lined with rows of hooks, teeth, and spines for dealing with their prey. The iconic trace fossil *Treptichnus pedum*, which defines the base of the Cambrian, has been postulated to be the result of the burrowing behavior of priapulan-like animals.

PRIAPULAN CLASSIFICATION

Classes and orders are usually not recognized within the Priapula; the phylum is divided into the three extant families:

FAMILY PRIAPULIDAE (Figure 18.7A–C). Relatively large (4–40 cm); trunk with superficial annulations; caudal appendage (absent from *Halicryptus spinulosus*) either a grapelike cluster of fluid-filled sacs (called vesiculae) or a muscular extension with cuticular hooks. Nine species, 4 genera: *Acanthopriapulus*, *Halicryptus*, *Priapulopsis*, and *Priapulus*

FAMILY TUBILUCHIDAE (Figures 18.6 and 18.7D). Small (less than 5 mm long); trunk not annulated; caudal appendage vermiform and muscular. Tubiluchids live in sediments of shallow tropical waters. Eleven species, 2 genera (*Tubiluchus* and *Meiopriapulus*)

FAMILY MACCABEIDAE (= CHAETOSTEPHANIDAE) (Figure 18.7E). Very small (less than 3 mm long); meiofaunal; trunk with rings of tubercles and posterior longitudinal ridges with hooks; no caudal appendage; posterior end of abdomen extensible and mobile, used for burrowing (posterior end first). Maccabeids are found in the Mediterranean Sea and Indian Ocean. Monogeneric, with only two described species (*Maccabeus tentaculatus* and *M. cirratus*)

Priapulan Body Plan

Body Wall, Support, and Locomotion

The priapulan body is covered by a thin, flexible cuticle that forms a variety of spines, warts, and tubercles (Figure 18.7). Hook-shaped scalids are often present around the mouth and on the introvert, and these are generally considered homologous with the spinoscalids of kinorhynchs and loriciferans. In all three groups the scalids function as sensory structures and assist in locomotion. Priapulans move through sediments by means of the introvert and peristaltic body muscle action. The cuticle contains chitin and is periodically shed as the animal grows. Beneath the cuticle lies an unciliated epidermis of thin, elongate cells with large fluid-filled intercellular spaces. Beneath the epidermis are well-developed layers of circular and longitudinal muscles. There are also complex muscle layers and bands associated with the pharynx, and a set of introvert retractor muscles (Figure 18.8A).

Adult priapulans have a large body cavity that may extend into the caudal appendage. The body cavity is lined by a simple noncellular membrane secreted by surface cells on the retractor muscles and is therefore a blastocoel (blastocoelom). The only exception to this is the meiofaunal species *Meiopriapulus fijiensis* that does possess a small epithelium-lined compartment around the foregut, and this cavity is apparently a true coelom. The fluid of the body cavity contains motile phagocytic amebocytes and free erythrocytes with hemerythrin.

Maintenance of body form and support are provided by the hydrostatic skeleton of the body cavity. The contraction of circular muscles around this cavity also facilitates protrusion of the introvert by increasing the internal pressure. Priapulans that move through the substratum do so largely by peristaltic burrowing, probably using the various hooks and other cuticular extensions to hold one part of the body in place while the rest is pushed or pulled along. *Maccabeus* is thought to use its ring of posterior cuticular spines for anchorage within its burrow (Figure 18.7E).

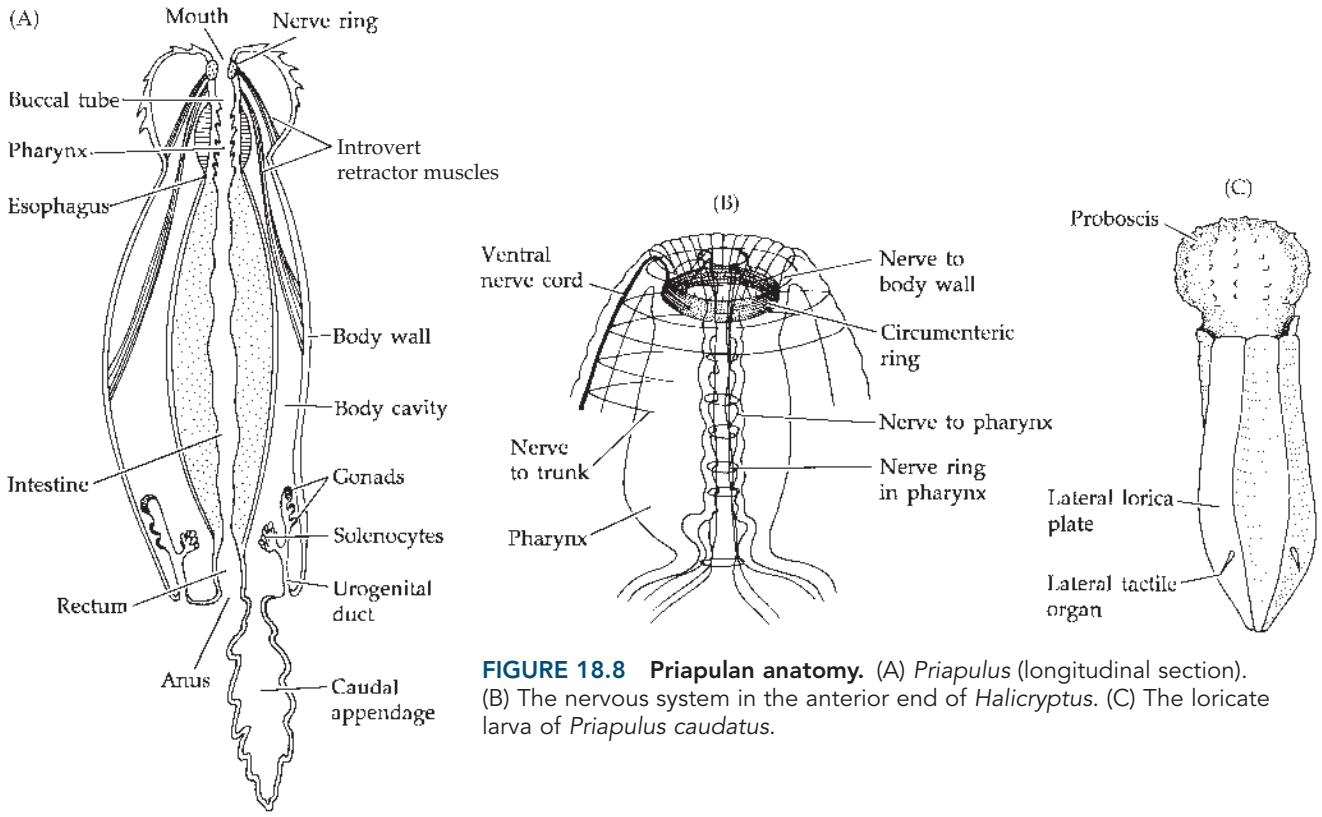

FIGURE 18.8 Priapulan anatomy. (A) *Priapulus* (longitudinal section). (B) The nervous system in the anterior end of *Halicryptus*. (C) The loricate larva of *Priapulus caudatus*.

Feeding and Digestion

Most priapulans (i.e., members of the family Priapulidae) live in soft sediments and prey on soft-bodied invertebrates such as polychaetes. During feeding, a portion of the toothed, cuticle-lined pharynx is everted through the mouth at the end of the extended introvert. As the prey is grasped, the pharynx is inverted; the introvert then retracts and the prey is drawn into the gut.

Tubiluchus corallicola (Figure 18.7D) lives in coral sand, as well as silty and muddy sediments, and feeds on organic detritus. The pharynx is lined with pectinate teeth, which the animal uses to sort food material from the coarse sediment particles. *Maccabeus tentaculatus*, a tube dweller, is a trapping carnivore. Eight short scalids, called **trigger spines**, arranged around the mouth opening are assumed to be touch sensitive, and these are in turn ringed by 25 branched scalids. It is suspected that when a potential prey touches the trigger spines, the other scalids quickly close as a trap.

The digestive system is complete and either straight or slightly coiled (Figure 18.8A). The portion of the gut that lies roughly within the bounds of the introvert comprises the buccal tube, pharynx, and esophagus, all of which are lined with cuticle and together constitute a stomodeum. In members of the genus *Tubiluchus*, the stomodeum also includes a region behind the esophagus called a **polythridium**, which bears a circlet of two rows of plates and may be used to grind food. The midgut or intestine is the only endodermally derived section of the digestive tract and is followed by a short proctodeal rectum. The anus is located at the posterior end of the abdomen, either centrally or slightly to one side. Nothing is known about the digestive physiology of priapulans, although it is likely that digestion and nutrient absorption occur in the midgut.

Circulation, Gas Exchange, Excretion, and Osmoregulation

Internal transport takes place through diffusion and movement of the fluid in the body cavity. The presence of the respiratory pigment hemerythrin in the body fluid cells suggests oxygen transport or storage functions, and many priapulans are known to live in marginally anoxic muds. In those species with a vesiculate caudal appendage, the lumen of that structure is continuous with the main body cavity, and such caudal appendages may function as gas exchange surfaces.

Clusters of solenocyte protonephridia lie in the posterior portion of the body cavity and are associated with the gonads as a urogenital system or complex (Figure 18.8A). Priapulan protonephridia are possibly unique in being composed of two or more terminal cells. A pair of urogenital pores opens near the anus. Priapulans inhabit both hyper- and hyposaline environments, so the protonephridia may function in both osmoregulation and excretion.

Nervous System and Sense Organs

The priapulan nervous system is intraepidermal and is constructed for the most part on a radial plan within the cylindrical body (Figure 18.8B). The brain is ring

shaped and wrapped around the buccal tube in the anterior part of the introvert. The main ventral nerve cord arises from this ring and gives off a series of ring nerves and peripheral nerves along the body. In addition, longitudinal nerves extend from the main nerve ring along the inner pharyngeal lining and are connected by the ring commissures.

Priapulans have several types of sensory structures. All introvert scalids, except the locomotory scalids in *Meiopriapulus fijiensis*, probably have a sensorial function, and smaller sensory structures—the so-called **flosculi**—are distributed over the trunk region. A flosculus is a sensory structure that includes a central sensory cilium surrounded by a circle or collar of seven modified microvilli. Besides scalids and flosculi, different setae, tubuli, and anal hooks may have receptor cells and hence serve a sensory function.

Reproduction and Development

Priapulans are gonochoristic, although males are unknown in *Maccabeus tentaculatus*. The reproductive organs are similarly placed and connected in both sexes. The paired gonads are drained by genital ducts, which are joined by collecting tubules from the protonephridia to form a pair of urogenital ducts exiting posteriorly through urogenital pores (Figure 18.8A).

Whereas macroscopic priapulans have external fertilization and spawn gametes into the water (first the males and then the females), at least species in the microscopic genus *Tubiluchus* appear to have internal fertilization. Cleavage is holoblastic, appears to be radial, and results in a coeloblastula (some accounts differ) that undergoes invagination. Gene expression studies on developing embryos of *Priapulus caudatus* have led to the surprising discovery that the anus is formed directly from the blastopore, whereas the mouth opening is formed by a group of ectodermal cells at the animal hemisphere of the embryo, thus these animals have deuterostomous development despite being part of the clade Protostomia. Gastrulation starts at the 64-cell stage with the invagination of the vegetal-most cells into a small blastocoel and the epibolic movement of the animal blastomeres toward the vegetal pole.

Direct development occurs only in *Meiopriapulus fijiensis*, in which the females brood the embryos. All other species develop through a series of **loricate larvae** (Figure 18.8C), which in some ways resemble loriciferans. The trunk of the larva is encased within a thick cuticular lorica into which the introvert can be withdrawn. The larvae live in benthic muds and are probably detritivores. The lorica is periodically shed as the larva grows; it is finally lost as the animal metamorphoses to a juvenile priapulan. At that time the caudal appendage forms in those species that possess this structure. The larvae of different genera vary somewhat in cuticular shape and ornamentation. Detailed larval development is best known for *Priapulus caudatus*. The newly hatched larva has a functional introvert, but mouth and anus are still closed, and no lorica is present yet. The lorica appears after the first molt, and additional scalids are added to the introvert. A mouth appears after the next molt, and during the following molts the trunk changes shape from being circular in cross section to having the flattened, bilateral symmetrical shape that typically is found in the *Priapulus* larvae. The exact number of larval stages is uncertain.

Phylum Loricifera: The Loriciferans

It may be apparent to you by now that interstitial habitats (the meiobenthic realm) are home for a host of bizarre and specialized creatures. Studies by zoologists D. Waloszek and K. J. Müller revealed that a rich meiofaunal ecosystem was in place as early as the upper Cambrian Era. And recently discovered microfossils now suggest that a rich meiofauna was already present in the early Cambrian, offering a solution to the problem (Darwin's dilemma) that the Cambrian Explosion appears to have sprung "out of nothing." Studies on modern meiofauna continue to reveal new animals, previously undescribed taxa, and myriad examples of convergent evolution associated with success in this environment. Among these recently discovered groups is the Loricifera, first named and described by Reinhardt Møbjerg Kristensen in 1983. The name Loricifera (Latin *lorica*, "corset"; *ferre*, "to bear") refers to the well-developed cuticular lorica encasing most of the body (Figure 18.9; Box 18C). The description of the phylum was initially based upon a single widespread species, *Nanaloricus mysticus*, but 37 other species have since been described. Most loriciferans have been found at depths of about 20–450 m in coarse marine sediments. One species, *Pliciloricus hadalis*, was collected in the western Pacific at a depth of over 8,000 m. Others, as yet undescribed, have been recorded from additional deep-sea muddy bottom locations. Most recently, a new type of larval form, called the **Shira-larva**, was described from depths of more than 3,000 m; it resembles Cambrian fossils from Australia. However, more surprising was the description in 2017 of an exceptionally preserved Cambrian loriciferan, *Eolorica deadwoodensis*, from western Canada. This fossil looks very similar to species in the extant family Pliciloricidae. To date, all 38 described extant species of loriciferans have been placed in three families (Nanaloricidae, Pliciloricidae, and Urnaloricidae) in a single order, Nanaloricida. All are free-living. Figures 18.9, 18.10 and 18.11 provide overviews of loriciferan anatomy.

In 2010, three species of loriciferans (all new to science) were discovered living and reproducing in a fully anoxic, high-sulfide, hypersaline basin in the deep Mediterranean Sea, called L'Atalante. Although prokaryotes and a few protists have long been known to spend their entire life in anoxic conditions, this was the first report of a metazoan proven to do so and to have obligate anaerobic metabolism. All three species lack mitochondria but

for more ebook, testbank, solution manuals requests, email: 960126734@qq.com

have hydrogenosomes in their cells, as seen in some ciliate protists. In this deep basin, these loriciferans occur in the highest abundance ever recorded for this phylum (up to 701 individuals per square meter). *Spinoloricus cinziae* (Figures 18.9E–F), one of the three new species from this hypersaline basin, was formally described in 2014.

The loriciferan body is minute (85–800 μm long, the abyssal *Titaniloricus inexpectatovus* a giant among them) but complex, containing over 10,000 cells. The adults of most are about the same size as large meiobenthic ciliated protists. It is divided into a head (introvert and mouth cone), neck, thorax, and loricate abdomen. The head, neck, and most of the thorax can telescope into the lorica. The mouth is located at the end of an introvert, called the **mouth cone,** that projects from the head and contains six protrusible **oral stylets** in some species. Furthermore, the mouth cone also can have up to eight **oral ridges**, each with a furca at the base where the eight muscles attach. Nine rings of spinelike **scalids** (200–400 scalids in all) of various shapes also protrude from the spherical head, most apparently with intrinsic muscles. In the pliciloricids, some of these projections bear joints near their bases, reminiscent of articulated limbs. The first ring consists of 8 anteriorly directed **clavoscalids**; the remaining eight rings of **spinoscalids** are directed posteriorly. In at least some species of

(an undescribed species from northwest France). (C) *Pliciloricus enigmaticus* (male), from the USA. (D) *Pliciloricus gracilis*, male, from the USA. (E,F) *Spinoloricus cinziae*, dorsal views in micrograph and line drawing. This is the first known metazoan living in an anoxic environment; from a deep basin in the Mediterranean Sea.

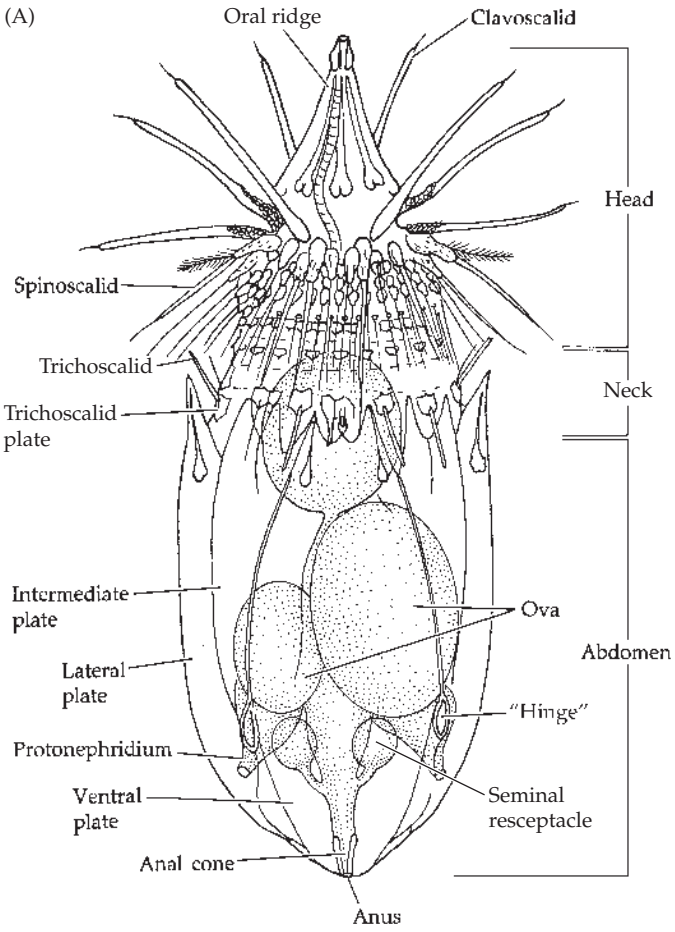

FIGURE 18.10 Anatomy of Loricifera. (A) An adult female loriciferan, *Nanaloricus mysticus* (ventral view). (B) The anterior end of *Nanaloricus mysticus*.

Nanaloricidae, the number of clavoscalids differs between males and females. The males may have 6 of the clavoscalids each split into three branches, resulting in a total of up 20 clavoscalids. The clavoscalids seem to be chemoreceptors, while the spinoscalids are both mechanoreceptors and locomotory. The 15 trichoscalids of the neck can be double or single. Recently it was discovered that the trichoscalids are attached to large cross-striated muscles, and in the family Nanaloricidae the adults use them to "jump" more than three times their own length, whereas in the family Pliciloricidae the trichoscalids may be used for swimming.

The lorica comprises six to ten plates in the family Nanaloricidae, which bear anteriorly directed spines around the base of the neck. In the family Pliciloricidae there are no plates, but there are cuticular plicae. In the genus *Pliciloricus* there are about 22 plicae, but in the genera *Rugiloricus* and *Titaniloricus* there are 30 to 60 plicae. Beneath the cuticle and the body wall there are several muscle bands, including those responsible for retraction of the anterior parts. The body cavity is presumably a blastocoelom (as is typical for the members of Scalidophora) and varies from rather spacious in Pliciloricidae to virtually absent in *Nanaloricus* (which would thus be acoelomate in the adult). Two musculatized **toes** occur caudally in the larva, on the abdomen, and function in both locomotion and adhesion. In the family Nanaloricidae, the Higgins larva has leaflike cuticular structures called **mucrones**. These structures may be involved in the swimming behavior of the larva.

The digestive tract is complete. A long, tubular, buccal canal leads from the mouth to a muscular pharynx bulb and esophagus (Figure 18.10B). The pharynx has both circular and longitudinal muscles. The lumen of these anterior gut structures is lined with cuticle. Behind the esophagus is a long midgut leading to a

BOX 18C Characteristics of the Phylum Loricifera

1. Triploblastic, bilaterally symmetrical, unsegmented, never vermiform, without epidermal cilia
2. Body cavity lining probably not peritoneal; presumably blastocoelomate or acoelomate
3. Body divided into a head (with a mouth cone and an introvert), neck, thorax, and loricate abdomen; the head-neck-thorax telescoping into the lorica
4. Mouth located on mouth cone, beset with spines (stylets); head (introvert) and neck with 7–9 rings of scalids
5. Gut complete
6. Without circulatory or gas exchange systems
7. One to two pairs of protonephridia, situated in gonads
8. Gonochoristic, parthenogenic (neotenous larvae), or hermaphroditic; development always including a unique, toed larva
9. All in marine interstitial environments (sand or mud); from shallow waters to the deep sea

FIGURE 18.11 The Higgins larva of two loriciferans. (A) *Pliciloricus gracilis* (ventral view; note the oral stylets and the tubular toes). (B) *Armorloricus elegans* (dorsal view; note the toes have mucrones for swimming).

short, cuticle-lined rectum and an anus located on an anal cone. One pair of salivary glands is associated with the buccal tube. Little is known about feeding in loriciferans, but some apparently eat bacteria.

The central nervous system includes a large circumpharyngeal ganglion and a number of smaller ganglia associated with the various body regions and parts. A large ventral nerve cord also bears ganglia. At least some of the scalids are probably sensory in function; however, videos have shown that at least the trichoscalids are involved in a jumping behavior.

Loriciferans are gonochoristic, although one species (*Rugiloricus renaudae*) is hermaphroditic. Males and females differ externally in the form and number of certain scalids. The male reproductive system comprises two dorsal testes in the abdominal body cavity, probably a blastocoelom. The female system includes a pair of ovaries and probably in a few species of *Nanaloricus* also two seminal receptacles. Fertilization is suspected to be internal. Loriciferans have one or two pairs of monoflagellate protonephridia that are uniquely located within the gonads.

Little is yet known about early development in loriciferans. In most species, a feeding, benthic **Higgins larva** develops. This larva (Figure 18.11) is built along the same general body plan as the adult, but it possesses a pair of "toes" at the posterior end that are used for locomotion. These toes are thought to also have adhesive glands at their bases. Early stages apparently contain yolk reserves in the cells of the body cavity. The cuticle is periodically shed as the individuals grow in size. In some species the larva metamorphoses to a so-called "postlarva" (juvenile), which resembles an adult female but lacks ovaries. In others, larval metamorphosis involves a molt directly to an adult.

The original discovery of loriciferans was a fortunate event because the first species described, *Nanaloricus mysticus* (Nanaloricidae), proved to have the simplest life cycle in the phylum with the only life stages being the Higgins larva, free-living postlarva, and adult. In the second described genus, *Rugiloricus*, a strongly modified postlarval stage was discovered (in *R. cauliculus*). Successive complexity was added to loriciferan life cycles, first with the discovery of parthenogenetic phases, and then with the newly discovered Urnaloricidae, which lack free adults (Figures 18.12 and 18.14). And we now know that deep-sea species hasten their life cycle by producing neotenous larvae, which give rise to two to four additional larvae by parthenogenesis. The larvae of some loriciferans can encyst for a period of time, before metamorphosis, and this process might include a new type of larva—the so-called "ghost larva." The newest discovered loops in these complex life cycles are shown in Figure 18.13. *Rugiloricus manuelae* lacks free-living postlarvae, similar to what is seen in the genus *Pliciloricus*. Figure 18.13 shows a typical life cycle for species in the family Pliciloricidae, and Figure 18.14 shows the hypothetical life cycle of the urnaloricid, *Urnaloricus gadi,* with two question marks—where are the adults?

Chapter Summary

This chapter introduced you to two important clades, Ecdysozoa (also described in Chapter 8) and Scalidophora. Ecdysozoa is well supported by both molecular phylogenies and morphology, and it is notable for its distinct three-layered cuticle that is molted by way of ecdysteroid hormonal control. Ecdysozoans also lack external epithelial cilia (except for those associated with sensory structures), do not have ciliated larvae (nor apical organs), and never undergo spiral cleavage. Of the eight ecdysozoan phyla, three (Kinorhyncha, Loricifera,

(*Continued*)

Chapter Summary (*continued*)

Priapula) belong to a putative clade called Scalidophora. Kinorhyncha and Loricifera are exclusively meiofaunal, while priapulans can be mega- or meiofaunal. All three phyla are strictly marine and benthic, are probably blastocoelic (with the one exception noted for *Meiopriapulus*), possess a proboscis bearing unique triradiate spines called scalids, and have other shared apomorphies. However, the clade Scalidophora remains to be confirmed by molecular phylogenetics.

All 300 or so species of kinorhynchs (the mud dragons) are less than 1 mm in length. They live in marine sediments or on algae, from the littoral to 9,500 m. Their body is divided into a head, neck, and 11-segmented trunk. On the head, the proboscis forms a retractable mouth cone and introvert covered with spines or scales, and the retracted introvert is closed by other scales called placids. All these structures, as well as the trunk spines, are what give these creatures a "dragon" appearance. Loriciferans were discovered in 1983, and today nearly 40 species have been described. The name refers to a cuticular lorica encasing most of the body. They are minute animals that live in marine sediments from 20 m to over 8,000 m. As in kinorhynchs, the proboscis forms a retractable mouth cone and introvert (covered with protrusible stylets and scalids in some species). Priapulans comprise a small phylum (22 extant described species) of strange wormlike marine burrowing or interstitial animals. They range in size from 1.5 mm to 40 cm. As with kinorhynchs and loriciferans, the proboscis forms a retractable mouth cone and introvert covered with various spines. Many priapulans have a caudal appendage that might serve for gas exchange.

Future research on the Scalidophora will likely focus on embryology and genomics, which are in its infancy for this clade, with only a single poor-quality genome available for Priapula (at the time of this writing), and none for Loricifera or Kinorhyncha. The relationships among scalidophorans, and to the other ecdysozoan phyla, remain to be further evaluated. Virtually nothing is known about the embryonic development of Loricifera. Also, because priapulan-like animals were so diverse and abundant in the Cambrian, it would be interesting to understand why this group is relatively marginal in today's oceans.

CHAPTER 19

Nematoida

Phyla Nematoda and Nematomorpha

As noted in Chapter 18, the eight ecdysozoan phyla are generally organized into three subclades: Scalidophora (phyla Kinorhyncha, Priapula, Loricifera; see Chapter 18), Panarthropoda (phyla Onychophora, Tardigrada, Arthropoda; see Chapter 20), and Nematoida (treated in this chapter). The Nematoida include two phyla, Nematoda (nematodes, or roundworms) and Nematomorpha (nematomorphs, or horsehair worms). Nematoid worms epitomize the vermiform animal body plan, some being so long and thin they are sometimes referred to as "threadworms." The clade Nematoida is well supported by both molecular and morphological data. Adults in both phyla share a special cuticle, mostly without chitin (chitin is restricted to the cuticular pharynx of nematodes and to the juvenile cuticle of nematomorphs). Neither phylum has protonephridia, and both lack circular musculature in the body wall. The epidermis has epidermal cords, and it is likely that two such cords, dorsal and ventral, are ancestral for the clade Nematoida. The epidermal cords include longitudinal nerve strands. Males in both phyla possess a cloaca, the exception being the marine nematomorphs (genus *Nectonema*) in which the posterior part of the intestine is reduced and therefore cannot form a cloaca. In female nematodes, however, the genital opening is separate from the anus and often far away from it, in the middle region of the body. One further corresponding character is the lack of cilia in sperm cells, although both taxa have highly modified spermatozoa that are not comparable with each other in their structure, and lack of cilia is common in terrestrial animals. As in the other ecdysozoan taxa, nematoids lack locomotory epidermal cilia.

The section on Nematomorpha was revised by Andreas Schmidt-Rhaesa.

*** Paraphyletic (excludes Hexapoda)

FIGURE 19.1 Examples of the phylum Nematoda.
(A) *Allantonema* sp. (order Tylenchida), an insect parasite. (B) *Sphaerulariopsis* sp. (order Tylenchida), an insect parasite. (C) *Heterodera glycines* (order Desmodorida), a plant parasite. (D) *Tylenchulus semipenetrans* (order Tylenchida), a plant parasite. (E) *Greeffiella* sp. (order Desmoscolecida), a free-living marine species. (F) *Hexamermis* sp. (order Mermithida), a parasite of various invertebrates. (G) *Heterorhabditis bacteriophora* (order Rhabditida), an insect pathogen. (H) *Draconema* sp. (order Desmodorida), a free-living marine species. (I) *Caenorhabditis elegans* undergoing facultative vivipary, or endotokia matricida (juveniles are seen escaping the mother's body).

Nematodes and nematomorphs are both slender worms. Specimens of the nematode order Mermithida (Figure 19.1F) can be easily confused with nematomorphs, because both are insect parasites with a free-living phase and large body size (usually in the range of several tens of centimeters). However, they are differentiated by the surface structure of the cuticle and the shape of the ends of their bodies. Nematomorphs emerge from their hosts as adults with diagnostic characters for identification to species; mermithid nematodes emerge as postparasitic juveniles and must undergo a final molt to reach the adult stage.

Nematodes molt three or four times during their development; the preadult stages resemble the adults in general and are therefore called juveniles (although the term "larva" is often applied as well, especially with parasitic species). In nematomorphs, only one molt has been observed—at the end of a growth phase of the parasitic juvenile. Nematomorphs possess a true larva, which is microscopic (< 1 mm) and morphologically completely different from the adult.

While Nematoda is a species-rich taxon with a great variety of lifestyles that has adapted to nearly every habitat on Earth, Nematomorpha are all very similar in their life cycle, which includes a parasitic phase and a free-living phase for reproduction.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Phylum Nematoda: Roundworms

Nematodes, the roundworms, are in the curious position of simultaneously being one of the least-known and one of the best-known animal phyla. How is this possible? They are one of the least known because, while nearly 27,000 species have been described, estimates of numbers of undescribed species range into the millions. Molecular studies have revealed that many named species are actually complexes of several genetically distinct species that are so far difficult or impossible to discriminate based on morphology. It has been suggested that every living animal and plant on Earth is host to one or more parasitic nematode species. Nematodes are nearly ubiquitous, they exist in almost every habitat and ecosystem on Earth (except the very driest), on every continent, and they are almost certainly the most abundant animals on the planet. Nematoda is the most abundant and speciose animal phylum in most marine sediments, including the abyss. It is one of the best-known animal phyla because the free-living soil nematode *Caenorhabditis elegans* has been adopted as a model organism in many fields, including neurobiology, developmental biology, toxicology, and genetics. Thousands of scientists around the world have focused their research on *C. elegans* with the goal of fully understanding every aspect of its biology and the developmental fate of every embryonic cell. *Caenorhabditis elegans* has a number of features that make it both relevant and powerful as a model for biological research. It is easy and inexpensive to maintain in laboratory conditions, it has a short life cycle (about three days), it produces a large number (300+) of offspring, and it has a transparent body that allows easy observation of all its cells. *Caenorhabditis elegans* is about 1 mm long and is a diploid, primarily self-fertilizing hermaphroditic roundworm. It was the first multicellular organism to have its entire genome sequenced. The complete cell lineage of *C. elegans*, from zygote to hatchling, is known, and its cell lineage is invariant—every individual is produced by the exact same sequence of cell divisions, which has been fully mapped. And with 959 somatic cells in adult hermaphrodite individuals, it is one of the best-documented cases of eutely. Males in this species, which are maintained at low numbers in natural populations, have 1,031 somatic cells. Once the target number of cells has been reached, growth in body size can only be accomplished by increases in the size of the cells themselves.

An enormous amount of literature exists on other nematodes as well, much of it dealing with parasitic species of economic or medical importance. Many of the large parasitic forms, such as the trichina worm (*Trichinella spiralis*), have been known since ancient times. Parasitic nematodes are sometimes called threadworms or pinworms.

Not all species of roundworms have the typical threadlike appearance, and their size may vary from a few microns to several meters in length (Figure 19.1). One of the smallest species known is *Hapalomus minutus*, just 80 μm (0.08 mm) long from sandy beaches and coral reefs. At the opposite end of the spectrum is the human Guinea worm (*Dracunculus medinensis*), up to 1.2 m long, and *Placentonema gigantissima*, the sperm whale nematode with females reaching over 8 m in length. Most free-living and plant-parasitic species are smaller than 1 mm.

Gastrointestinal nematode parasites have been shown to be important drivers of selection in wild vertebrate communities, and estimates of the number of undescribed nematodes that are parasites of vertebrates alone are on the order of 25,000 species. Skin-penetrating parasitic nematodes infect around one billion people worldwide. Nematodes can be found in aquatic (marine and freshwater) and terrestrial ecosystems ranging from the tropics to the poles, and at all elevations. In 2011, a nematode 500 μm (0.5 mm) long was even found living in ancient waters several miles below the Earth's surface in South Africa. Named *Halicephalobus mephisto*, after Mephistopheles (in reference to the devil in the Faust legend), this is the deepest-living metazoan yet discovered. It is thought to inhabit water-filled rock fractures and feed on subterranean bacteria. Some species are generalists, but many have very specific habitats. For example, the sour paste nematode, *Panagrellus redivivus*, described by Linnaeus in 1767 (as *Chaos redvivum*), was isolated from bookbinding glue.

Marine roundworms are considered the most diverse and widespread group of nematodes, occurring from shores to the abyss, and about 11,400 species have so far been described. Most studies of free-living marine meiobenthic communities have shown nematodes to be the most species-rich phylum in that environment. However, in spite of their abundance, marine nematodes are poorly known, most species remain undescribed, and their importance in benthic systems is little appreciated, though their relative abundance is sometimes used in biomonitoring. Some terrestrial soil environments yield as many as three million nematodes per square meter, and many thousands of nematodes occur in a handful of garden soil.

Many soil nematodes can undergo a resting phase, a period of extreme quiescence, or even cryptobiosis (nearly complete suspension of their metabolism) when conditions become unfavorable. Roundworms even survive the extreme cold and dryness of the Antarctic Dry Valleys in an anhydrobiotic state.

Nematodes have developed a multitude of parasitic lifestyles, which is why they can affect almost every animal and plant on Earth, including us. In fact, it has been estimated that up to one-third of all humans, mainly in the developing world, carry a nematode infection. Some cause serious damage to crops and livestock, and some are pathogenic to humans. More crop losses worldwide are caused by nematodes than

all arthropods combined. Most pet owners eventually encounter parasitic nematodes, as they are commonly seen in the feces and vomit of dogs and cats. The filarial worm, *Onchocerca volvulus*, is transmitted to humans through the bites of black flies and causes an eye disease called "river blindness" that is thought to infect nearly 40 million people in Latin America and Africa.

Nematodes (Greek *nema*, "thread"; *odes* "resembling") are vermiform blastocoelomates or acoelomates, with thin unsegmented bodies that are usually distinctly round in cross section (Box 19A). They possess digestive, nervous, reproductive, and excretory (though not of the nephridial type) systems but lack a discrete circulatory or respiratory system. To the untrained and unaided eye, most nematodes look very much alike, but there are significant variations in external body form, especially among the meiofaunal species (Figures 19.1 and 19.4). Although poorly known from the fossil record, a few species have been described from Early Cretaceous Lebanese amber, Late Cretaceous Burmese amber, and some Cenozoic amber. The earliest known unambiguous nematode is the lower Devonian *Palaeonema phyticum*. However, some specialists have suggested the Cambrian "Orsten" species *Shergoldana australiensis* might be a nematode or perhaps a member of the stem-group Nematoida, due to the similarity of its anterior end with that of nematomorphs.

BOX 19A Characteristics of the Phylum Nematoda

1. Triploblastic, bilateral, vermiform, unsegmented, and blastocoelic (or acoelic)
2. Body round in cross section and covered by a layered cuticle (chitin present in the pharyngeal cuticle of some species); growth in juveniles accompanied by cuticular molting until reaching the adult form; generally with four juvenile stages
3. Body wall with only longitudinal muscles (no circular muscles), with muscle arms
4. With unique cephalic sense organs (amphids); some with unique caudal sense organs (phasmids)
5. Complete digestive system; various oral structures arranged in radially symmetrical pattern
6. Most with unique secretory-excretory system, composed of one or two renette cells or a set of collecting tubules
7. Without special circulatory or gas-exchange structures
8. Epidermis cellular or syncytial, forming longitudinal cords housing nerve cords
9. Gonochoristic; wide range of reproductive modes
10. With unique cleavage pattern; not radial or spiral
11. Eutely present in at least some species (or some organs)
12. Found in marine, freshwater, and terrestrial environments, free-living and parasitic, sometimes with complex life cycles

Classification of Phylum Nematoda

Chitwood and Chitwood's 1933 anatomy-based classification of roundworms long prevailed, with a division of the phylum into Aphasmidia and Phasmidia, later changed to Adenophorea ("gland bearers") and

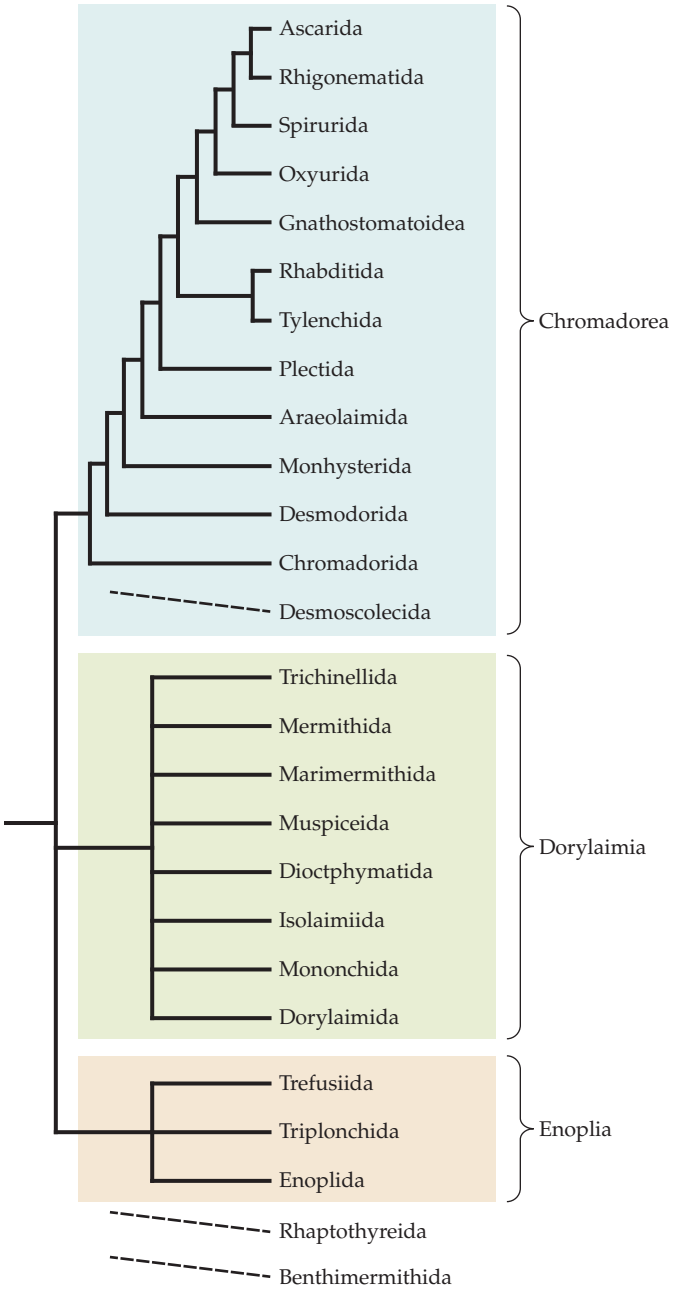

FIGURE 19.2 Nematoda molecular phylogenetic framework. Consensus phylogenetic view of Nematoda, combined from De Ley and Blaxter (2002), Sudhaus (2011), and Schmidt-Rhaesa (2014).

for more ebook/ testbank/ solution manuals requests email 9601267346@qq.com

Secernentea ("secretors"), respectively. More recent work, however, found Secernentea to be a derived clade within Chromadorea, whereas Adenophorea is probably paraphyletic (although the name is commonly still used). Molecular phylogenetics, bioinformatics, and digital communication technologies have substantially impacted nematode systematics over the past two decades. Blaxter et al. (1998) created the first molecular framework for the classification of Nematoda, using small subunit (SSU) rRNA sequences from 53 nematode species. Since then, SSU rRNA sequences available in public databases have increased enormously, some recent phylogenies have included over a thousand terminal taxa, and a phylogenomic analysis based on 56 nematode genomes has been published (International Helminth Genomes Consortium, 2019). (More than a hundred nematode genomes are currently available in public databases.) A new classification is emerging from the molecular data, but much more work remains to be done, as it fails to recognize many of the traditional nematode orders. The molecular framework confirms the presence of three principal early nematode lineages, named Chromadorea, Enoplia, and Dorylaimia (Figure 19.2), although the exact order of appearance of these three lineages (and relationships of their contained subclades) is not yet resolved. Thus, our consensus/working classification recognizes the three classes–Chromadorea, Enoplia, and Dorylaimia–and simply lists the major subclades alphabetically as orders. For a more detailed look at nematode classification, see De Ley and Blaxter (2002, 2004), Holterman et al. (2006), Meldal et al. (2007), and Schmidt-Rhaesa (2014), with some more recent changes based on genomics.

SYNOPSIS OF MAJOR GROUPS

CLASS CHROMADOREA With porelike or slitlike amphids, which vary from labial pores or slits to postlabial elaborate coils and spirals; cuticle usually annulated, sometimes ornamented with projections and setae; phasmids present or absent, generally posterior; esophagus usually divided into bulbs, with 3 to 5 esophageal glands; excretory system glandular or tubular, female with 1 or 2 ovaries.

ORDER ARAEOLAIMIDA A large clade with ~400 described species; mainly marine, but some species in humid terrestrial habitats. *Aphanolaimus*, *Araeolaimus*, *Odontophora*, *Sabatieria*, etc.

ORDER ASCARIDA (= ASCARIDIDA) Parasitic in the small intestines or lungs of mammals; including the human parasite *Ascaris lumbricoides* (the most common human helminth infection worldwide) and the pig parasite *A. suum*.

ORDER CHROMADORIDA Marine, free-living (occasionally in fresh water or soil). *Acantholaimus* (mostly in deep sea), *Achromadora* (on mosses and wet soils), *Chromadora*, *Chromadorita*, *Euchromadora*, *Neochromadora*, *Paracanthonchus*, etc.

ORDER DESMODORIDA Very large order of almost solely marine nematodes that includes the subfamily Stilbonematinae, long threadlike roundworms covered with a layer of symbiotic chemolithoautotrophic prokaryotes. *Aponema*, *Draconema*, *Desmodora*, *Ethmolaimus*, *Globodera*, *Heterodera*, etc.

ORDER DESMOSCOLECIDA Small to minute, free-living, almost exclusively marine (some

freshwater and moist soil species in the genus *Desmoscolex*). Most species recognizable by an annulated cuticle covered with minute mineral particles. *Desmoscolex*, *Greeffiella*, etc.

"ORDER GNATHOSTOMATIDA" Some workers put this cosmopolitan group within the order Spirurida, but this has not been supported by recent molecular studies. And, despite some anatomical features that seemed to unite the gnathostomatidans, the grouping is almost certainly artificial, and further studies are necessary to unravel the phylogenetic relationships of its genera. These are large, 2–6 cm or longer worms with distinctive pseudolabia that may bear teeth or long ramified appendages; the pseudolabia allow for retraction and expansion of the head in many genera. All are parasites, the hosts typically being aquatic and cold-blooded vertebrates, although the genus *Gnathostoma* is parasitic in mammals. Adult worms usually burrow into the mucosa of the host's stomach or intestine, or in sea otters into the esophagus or kidneys. In two nonmarine genera, *Gnathostoma* and *Spiroxys*, embryogenesis is known to occur in fresh water, and the motile second-stage juveniles (J2) are ingested by copepods (the obligatory intermediate hosts), where they develop into the infective third stage (J3) in the coelomic cavity. J3 stages re-encapsulate in the muscles and mesentery of the final host.

ORDER MICROLAIMIDA Lacking any known anatomical synapomorphies. Cuticle striated, annulated, smooth or punctate; buccal cavity usually with more or less pronounced dorsal tooth and smaller subventral teeth. Erected by Leduc et al. (2017), on the basis of molecular studies, to house the rare, free-living marine Paramicrolaimidae as well as *Molgolaimus* (formerly in Desmodorida and not included in our tree).

ORDER MONHYSTERIDA A large and complex lineage of roundworms with nearly 1,000 described species. Marine, freshwater, and terrestrial. *Astomonema*, *Gammarinema* (known only from the gill chambers of malacostracan Crustacea), *Linhomoeus*, *Parastomonema*, *Rhynchonema*, *Theristus*, etc.

ORDER OXYURIDA Pinworms usually parasitic in the guts of vertebrates, comprising 4 families and including the human pinworm, *Enterobius vermicularis*. Known from almost every primate genus. The life cycle is direct, with no free-living stage; transmission occurs through ingestion of eggs. Also *Gyrinicola, Oxyuris*, *Skrjabinema*, *Syphacia*, *Trypanoxyuris*, etc.

ORDER PLECTIDA An enigmatic order that may be paraphyletic; many marine species, as well as some in fresh water, soil, fungal mats, rotting wood, and thermal springs. *Anaplectus*, *Aphanolaimus*, *Deontolaimus* (*D. monohysteria* is a commensal in the gill chamber of the terrestrial hermit crab *Coenobita scaevola* in the Indian Ocean); also *Chronogaster*, *Leptolaimus*, *Metateratocephalus*, *Plectus*, *Tylocephalus*, etc.

"ORDER RHABDITIDA" Rhabditids comprise a large, nonmonophyletic group of saprobic or bacterivorous roundworms living in many types of organic matter, such as decomposing plants, algal deposits on beaches, decaying fruits, rotting cacti, material from frass tunnels of insects, dung of vertebrates, and cadavers of invertebrates and vertebrates. In various rhabditid lineages physiological adaptations to living in ephemeral terrestrial habitats and to life cycles in tight association with other animals have generated a set of features that facilitated the evolution of parasites in arthropods, molluscs, and vertebrates. *Caenorhabditis elegans* is an important model species, whereas species of *Heterorhabditis* are used as biocontrol agents of pest insects. Many rhabditid species are cosmopolitan. In one lineage, the diplogastrids, the first molt takes place within the embryonic eggshell (e.g., *Butlerius*, *Koerneria*, *Odontopharynx, Pristionchus*). We include two superfamilies, Anguillicoloidea and Camallonoidea (sometimes placed in a separate order, Camallanida), among the Rhabditida. Anguillicoloids are parasites in the swim bladders of freshwater eels; camallonoids are parasites in the guts of predatory vertebrates. Other important genera include *Camallanus*, *Cucullanus*, *Cephalobus*, *Myolaimus*, and *Steinernema.*

ORDER RHIGONEMATIDA Recent molecular analyses have not supported older views of rhigonematids as a family of Oxyurida, nor Ascarida, and this poorly understood and mostly parasitic group is treated as an order until further resolution can be obtained. *Brumptaemillus*, *Rhigonema*, *Zalophora*, etc.

ORDER SPIRURIDA Gut and tissue parasites of vertebrates (except fishes) that typically utilize an invertebrate intermediate host. In the superfamily Filarioidea (parasites of amphibians, reptiles, birds, and mammals), the eggs are thin shelled, like a sheath, and contain the miniaturized first-stage juvenile (J1), the infective **microfilaria** (e.g., *Brugia*, *Dracunculus*, *Onchocerca*, *Loa*, *Mansonella*, *Pelecitus, Wuchereria*). Filariae are tissue or cavity dwellers and can be anywhere in the host (coelomic cavity, blood and lymphatic vessels, subcutaneous tissues, the surface of the skin, the brain, etc.). Filarial nematodes are transmitted by blood-feeding arthropods, most often dipterans such as mosquitoes, midges, and simuliid and tabanid flies.

ORDER STRONGYLIDA The "bursate nematodes" are a monophyletic taxon characterized by an expansion of the tail in males as a copulatory organ, the caudal bursa. Early molecular studies suggest strongylids may be a clade within the larger order Rhabditida, and hence are not included in our phylogenetic tree. The supporting rays of the bursa are the channels through which nerve tissue runs to sensory papillae at the extremities. The bursa is divided into paired ventral and lateral lobes, with a single median dorsal lobe (these lobes may be variously fused). A large order (420 genera) with many important parasitic species, including the "hookworms" (family Ancylostomatidae, parasites

for more ebook/ testbank/ solution manuals requests email 9601267346@qq.com

of mammals). Two common hookworm infections in humans are caused by the species *Ancylostoma duodenale* (Old World hookworm) and *Necator americanus* (New World hookworm). Hookworm eggs are deposited in the stools of infected people. If these end up in the environment, they can hatch into juvenile worms, which can then penetrate the skin. One type can also spread through contaminated food. Risk factors include walking barefoot in warm climates where sanitation is poor. Species in this order infest all classes of terrestrial vertebrates on all continents, primarily as gastrointestinal parasites but also as pulmonary infections. Some species of *Stephanurus* infect the renal system of squids. The families Chabertiidae and Haemonchidae are of importance in livestock and ruminant health. Most strongylid life cycles are direct, with the host infection occurring by ingestion or skin penetration by the third juvenile stage (J3). Some species use molluscs or annelids as intermediate hosts. Lungworms (suborder Metastrongylina) infect the respiratory system, and occasionally other tissues, of mammals; eggs or juveniles released by female worms are carried in the blood and lodge in pulmonary capillaries, the juveniles breaking into the alveoli and eventually ascending the trachea, there being swallowed to pass into the feces. Also *Oesophagostomum*, etc.

ORDER TYLENCHIDA The largest and most economically important group of plant-parasitic nematodes, tylenchids have diverged to exploit all plant parts (one group even parasitizes the hemocoel of arthropods). Economically important genera include *Anguina* (seed galls, etc.), *Globodera* (pathogens of potatoes and other Solanaceae), *Pratylenchus* and *Meloidogyne* (root endoparasites that attack bananas, cereals, coffee, corn, legumes, and many fruits), *Hirschmanniella* (important rice pathogens), *Tylenchulus* (citrus parasite), and *Rotylenchulus* (a cotton pathogen). Also *Allantonema*, *Anguina*, *Aphelenchus*, *Bursaphelenchus*, *Criconema*, *Helicotylenchus*, *Sphaerulariopsis*, etc.

CLASS ENOPLIA With pocketlike amphids, not spiral, usually postlabial; cuticle smooth or finely striated; phasmids present or absent; esophagus cylindrical or bottle shaped with 3 to 5 esophageal glands; simple nontubular excretory system, usually a single cell; female generally with 2 ovaries; male generally with 2 testes.

ORDER ENOPLIDA A large and diverse taxon of large-bodied, mostly marine species (a few freshwater and terrestrial species are known). *Belbolla*, *Bernardius*, *Enoplus*, *Halalaimus*, *Oncholaimus*, *Oxyonchus*, *Syringolaimus*, *Viscosia*, etc.

ORDER TREFUSIIDA The orders Trefusiida and Triplonchida were once viewed as subgroups within the order Enoplida, but this has not been supported by recent molecular studies, which tend to place the lineages as coequal in an unresolved trichotomy. *Trefusia*, *Tripylina*, *Trischistoma*, etc.

ORDER TRIPLONCHIDA A large and diverse group of mostly free-living species found in nearly every habitat on Earth. Many soil, moss, freshwater, marine, and subterranean species, including a large radiation in Lake Baikal. *Trichodorus, Paratrichodorus* (vectors of plant-pathogenic tobraviruses), *Tobrilus*, and many others.

CLASS DORYLAIMIA A clade suggested by recent molecular phylogenetic studies.

ORDER DIOCTOPHYMATIDA A small clade of vertebrate parasites, especially in carnivorous mammals and birds; humans can be accidently infected. About 20 species, including the giant kidney worm *Dioctophyme renale* with body length exceeding 1 m (the second-largest known nematode). *Dioctophyme. renale* infects carnivorous mammals and occasionally others (horses, cows) and rarely humans; the infective third-stage juveniles (J3) occur in oligochaetes, which are consumed by the final hosts. Also *Eustrongylides*, *Hystrichis*, *Soboliphyme* (with its impressive cephalic sucker), etc.

ORDER DORYLAIMIDA A diverse order (18 families; over 2,640 described species), all free-living except plant parasites of the family Longidoridae, and found in nearly every habitat on Earth. Soil species can be highly diverse (100 g of soil may contain more than a dozen species in temperate regions); 0.3 to 1 cm long. Some free-living species are vectors of plant parasites. *Dorylaimus*, *Eudorylaimus*, *Longidorella*, *Tylencholaimus*, *Xiphinema*, etc.

ORDER ISOLAIMIIDA A monogeneric order, *Isolaimium*, with 12 described species of free-living terrestrial roundworms. Phylogenetic placement of this order is unclear.

ORDER MARIMERMITHIDA Rare parasites of marine invertebrates during their juvenile stage; adult worms free-living. Very large, 1 to 15 cm long. Seven described species. Worldwide at all depths. *Aborjinia*, *Marimermis*, *Thalassonema*, etc.

ORDER MERMITHIDA Large insect parasites; emerge from their hosts as postparasitic juveniles that undergo a final molt to reach the adult stage. *Hexamermis*, *Mermis*, etc.

ORDER MONONCHIDA Free-living soil and freshwater nematodes; ~460 described species, 1 to several millimeters in length. *Anatonchus*, *Clarkus*, *Iotonchus*, *Miconchus*, *Mylonchulus*, etc.

ORDER MUSPICEIDA Poorly known, mostly tiny parasites in the skin, eyes, and vascular and muscular sysems of vertebrates. Lacking phasmids (their caudal glands were once interpreted as phasmids). Nine genera, including *Maseria*, *Muspicea*, and *Robertdollfusa*.

ORDER TRICHINELLIDA (= TRICHOCEPHALIDA) Parasites of vertebrates. *Huffmanela*, *Trichinella*, *Trichina, Trichuris,* etc.

INCERTAE SEDIS

ORDER BENTHIMERMITHIDA Rare marine nematodes, in littoral to deep sea. Juveniles typically parasitic in various invertebrates; adults free-living and nonfeeding, ranging in size from <1 mm to over 17 cm. *Trophomera*, etc.

ORDER RHAPTOTHYREIDA Rare marine nematodes found at depths of 800 to 4,600 m. Mouth and gut vestigial, amphids large and featherlike; thought to live symbiotically with autotrophic prokaryotes (as seen in siboglinid worms and their chemoautotrophic bacterial symbionts). Once placed in the class Enoplea, molecular studies have left its relationships uncertain. Two species: *Rhaptothyreus typicus* and *R. minor*.

The Nematode Body Plan

Body Wall, Support, and Locomotion

Nematodes possess a relatively conserved basic body plan that consists of an external cylinder (the body wall) and an internal cylinder (the digestive system), which are separated by a blastocoelic (pseudocoelomic) body cavity filled with fluid under pressure, although in some small species this cavity does not exist. The blastocoel is not lined by mesodermally derived

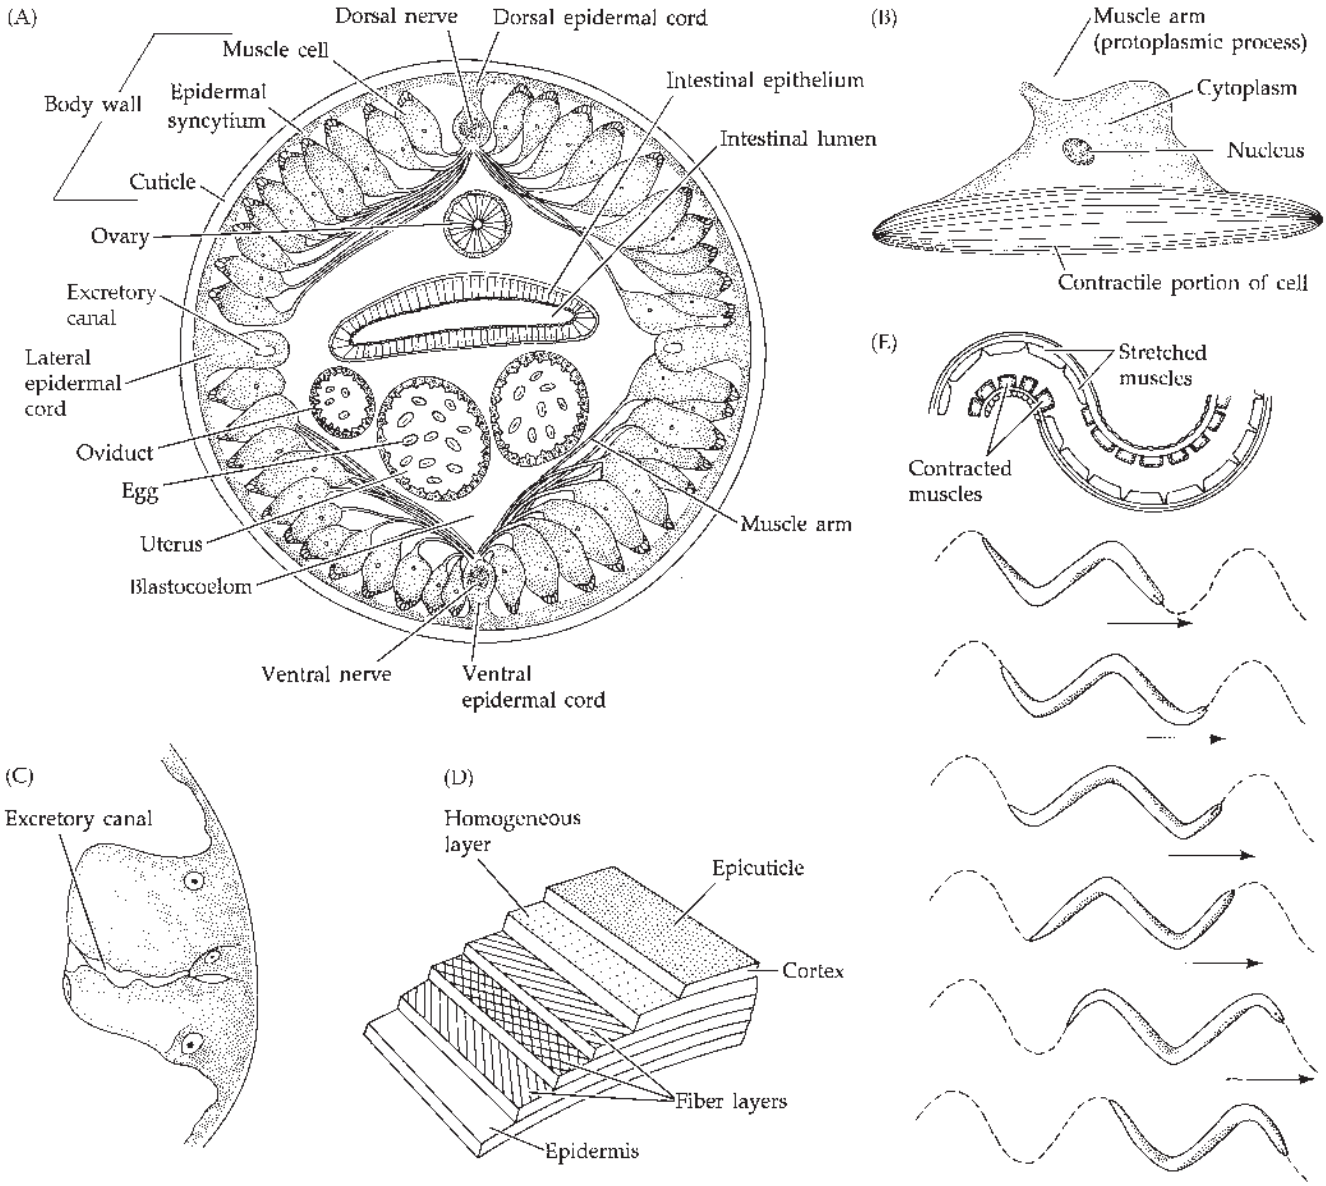

FIGURE 19.3 Selected anatomical and locomotory features of nematodes. (A) Stylized section through a female nematode such as *Ascaris*. (B) A single longitudinal muscle cell, illustrating the origin of the muscle arm. (C) The lateral epidermal cord of *Cucullanus* (order Rhabditida). (D) The layers of the cuticle. (E) Undulatory locomotion in a free-living nematode results from the action of the longitudinal muscle fibers. The concave areas along the body represent positions of muscle contractions; the convex areas are regions of the muscle stretching. Leverage is gained against surrounding objects of the substratum in the environment.

epithelium. As in other ecdysozoans, the nematode body is covered by a well-developed and complexly layered cuticle secreted by the epidermis and lacking motile cilia (Figures 19.3 and 19.4). The outermost cuticle layer, the **epicuticle**, secretes a **glycocalyx** surface coating that protects the worm from microbial predators and parasites, and it might facilitate locomotion by lubrication. The cuticle forms a flexible exoskeleton that invaginates at the mouth, cloaca, and rectum as well as at the amphids, phasmids, secretory-excretory pore, and vulva. The cuticle is mainly composed of lipids and proteins associated with mucopolysaccharides. Collagen, a structural protein, is the major component of the cuticle (>80%). Nematodes lack chitin in their cuticle, except for the pharyngeal cuticle of some species (chitin also occurs in the eggshell). As well as serving as an antagonist for the contraction of the longitudinal muscles, the cuticle is semipermeable and plays a role in the secretion-excretion or uptake of substances. The cuticle is also responsible in part for allowing nematodes to live in hostile environments, such as dry terrestrial soils and the digestive tracts of host animals, for it drastically reduces the permeability of the body wall. Predominantly terrestrial or parasitic nematodes usually have a dense, fibrous inner layer of the cuticle, whereas most of the free-living marine and freshwater forms lack this inner layer.

The cuticle is a complex structure, and it is highly variable among nematodes. It may be relatively smooth, or covered with sensory setae and wartlike bumps. The cuticle in many roundworms has rings or **annules**, or it is marked with longitudinal ridges and grooves (Figure 19.4). In many marine forms, it contains radially arranged rods, punctuations, or other inclusions of various shapes. As a nematode grows, it sheds its cuticle and grows a new one through a series of four molts (the first occurs within the egg membrane in some species) during its lifetime. Thus, the intermolt (instar) stages are called J1 through J4, which is followed by the adult. Although molting is likely induced by a steroid hormone, the exact nature of the hormone is not yet known (the steroid ecdysone triggers molting in arthropods). The new, postmolt cuticle commonly has epidermal folds (plicae) over which the new cuticle becomes highly convoluted, enabling the worm to increase in length in an accordionlike manner after ecdysis.

The epidermis (which is sometimes called the "hypodermis") varies among the different taxa, from cellular to syncytial, but is typically thickened into unique dorsal, ventral, and lateral **longitudinal cords** (Figure 19.3A,C). The dorsal and ventral cords house

longitudinal unpaired nerve cords, whereas the lateral thickenings contain excretory canals (when present, as in *Ascaris*) and neurons. Internal to the epidermis is a relatively thick layer of obliquely striated longitudinal muscle arranged in four quadrants. The muscles are connected to the dorsal and ventral nerve cords by unique extensions called **muscle arms** (Figure 19.3A,B). This arrangement is different from the usual neuromuscular junctions in most other animals; in nematodes the connections are made by special extensions of the muscle cells rather than of the neurons. Each neuron can receive many, even hundreds of muscle arms. Oddly, a similar condition apparently exists in some echinoderms and in the cephalochordate *Branchiostoma*, presumably cases of convergent evolution. Also, in some nematomorphs, kinorhynchs, platyhelminths, annelids, and gastrotrichs the longitudinal body wall muscles bear extensions similar to the nematode muscle arms. Whether these are homologous or convergent has not been thoroughly studied. There is no circular muscle layer in nematodes, nor in nematomorphs, a condition viewed as homologous by most workers.

The fluid-filled blastocoelom is not spacious. The apparently large body cavity seen in many laboratory specimens is often an artifact caused by shrinkage of tissues in alcohol. Modern microscopy techniques reveal that the organs of most nematodes occupy nearly all of the internal space, and in very small species the cavity may be entirely obliterated. However, in large species such as *Ascaris* a discernable blastocoel is clearly present. The cuticle provides most of the body support in nematodes. In the absence of circular body wall muscles, some types of locomotion, such as peristaltic burrowing, are impossible. Nematode movements depend on waves of muscle contractions, which travel backward along the body. These movements drive the worm forward, whether it is swimming through water or crawling through soil particles or animal or vegetal tissues. These contractions of the longitudinal muscles produce a whiplike undulatory motion (Figure 19.3E). Among the free-living nematodes this movement pattern relies on contact with environmental substrata, against which the body pushes. The muscles act against the hydrostatic skeleton and the cuticle, which serve as antagonistic forces to the muscle contractions. When placed in a fluid environment and deprived of contact with solid objects, benthic nematodes thrash about rather inefficiently. Some actually do swim (but not very well), and some are able to crawl along using various cuticular spines, grooves, ridges, and glands to gain purchase on the substratum (Figures 19.1E,H and 19.4).

Feeding and Digestion

The vast range of environments inhabited by nematodes is paralleled by the diversity of feeding habits and associated anatomical and behavioral adaptations. Many infaunal nematodes are direct deposit feeders. Others are detritivores or microscavengers, living in or on dead organisms or fecal material. Many of these species apparently do not feed directly on the carcasses they inhabit, but feed on the microorganisms (fungi and bacteria) that grow in the decomposing organic matter. Many free-living nematodes are predatory carnivores, feeding on a variety of other small animals, including other nematodes. Others feed on diatoms and other protists. Plant parasitic nematodes use a specialized oral structure, the **stylet**, to pierce individual root cells and suck out the contents (Figure 19.5F). The high species diversity of nematodes (and other small animals) in the marine meiofaunal habitat has puzzled ecologists for decades. Stable-isotope studies have shown that tidal flat meiofaunal nematodes utilize at least three different trophic levels (from primary to tertiary consumers) and that omnivory and herbivory (mainly on diatoms and dinoflagellates) predominate.

Bacterial symbioses occur in some nematodes. For example, species of *Astomonema* and *Parastomonema* that inhabit sulfur-rich sediments harbor chemoautotrophic bacteria in their highly reduced guts. These worms meet their nutritional requirements by absorbing some of the metabolic products of the bacteria. Some other nematodes (family Stilbonematidae) inhabit sulfide-rich oxygen-poor sediments, where symbiotic bacteria coat their cuticle. These nematodes are able to twist themselves in such a way that they can feed on the bacteria "farmed" on their body surface.

Insect pathogenic nematodes (e.g., Steinernematidae and Heterorhabditidae) carry gram-negative bacteria in their intestines that help them kill their insect hosts. The bacteria, once introduced into the host, grow and reproduce to become food for the nematode, which also grows and reproduces in the insect cadaver.

Nematode parasites have been described from every major group of plants and animals, and they have evolved a multitude of life history patterns. In invertebrates and vertebrates (including humans), nematodes subsist on a variety of body fluids and organs, where they can cause extreme tissue damage. The well-known human parasite *Ascaris lumbricoides*, the most common parasitic worm in humans, can grow to 35 cm in length.

Nematode digestive tracts vary greatly in complexity and regional specialization. The anteriorly located mouth is usually surrounded by **lips** (one dorsal and two ventral parts, some or all of which may be fused together and may form elaborate prolongations), with each lip typically bearing a papilla (Figure 19.5). **Labial probolae** are flaplike cuticular processes surrounding the mouth opening in many cephalobid nematodes—there are three flaps, one dorsal and two subventral. **Cephalic probolae** are simple or complex cuticular processes arising from the lips in many cephalobid nematodes; there are six in total—two lateral, two subdorsal, and two subventral. Lips, labial and cephalic probolae, spines, teeth, jaws, and other armature are arranged in radially symmetrical patterns (Figure 19.5). The mouth leads to a buccal cavity or **stoma**, the shape of which is variable depending on the feeding habits of the nematodes. The stoma connects to the muscular pharynx (Figure 19.6).

The basic structural features of the pharynx, sometimes called an esophagus by nematologists, are a triradiate lumen, muscles, one or more valves, and dorsal and ventral glands and neurons. The pharynx is elongate and may be subdivided into distinct muscular and glandular regions, the details of which are of considerable taxonomic importance (Figure 19.6A–G). The muscles of the pharynx pump food material from the buccal cavity into the intestine. The pharyngeal cuticle can have chitin. In most nematodes the intestine is a simple tube composed of a single layer of cells ensheathed by a basal lamina. In some cases it is possible to discern an anterior, middle, and posterior region of the intestine. The posterior portion of the intestine leads to a short proctodeal (i.e., ectodermally derived) rectum and a subterminal anus on the ventral surface of the body (Figure 19.6L). In males the rectum opens up into a cloaca, which also receives products of the reproductive system. The ventral side of a roundworm can be recognized by the presence of the vulva (egg-laying organ) and anus in females or by the cloacal opening in males.

The esophageal glands and the midgut lining secrete digestive enzymes into the intestinal lumen. Initial digestion is extracellular; final intracellular digestion occurs in the intestine, following absorption across the surfaces of the microvilli of the intestinal cells (Figure 19.6K). In mermithid nematodes (most of which are parasites of insects) the pharynx is modified as a **stichosome**, a region of large glandular cells (sometimes called stichocytes) important in protein synthesis. In mermithids, modification of the intestine creates a **trophosome**, a region of enlarged, solid cells that form a closed food storage organ.

FIGURE 19.6 Nematode anatomy. (A–G) Variation in pharynx structure gut anatomy among different nematodes. Note the different degrees of regional specialization. Circulation, Gas Exchange, Excretion, and Osmoregulation

Nematodes have no specialized circulatory or gas exchange structures. As in many other very small invertebrates, particularly blastocoelomates, diffusion and movement of body cavity fluids accomplish these functions. Some parasitic nematodes possess a form of hemoglobin in these fluids that presumably transports and stores oxygen. Both aerobic and anaerobic metabolic pathways are found among the nematode groups, and many of these worms are able to shift from one mechanism to the other according to environmental oxygen concentrations. Facultative anaerobiosis is surely significant in parasitic nematodes and those that live in other anoxic environments. The blastocoelom serves as a circulatory system, transporting molecules such as CO_2 from the tissues of origin (mostly muscle and reproductive tissue) to the epidermis and intestine for excretion into the environment.

Nematodes have no nephridial structures known to be homologous to those of other metazoans, and soluble waste products are apparently concentrated prior to their elimination. For this purpose they have unique excretory structures, unlike the protonephridia of other protostomes (Figure 19.7). The presumed ancestral condition occurs in certain free-living taxa and has been modified among other groups, especially within specialized parasitic forms. In many free-living threadworms, the system comprises one or two glandular **renette cells** that connect directly to a midventral excretory pore (Figure 19.7A,E,F), and sometimes a third cell forms an ampulla at the opening. Modifications to this system often include

(B) Schematic of the excretory system of *Oesophagostomum* (order Strongylida), wherein the renette cells are associated with lateral excretory canals. (C) The so-called "H system" of collecting canals remaining after the loss of the glandular renette cell bodies (*Camallanus* sp., order Rhabditida). (D) Modification of the H system (inverted Y), with an anterior excretory pore and lateral canals (in many ascarids). (E) Excretory canal in *Steinernema* (order Rhabditida), lateral view. (F) Excretory pore (lateral view) in *Steinernema* (order Rhabditida).

various arrangements of intracellular collecting ducts within the cytoplasm of extensions of the renette cells (Figure 19.7B). In many parasitic species the renette cell bodies are lost completely, leaving only the system of tubules in an H or inverted Y pattern (Figure 19.7C,D). Many members of the class Enoplia lack renette cells altogether. Instead they have numerous unicellular units distributed along the entire length of the body, each cell opening to the outside via a duct and a pore. It has been suggested that if these ducted cells are excretory in function, they might represent nonciliated protonephridia, but good evidence of this has not been found. In some species the renette cells secrete a substance used by the roundworm to attach to the substrate. In all cases, these excretory structures probably also function in osmoregulation.

Most nematodes are ammonotelic, although some excrete increased amounts of urea when in a hypertonic environment. Apparently much of the loss of nitrogenous wastes is across the wall of the midgut, and the renette cells are primarily osmoregulatory. Water balance is also aided by the activities of other tissues, organs, and structures. In some roundworms, the cuticle is differentially permeable to water in that it allows water to enter but not to leave the body. This condition is advantageous under conditions of potential desiccation, but it presents problems in hypotonic environments where excess water must be eliminated; such elimination is apparently accomplished by the renette cells (when present), by the gut lining, and by the epidermis.

Nervous System and Sense Organs

The classic studies of nematode neuroanatomy were by R. Hesse (1892) and R. Goldschmidt (1908, 1909) who showed that nematodes have 250 to 302 neurons, and their position and structure is roughly the same throughout the phylum (Figures 19.8 and 19.9A,B). Today we know more about the nervous system of *C. elegans* than any other animal, the adult hermaphrodite of this species having exactly 302 neurons, each with a predictable cell lineage. Similarly, *Ascaris suum* females have 298 neurons, also with invariant identity and structure.

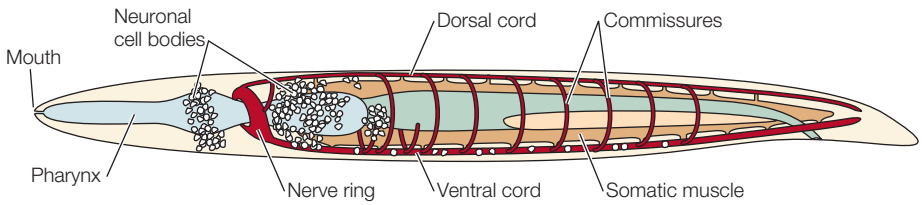

FIGURE 19.8 **The nematode nervous system.**

Nematodes have a simple circumoral nerve ring that encircles the pharynx, composed mainly of axonal and dendritic processes of neurons whose cell bodies lie in bundles anterior and posterior to the ring itself. These bundles are encased in a lamina and often referred to as ganglia, but unlike the ganglia of most other animals, they do not contain a **neuropil** (a network of interwoven nerve fibers and synapses, together with glial filaments, that characterize most bilaterians), only cell bodies. Associated with the nerve ring are longitudinal nerves that extend anteriorly and posteriorly. The anterior nerves (six in total) connect with cephalic sensory organs (sensilla) and labial papillae in the anterior end, arranged in a sixfold symmetry around the mouth. These structures have the nature of mechanoreceptors and chemoreceptors. **Amphids** (= amphid sensilla) are paired organs located laterally on the head. They consist of an external pore leading inward to a short duct and amphidial pouch. The pouch is associated with a unicellular gland and an amphidial nerve from the cerebral nerve ring (Figure 19.9A,B). The receptor sites of amphids are derived from modified cilia, but recall that motile cilia do not occur in nematodes. It is thought that the amphids

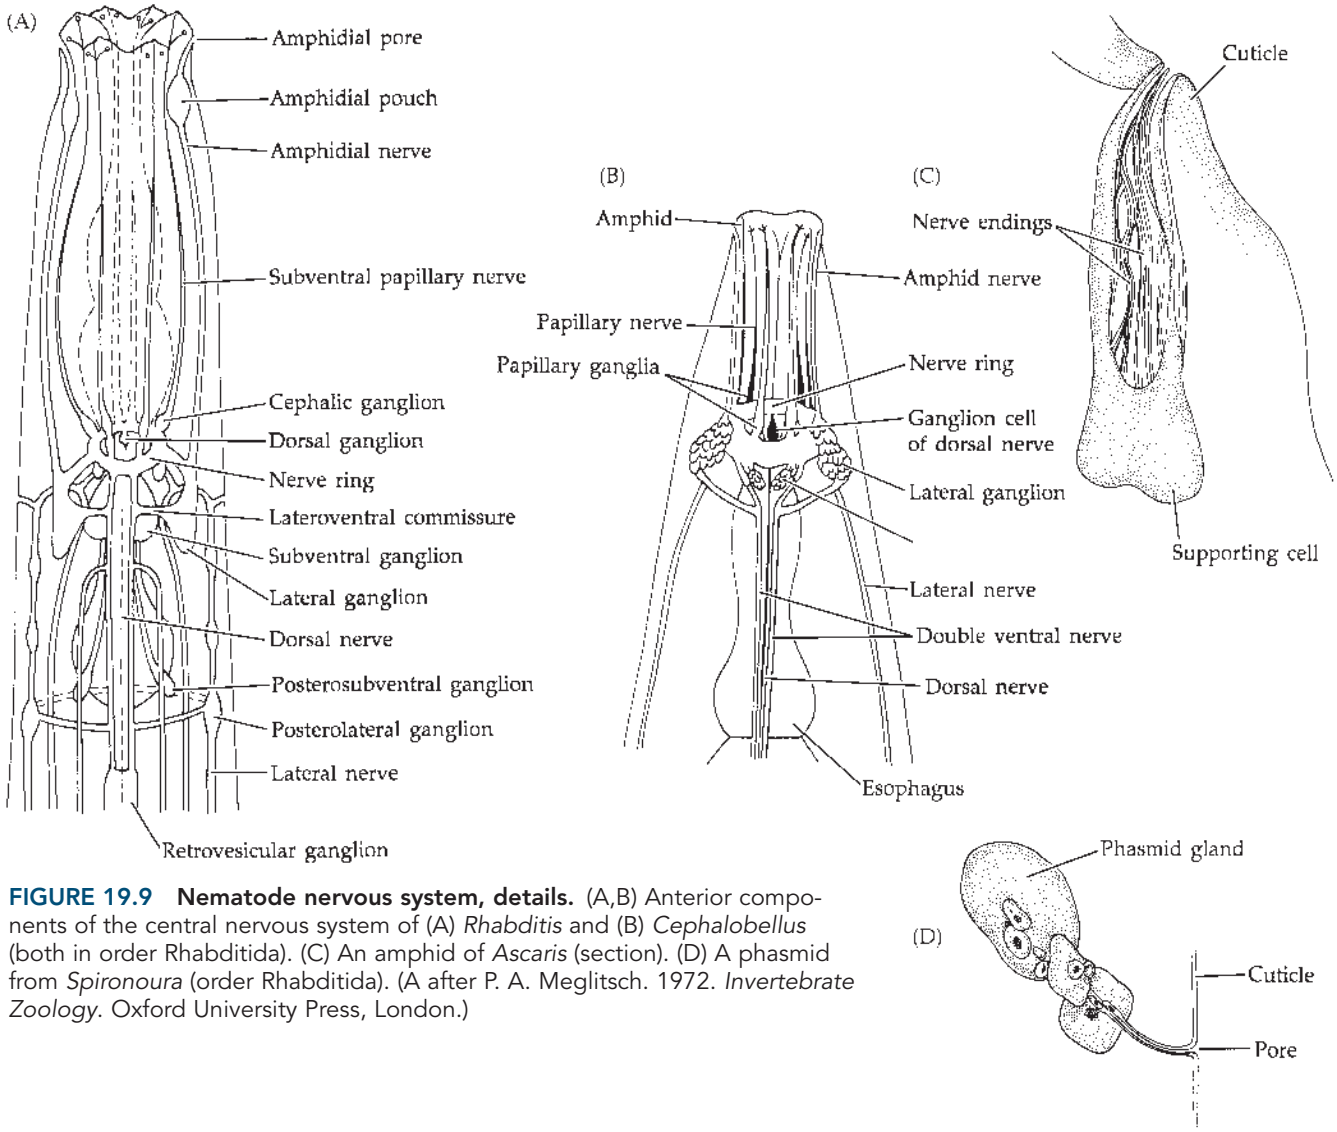

FIGURE 19.9 **Nematode nervous system, details.** (A,B) Anterior components of the central nervous system of (A) *Rhabditis* and (B) *Cephalobellus* (both in order Rhabditida). (C) An amphid of *Ascaris* (section). (D) A phasmid from *Spironoura* (order Rhabditida). (A after P. A. Meglitsch. 1972. *Invertebrate Zoology*. Oxford University Press, London.)

are polymodal—chemosensory, touch, and osmotic receptors.

Via a series of associated ganglia, longitudinal nerves also extend posteriorly through the epidermal cords (Figure 19.9A). The major nerve trunk is ventral and includes both motor and sensory fibers. It is formed from the union of paired nerve tracts that arise ventrally on the nerve ring and fuse posteriorly, where the main trunk bears ganglia. The dorsal nerve cord is motor, and the less well-developed lateral nerve tracts are predominantly sensory. Lateral commissures connecting some or all of the longitudinal nerves occur in many nematodes. Both the ventral and dorsal nerve cords are closely associated with the epidermis and are separated from the body cavity and somatic musculature by a basal lamina.

Most members of the class Chromadorea possess a posteriorly located pair of glandular structures called **phasmids** (= phasmid sensilla) (Figure 19.9D). These structures are also considered to be chemoreceptors. Some freshwater and marine free-living nematodes in the class Enoplia possess a pair of anterior pigment-cup ocelli as well, and at least some nematodes contain proprioceptor cells in the lateral epidermal cords. These sensory cells contain a fixed cilium and appear to monitor bending of the body during locomotion. A ciliary-type photoreceptor has been reported from only one species, *Oncholaimus vesicarius*. However, even nematodes lacking photoreceptors react to visible and UV light, indicating the presence of dermal light sensitivity (as has been documented in other invertebrate phyla). Recently it was shown that LITE-1, a taste receptor homolog protein known from other invertebrate phyla, mediates UV-light-induced avoidance behavior in *C. elegans*. In this species, the LITE-1 protein serves as a photoreceptor by directly absorbing both UVA and UVB light. Interestingly, LITE-1 shows no sequence homology with the two known metazoan photoreceptor proteins, opsins and cryptochromes, nor any other known photoreceptors in microbes or plants. Evolutionary workarounds for absence of opsins (and opsin photoreceptor genes) in roundworms is also seen in studies of *C. elegans* that found the worms capable of detecting and discriminating colors as a way to avoid toxic microbes in their environment (rotting vegetation). It appears that *C. elegans* may have co-opted a pair of conserved stress-response genes for this purpose, suggesting that a cellular stress response pathway may mediate spectral discrimination by photosensitive cells in these worms.

The most complex behaviors, such as locomotion, navigation, and mating, are mediated by the somatic muscles, which run longitudinally in four bands from head to tail. Nematodes crawl by propagating a wave of muscle contraction along the body in the dorsoventral plane; waves traveling from head to tail result in forward movement, while waves traveling in the opposite direction result in backward movement.

Reproduction, Development, and Life Cycles

Most nematodes are gonochoristic (with males and females) and show some degree of sexual dimorphism (Figure 19.10A,B). The female reproductive system (Figure 19.10A) usually consists of one or two elongate ovaries that gradually hollow as oviducts and then enlarge as uteri (Figure 19.10C–E). The uteri converge to form a short vagina connected to the single gonopore, exiting via the vulva. The female gonopore is completely separate from the anus, opening on the ventral surface near the middle of the body or sometimes just above the anus. However, hermaphroditism (including self-fertilization), parthenogenesis, pseudogamy, and an alternation of hermaphroditism or parthenogenesis with gonochory also occur in various species. And, in some there is a coexistence of males, females, and hermaphrodites (a mode called "trioecy"). In many species, such as *C. elegans*, there are two sexes but these are hermaphrodite and male, the former being viewed as a female that produces a limited number of sperm cells that can reproduce either by self-fertilization or by cross-fertilization involving mating with a male. **Pseudogamy** (also called sperm-dependent parthenogenesis or gynogenesis) is a special type of asexual reproduction in which females use the sperm of males (often from another species) to activate their oocytes. However, the sperm DNA is not used, and the embryos develop only from the maternal DNA to give rise to females. For example, *Mesorhabditis belari* produces only 9% males, whose sperm is necessary to fertilize and activate the eggs. However, most of the fertilized eggs develop without actually using the sperm DNA and so produce only daughters, and only in 9% of the eggs is the male DNA utilized, producing sons.

Males tend to be smaller than females and are often sharply curved posteriorly (leading to the common name "hookworm" for some parasites). The male reproductive system (Figure 19.10B,F) typically includes one (or two) threadlike tubular testes, each of which is regionally differentiated into a distal germinal zone, a middle growth zone, and a proximal maturation zone near the junction with the sperm duct. The sperm duct extends posteriorly, where it enlarges as a seminal vesicle leading to a muscular ejaculatory duct that joins the hindgut near the anus. Some species have prostatic glands that secrete seminal fluid into the ejaculatory duct. Most male nematodes possess a copulatory apparatus, including one or two cuticular **spicules** that transfer sperm (Figure 19.10F). Another structure called the **gubernaculum**, a sclerotized region of the dorsal wall of the cloaca that serves to anchor and guide the spicules during copulation, may be present (Figure 19.10F).

Prior to copulation the males produce sperm and store them in the seminal vesicle, while the females produce eggs that are moved into the uteri. Spermatozoa are aflagellate and lack axonemes; they may be round or elongate depending on the species. Potential mates

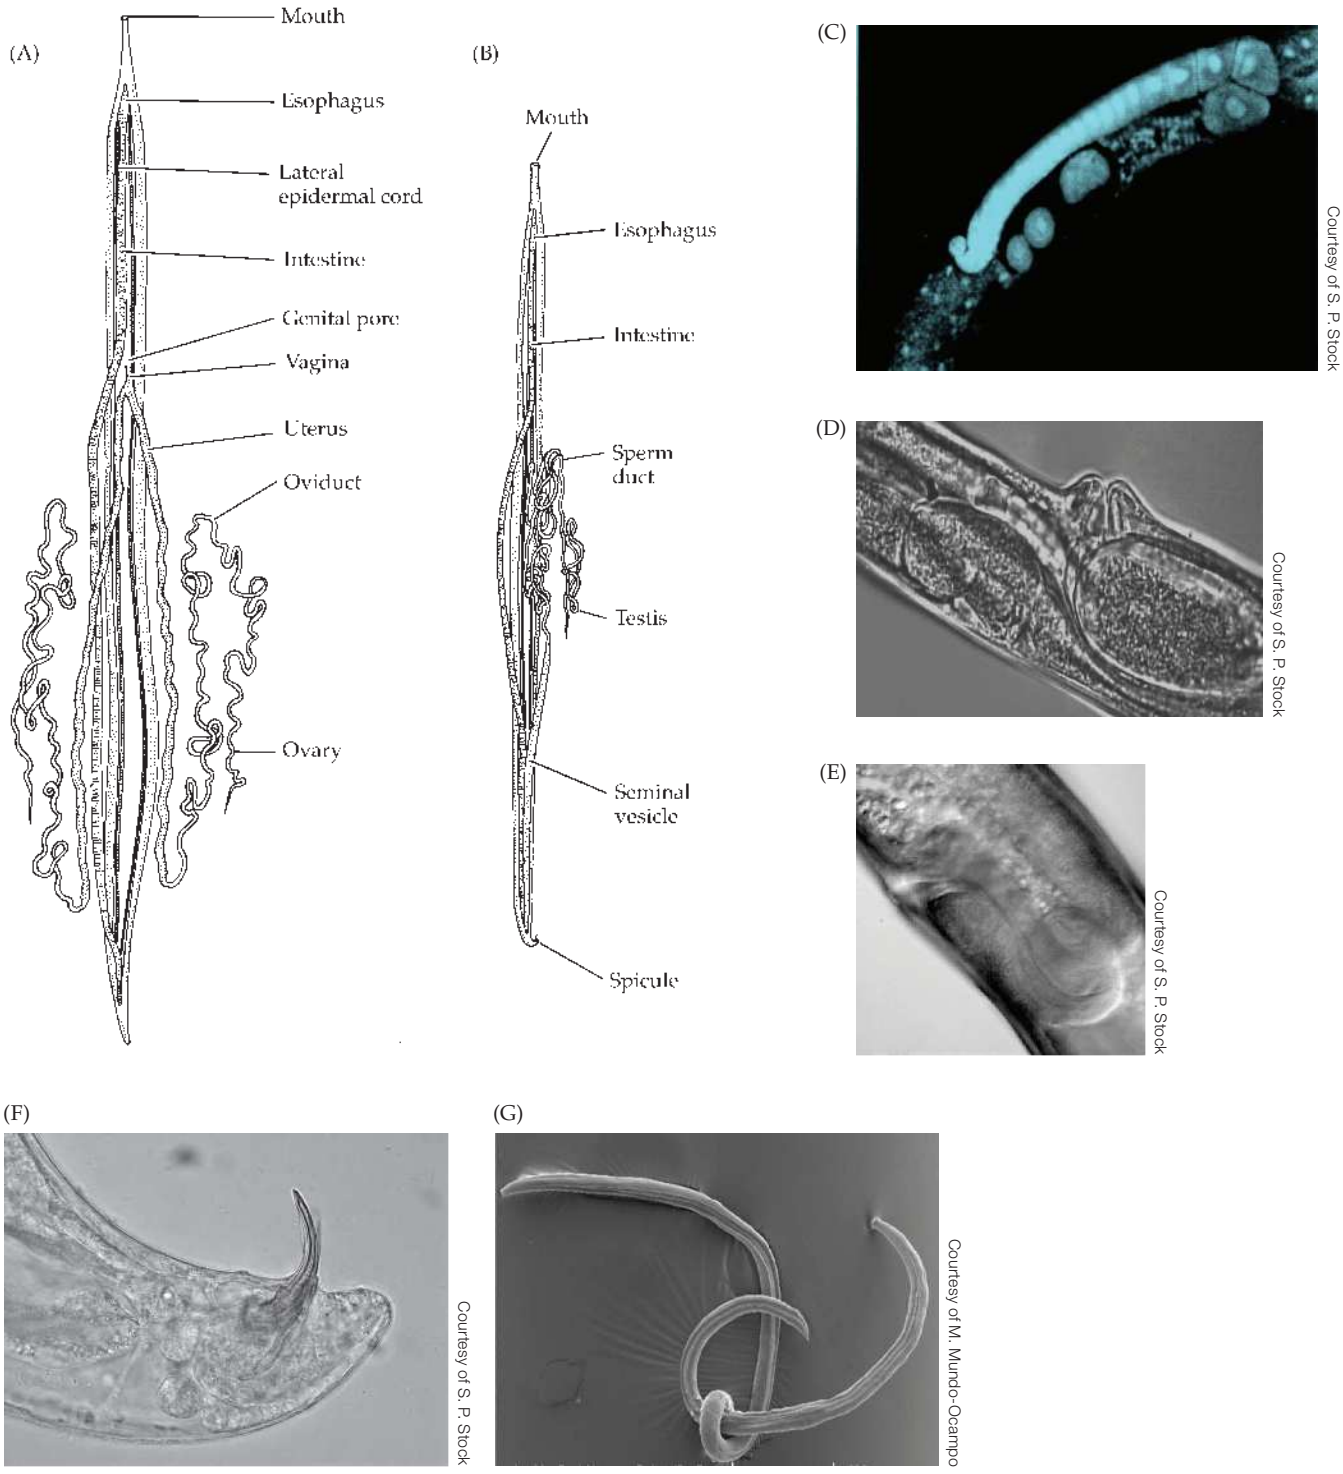

FIGURE 19.10 Nematode reproductive systems. (A,B) Female and male reproductive system of *Ascaris* (dissected). (C) Confocal microscopy image of female ovary of *Heterorhabditis bacteriophora* (an insect pathogen, order Rhabditida). (D) Liplike vulva and vagina of *Plectonchus* sp. (order Rhabditida), a soil microbivore. (E) The insect parasite *Hexamermis* sp. (order Mermithida) has an S-shaped vagina, with the gonopore surrounded by a slightly raised vulva. (F) Spicules and gubernaculum of *Steinernema* sp. (order Rhabditida), an insect pathogen. (G) SEM of male and female *Plectonchus* (order Rhabditida) mating.

make contact (females of some species are known to produce male-attracting pheromones), and the male usually wraps his curved posterior end around the body of the female near her gonopore (Figure 19.10G). Thus positioned, the copulatory structures are inserted into the vagina, and sperm are transferred by contractions of the ejaculatory duct. Fertilization usually occurs within the uterus. A relatively thick double-layered shell, or egg

envelope, forms around each zygote; the inner layer is derived from the fertilization membrane, and the outer layer is produced by the uterine wall. The zygotes are usually deposited in the environment where development takes place. In female (and maternal hermaphrodite) nematodes of many groups (e.g., rhabditids), the zygotes may hatch inside the uterus, a process known as facultative vivipary or **endotokia matricida**, which causes the mother's death (Figure 19.1). The juveniles that hatch within the female remain there, obtaining nutrients from the mother until its body ruptures, liberating the progeny into the environment as infective juveniles. In at least some cases, this phenomenon is promoted by low food supply in the environment, and it thus secures development of juveniles that are well equipped with energy reserves for long-term survival.

In the few known hermaphroditic species, sperm and egg production take place within the same gonad (an ovotestis). Sperm formation precedes egg production, so the animals are technically protandric; but they do not engage in cross-fertilization, as occurs in most sequential hermaphrodites. Rather, the sperm cells are stored until ova are produced, and self-fertilization occurs.

Nematologists typically divide embryogenesis into a "proliferation phase," where nearly all embryonic cell divisions take place and the vast majority of blastomeres are generated, and a "morphogenesis phase," where the ball of cells gradually transfoms into a worm. Interestingly, in *C. elegans* embryogenesis, 113 cells undergo programmed cell death (apoptosis) through a distinct programmed process under the control of over 20 genes. Complete development, from fertilization to hatching, takes 840 minutes in this species.

Development among free-living nematodes is typically direct, although the term "larva" is sometimes used for juvenile stages (something we avoid here). Cleavage is holoblastic and subequal, but the pattern appears to be unique among the Metazoa. The orientation of blastomeres during early cleavage is fairly consistent within those species of nematodes that

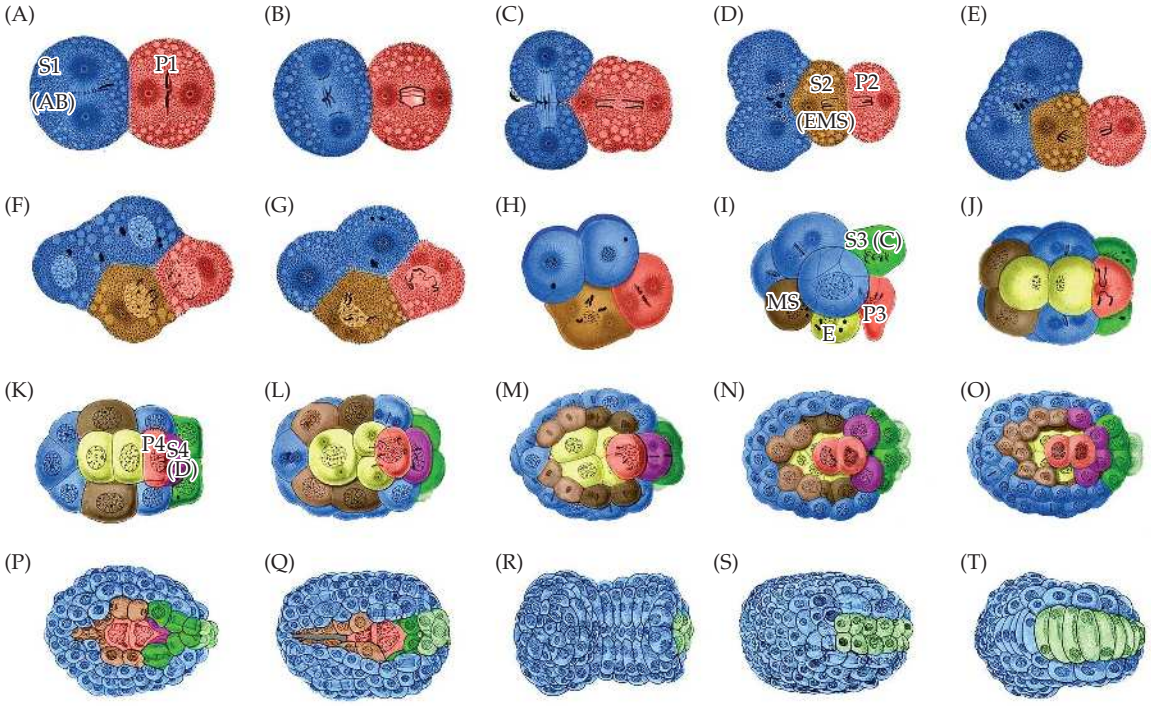

FIGURE 19.11 Embryonic development of *Parascaris equorum*, from the 2-cell stage to early morphogenesis. In nematodes, the early cleavages are typically asymmetric, sequentially separating a small number of somatic lineage founder cells from the germline. (A) The first division of the zygote yields a somatic founder cell S1 (= AB) and P1 cell. In the 2-cell stage, the first somatic founder cell AB divides with a transverse orientation of the cleavage spindle, generating two daughters of equal developmental potential (C). In contrast, its sister, the germline cell P1, undergoes a rotation of the nuclear/centrosome complex leading, first, to a longitudinal orientation of the spindle and, subsequently, to the generation of the somatic cell EMS and a new germline cell P2 (D). Thus, asymmetric divisions of the germline cells (P1–P3) result in somatic founder cells S2–S4 (= EMS, C, D) and the primordial germ cell P4 (= PGC). S2 (= EMS) divides into two daughters (MS and E) with different fates. Somatic founder cells, but not germline cells, pass once through the process of chromatin diminution (indicated by black spots). Gastrulation starts with the translocation of E cells (gut precursors) into the interior while descendants of MS, P4, D, and C temporarily cover the ventral surface (K–O). Eventually, these cells are also internalized (P, Q) and S1 (AB) cells occupy the complete surface of the embryo before morphogenesis begins with a ventral indentation (R). The dorsal view at this stage (S, T) shows those descendants of S3 (C) contributing to posterior hypodermis.

for more ebook/ testbank/ solution manuals requests: email 9601267346@qq.com

have been studied, but it cannot be assigned to either a radial or spiral pattern. Early cleavage is asynchronous, unequal, and invariant in *C. elegans*, while it is synchronous, equal, and not invariant in *Enoplus brevis*. Figure 19.11 illustrates this cleavage pattern and some details of cell fates (in *Parascaris equorum*). In most species (e.g., *C. elegans*) the blastomeres are probably fixed early to a specific invariant lineage program, and experimentally eliminated cells are not replaced by others. However, in some species (e.g., *Acrobeloides nanus*) early blastomeres are multipotent and compete for a primary fate, and the loss of one cell may cause a switch in the developmental program of another. Probably in most nematodes (e.g., *C. elegans*) the cells of the four-cell embryo are clustered in a rhombic fashion, but in some (e.g., *Diploscapter coronatus*) the cells of the four-cell embryo are spread out in a linear chain.

A stereoblastula or slightly hollow coeloblastula forms and undergoes gastrulation by epiboly of the presumptive ectoderm combined with an inward movement of presumptive endoderm and mesoderm. After a specific point in development, few nuclear divisions occur, and most subsequent growth, even after hatching, is via the enlargement of existing cells. The gut of *C. elegans* has been shown to derive from all the progeny of the E blastomere, a cell of the eight-cell stage. Most nematodes undergo four postembryonic juvenile stages, separated by molts. In a few, however, such as the diplogastrids, the first of these stages transpires while the nematode is still within the egg membrane, in the embryonic phase, thus they have only three postembryonic juvenile stages.

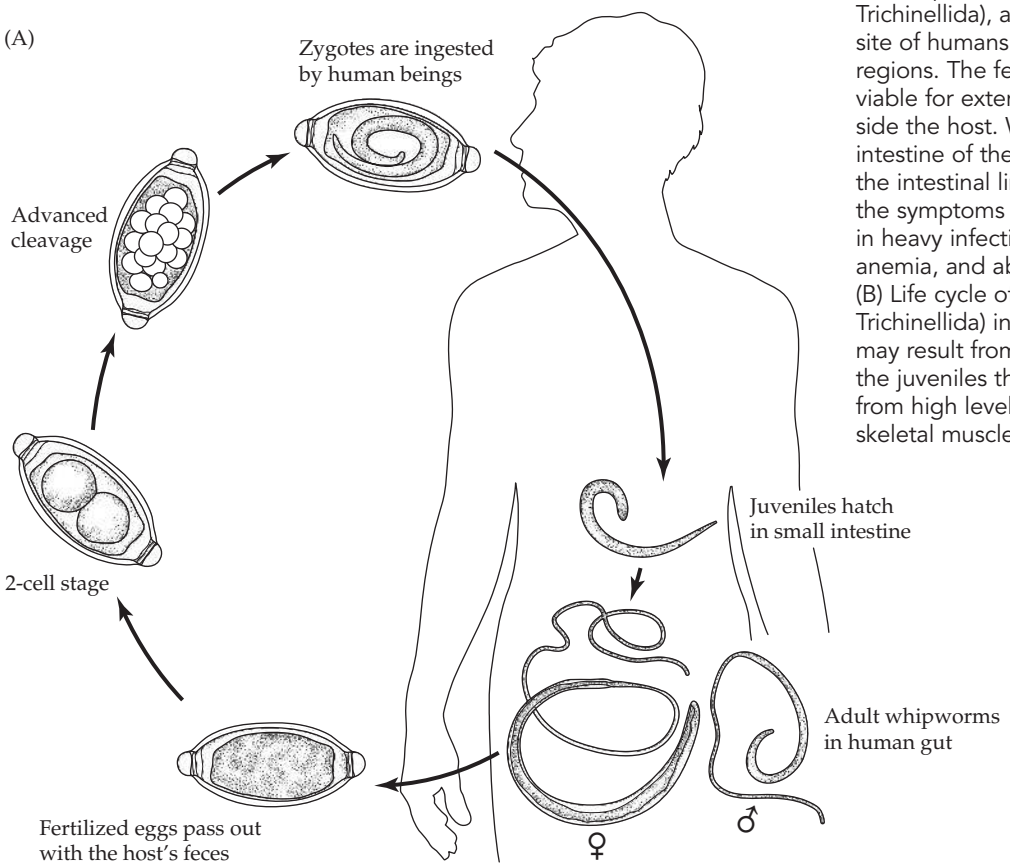
Some groups of roundworms have evolved a strategy to survive adverse environmental conditions by forming a resistant juvenile known as the **dauer stage**, which tolerates different kinds of environmental stress. In *C. elegans*, for example, the second-stage juvenile (J2) can develop either into a normal third-stage juvenile (J3), which molts into an adult, or into a dauer stage. In this species, dauer formation is regulated by at least three environmental cues: starvation, high temperature, and high population density. Nematodes have been kept frozen for over 25 years and then revived. In 2019 a group of Russian scientists published a short note claiming to have revived 41,000-year-old nematodes from Arctic permafrost, but they did not elucidate whether the specimens found were resistant stages or adult worms. And, in 2019 scientists discovered eight species of nematodes living in Mono Lake, California, one of the most inhospitable lakes on Earth for animal life. The lake is three times as salty as the ocean, has a pH of 9–10, and is highly enriched in arsenic. The only other metazoans living in the lake are a brine shrimp and an alkali fly. And, remarkably, the eight nematode species are in different phylogenetic lineages and appear to be the result of several independent colonization events.

Life Cycles of Some Parasitic Nematodes

Plant and animal parasite clades have evolved numerous times among nematodes, and all have a specialized stage for infestation, usually called the infective juvenile (or infective "larva"), which shows striking similarity to the dauer stage of free-living species, and this likely represents an important preadaptation toward parasitism. The study of parasitic nematode life cycles is a field unto itself, and we present only a few illustrative life history cycles here (Figures 19.12 and 19.13). An example of a simple parasitic life cycle is that of the whipworm *Trichuris trichiura* (class Dorylaimia) (Figure 19.12A). These relatively large (3–5 cm long) nematodes reside and mate in the human gut, and the fertilized eggs are passed with the host's feces. Females produce 2,000 to 10,000 eggs per day. Reinfection occurs when another host ingests the embryos. A more complicated life cycle is that of the trichina worm, *Trichinella spiralis*, the causative agent of human trichinosis (Figure 19.12B). This roundworm completes all stages of development in its human (or other carnivorous mammal) host; infective juveniles excyst in the gut, where they mature and reproduce, and the newborn juveniles migrate to the muscles, where they encyst. The parasite is passed by consumption of contaminated muscle tissue (such as when humans consume undercooked pork). Some species of *Trichinella* infest reptiles and birds and do not form encapsulated juveniles. Other important human parasites include two species of hookworms, *Necator americanus* in the New World and *Ancylostoma duodenale* in the Old World. Skin-penetrating nematodes rely on a developmentally arrested infective third-stage juvenile that searches for hosts by a poorly understood process that involves both thermal and olfactory cues.

Most parasites of vertebrates belong to the class Chromadorea, which includes such notables as hookworms, pinworms, ascarid worms, and filariid worms. One of the most dramatic nematode infections in humans is filariasis, caused by any of a number of secernentean nematodes called the filariids. These threadlike parasites require an intermediate host, typically a blood-sucking insect (e.g., fleas, biting flies, mosquitoes). One such filariid is *Wuchereria bancrofti*, whose vector is a mosquito. When present in humans in high numbers, masses of adult *Wuchereria* block lymphatic vessels and cause fluid accumulation (edema) and severe swelling, a condition resulting in grotesque enlargement of body parts and known as lymphatic filariasis, or **elephantiasis**. Such infections often affect the legs and arms, the scrotum in males, and breasts in females. Some 120 million people in 73 countries are infected with lymphatic filariasis.

Onchocerca volvulus, another filariid nematode, is the causative agent of river blindness, transmitted by



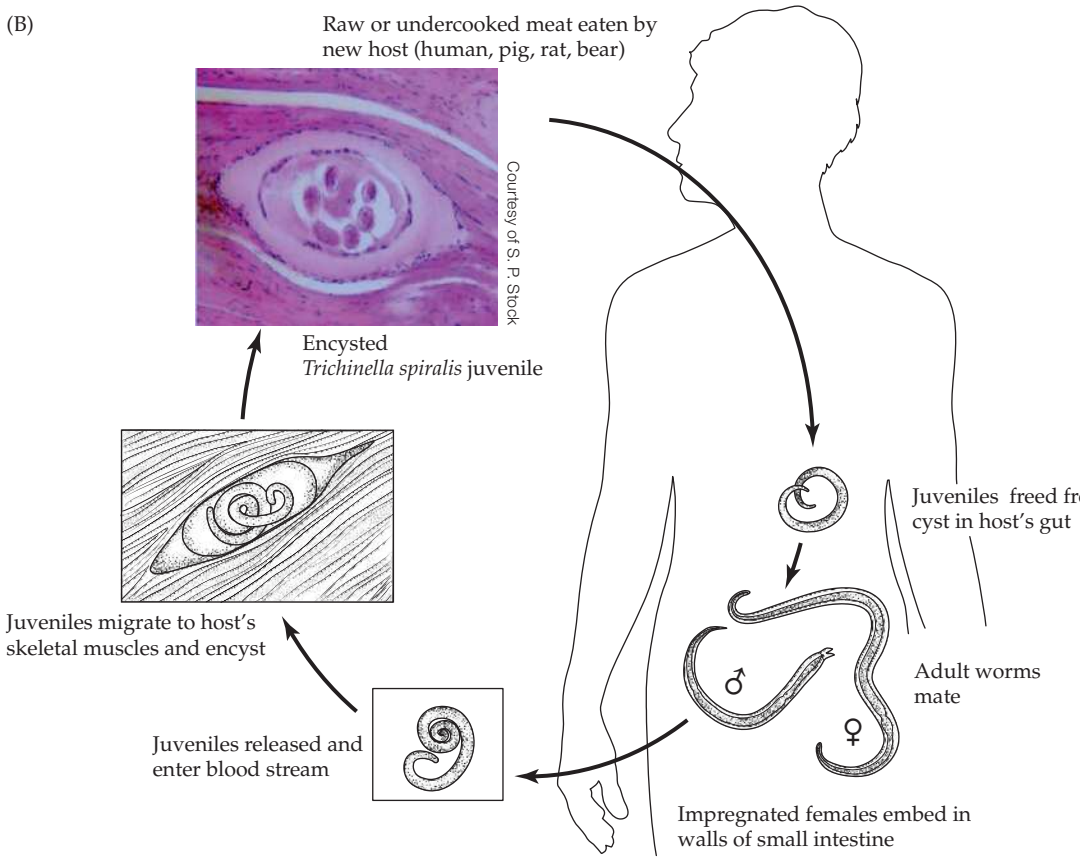


FIGURE 19.12 Life cycles of some parasitic roundworms. (A) Life cycle of the whipworm *Trichuris trichiura* (order Trichinellida), a common intestinal parasite of humans in tropical and subtropical regions. The fertilized eggs can remain viable for extended periods of time outside the host. Whipworms parasitize the intestine of the host and suck blood from the intestinal lining. In low-level infections, the symptoms are minor or absent, but in heavy infections intestinal bleeding, anemia, and abdominal pain can occur. (B) Life cycle of *Trichinella spiralis* (order Trichinellida) in humans; serious symptoms may result from the burrowing activity of the juveniles through the intestinal wall and from high levels of encysted juveniles in skeletal muscle tissue.

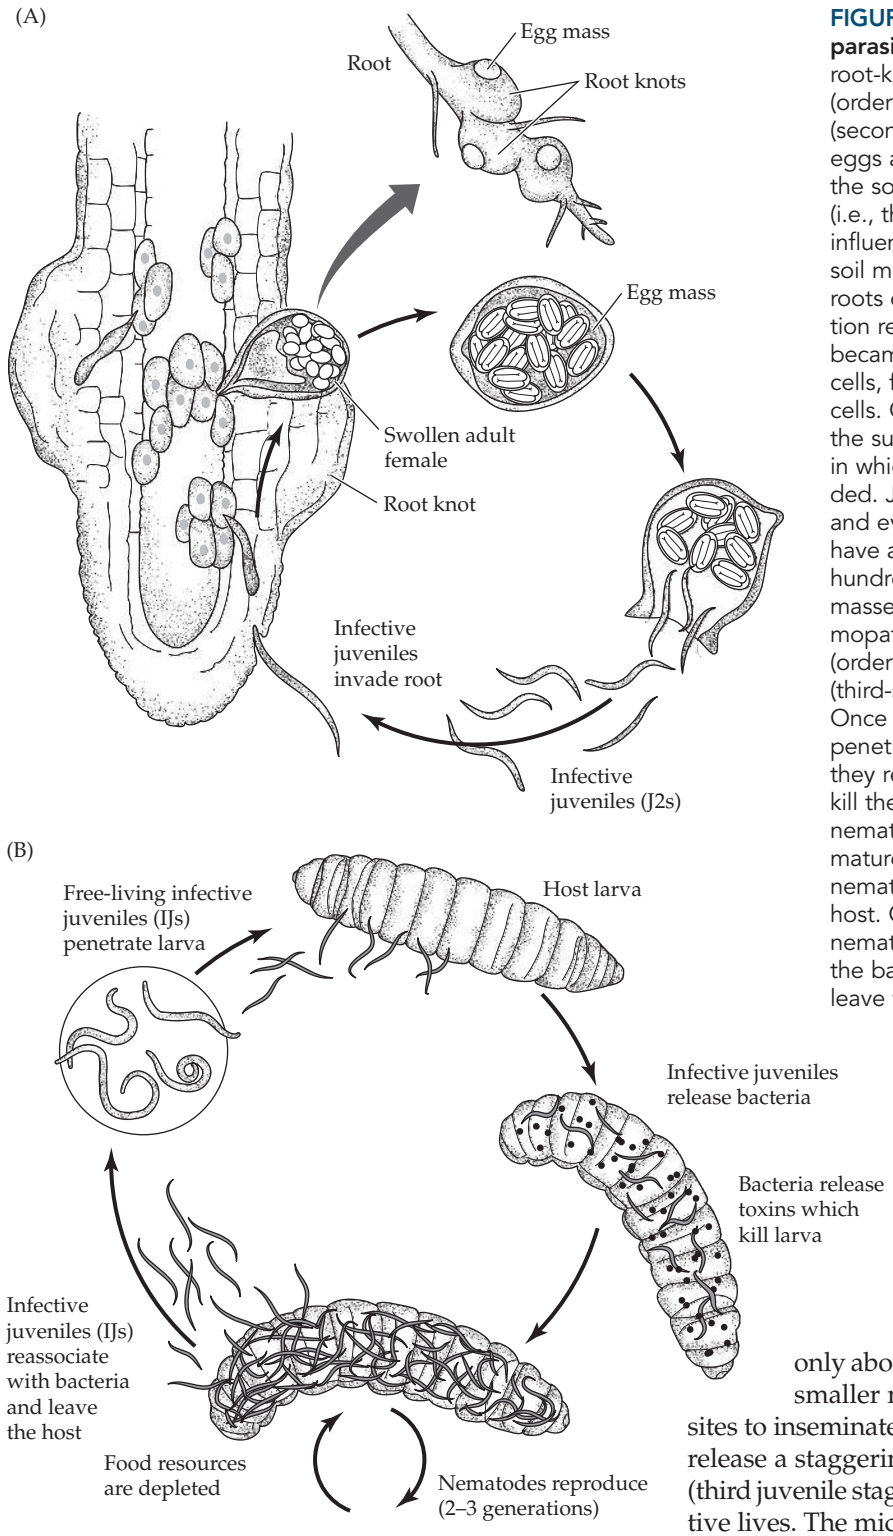

FIGURE 19.13 Life cycles of some parasitic roundworms. (A) Life cycle of the root-knot nematode *Meloidogyne incognita* (order Tylenchida). Infective juvenile stages (second stage juveniles, or J2s) hatch from eggs and have a short free-living stage in the soil, in the rhizosphere of the host plants (i.e., the narrow region of soil that is directly influenced by root secretions and associated soil microorganisms). J2s may reinvade the roots of the host plants in the root elongation region and migrate in the root until they became sedentary. J2s feed on parenchyma cells, forming feeding sites known as giant cells. Concomitant with giant cell formation, the surrounding root tissue gives rise to a gall in which the developing juvenile is embedded. J2s undergo morphological changes and eventually become adults. Females have a saccate shape and produce many hundreds of eggs that they lay in gelatinous masses. (B) Generalized life cycle of an entomopathogenic nematode, *Steinernema* sp. (order Rhabditida). Free-living infective stages (third-stage juveniles, or IJs) live in the soil. Once they encounter a suitable host, they penetrate it and release symbiotic bacteria as they reach the host's body cavity. The bacteria kill the host by septicemia and reproduce. The nematodes then feed on the bacteria as they mature and grow into adults. Two to three nematode generations can develop inside the host. Once food resources are depleted, the nematodes become IJs and reassociate with the bacteria in a mutualistic manner until they leave the cadaver in search of a new host.

bites from certain black fly species (Simuliidae). The disease (and the parasite) comes out of Africa, where it is endemic in 27 countries, but it also occurs in 6 Latin American countries as a result of the slave trade. If left to run its course, river blindness is a disease for life. Adult worms can live 12 to 15 years and be sexually active for 9 to 11 years. Adults live in large nodules under the skin—a telltale diagnostic feature. Each nodule harbors 2 to 3 female individuals measuring up to 50 cm in length (but only about 0.5 mm in diameter), and the much smaller males (to 4 cm long) migrate to these sites to inseminate the females. Once fertilized, females release a staggering 1,300 to 1,900 microfilarial worms (third juvenile stage) per day throughout their reproductive lives. The microfilariae are also the infective stages in this disease. It is the microfilarial stage that is transmitted to humans by the biting black flies. Once in the blood stream, these tiny (250–300 μm long) microfilariae circulate throughout the host's body, some eventually arriving in the eyes, where they infest the vitreous chamber, retina, and optic nerve. Here, when the microfilariae die, they cause scarification, leading to visual impairment and eventually blindness. It is estimated that 37 million people in Africa have onchocerciasis, hundreds of thousands of them eventually becoming blind.

In the 1970s, the drug avermictin (Ivermectin) was developed from a bacterium (*Streptomyces avermectinius*) found on a golf course in Japan. The drug kills or permanently sterilizes many adult filariid worms, with few side effects to the host animal. At first this drug was broadly developed for use on husbandry animals, cats, and dogs, but in 1996 the FDA approved its use in humans. Recent studies have shown that a large part of the pathogenicity of filarial worms is due to immune response of the host toward the nematode's naturally occurring *Wolbachia* bacterial symbionts. Also, it has been demonstrated that elimination of *Wolbachia* from the worms generally results in either their death or sterility. Consequently, current strategies for control of filarial nematode diseases include elimination of *Wolbachia* via administration of antibiotics such as doxycycline, which are more effective and less harmful than most antinematode medications.

Plant parasitic nematodes annually cause billions of dollars in crop losses worldwide. Some of the most damaging and widely distributed plant parasites are root-knot nematodes (*Meloidogyne*) and root-cyst nematodes (e.g., *Heterodera, Globodera*). In the soil, root-knot nematode eggs develop into nonmotile first-stage juveniles (J1) that reside inside the translucent egg case, where they molt into a motile J2 stage. The J2 can infect plants by attacking the root tips and moving to the area of cell elongation, where they initiate a feeding site by injecting esophageal gland sections into the cells. The secretions cause dramatic physiological changes to the root cells, transforming them into giant syncytial cells that die when the nematode dies. Figure 19.13A shows the life cycle of a root-knot nematode that attaches to the roots of a host tomato plant. However, other species can cause damage to the aerial parts of the plants, including leaves, stem, flowers, and seeds. Some species transmit plant pathogens (viruses and bacteria) through their feeding activity on roots. For example, *Xiphinema index* acts as a vector for the grapevine fan-leaf virus, an important disease of grapes. Some species, such as the pine wood nematode *Bursaphelenchus xylophilus*, are important forestry parasites worldwide.

Many nematodes parasitize invertebrates in both aquatic and terrestrial ecosystems. One of the most interesting groups is the so-called insect-pathogenic (or entomopathogenic) nematodes. Many of these nematodes associate (mutualistic symbiosis) with certain gram-negative bacteria, which they harbor in their intestines. Once the nematodes enter a suitable host, they release the bacteria, which kill the insect host by a massive septicemia in 24 to 48 hours. The bacteria then become the nematode's food, allowing them to mature and reproduce in the insect cadaver. Figure 19.13B shows a generalized entomopathogenic life cycle. These nematodes have been successfully used in the control of many agricultural insect pests. The worms with their symbiotic bacteria are raised and sold worldwide as biological control agents. Some of the more interesting symbiotic nematodes are those that, during their dauer stage, inhabit the reproductive tract of a solitary bee and then, as adults, inhabit the bee's brood cells, where they feed on the fungi and bacteria growing in their host's brood chambers.

Phylum Nematomorpha: Horsehair Worms and Their Kin

The Nematomorpha comprises a small group of long worms. There are about 365 described species of nematomorphs (Greek *nema*, "thread"; *morph*, "shape"), commonly called the hair, horsehair, or gordian worms. The phylum name (and the common name of hair and horsehair worms) derives from the threadlike shape of these animals (Figure 19.14) and from the belief held for some time after their discovery in the fourteenth century that they actually arose from the hairs of horses' tails. They are generally from 1 to 3 mm in diameter and up to 1 m in length. Many of the highly elongate forms tend to twist and turn upon themselves in such a way as to give the appearance of complicated knots, hence the name gordian worms. In the American Midwest large clumps of intertwined groups of *Gordius difficilis* are commonly found in cold, spring-fed habitats. Most species occur in fresh water, but five marine species have also been described. Characteristics of this phylum are listed in Box 19B.

BOX 19B Characteristics of the Phylum Nematomorpha

1. Triploblastic, bilaterally symmetrical, unsegmented, vermiform; body long and very thin
2. Body cavity largely obliterated by mesenchyme and organs
3. Cuticle well developed, with a single cuticular molt reported in some species
4. Body without functional cilia or flagella
5. Body wall containing only longitudinal muscles (no circular muscles)
6. Gut reduced to various degrees
7. With an aquatic larva and a unique juvenile stage that is parasitic in terrestrial arthropods
8. Epidermis forming longitudinal cords housing longitudinal nerves
9. Without special excretory, circulatory, or gas exchange organs
10. Gonochoristic; at least one known parthenogenetic species
11. With unique cleavage pattern
12. Adults mostly found in fresh water and wet terrestrial habitats, with five known marine pelagic species; all parasitic during the juvenile phase but free-living as adults

for more ebook/ testbank/ solution manuals requests: email 9601267346@qq.com

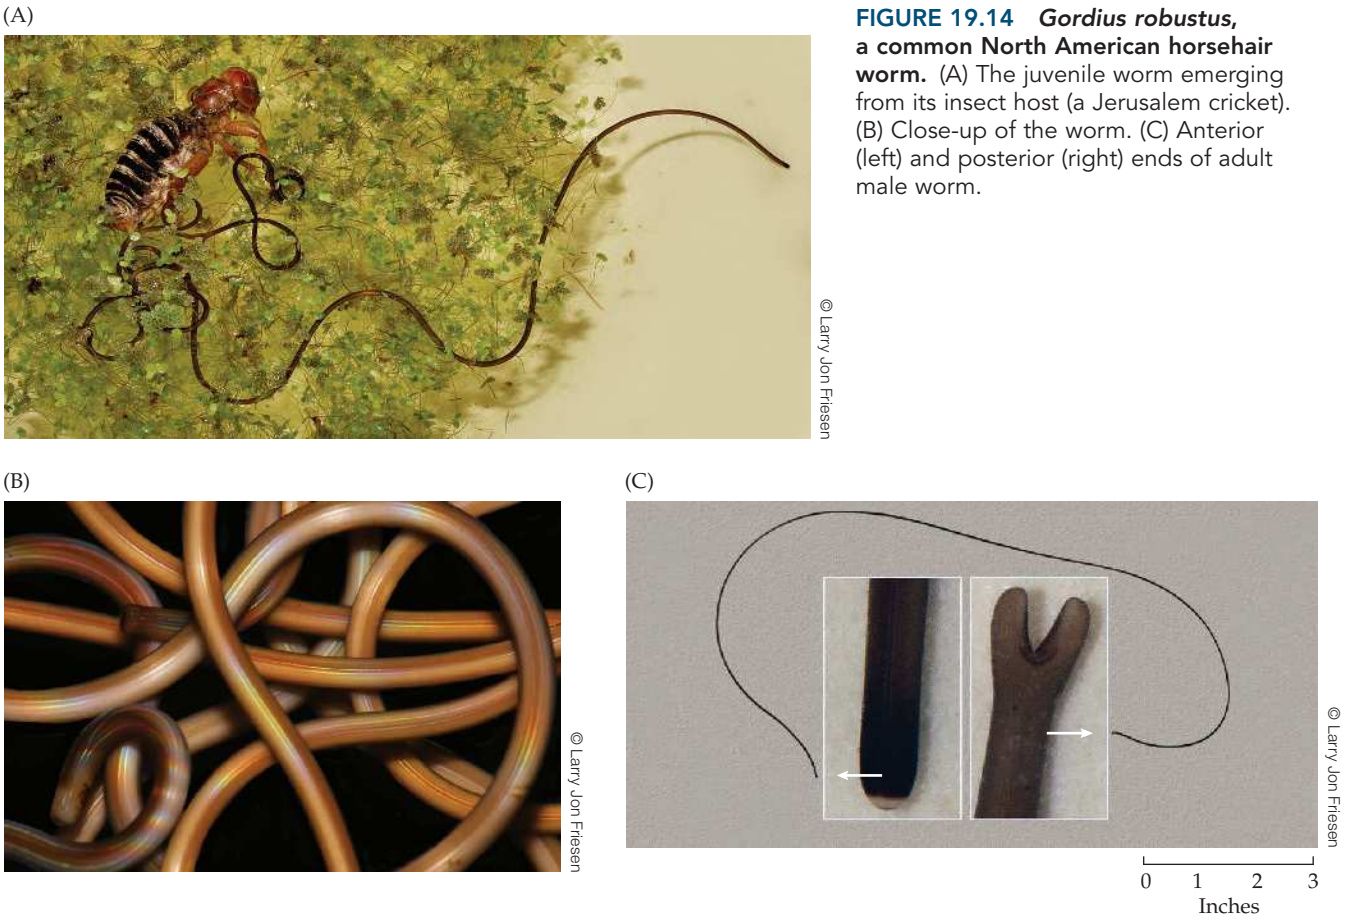

FIGURE 19.14 ***Gordius robustus*, a common North American horsehair worm.** (A) The juvenile worm emerging from its insect host (a Jerusalem cricket). (B) Close-up of the worm. (C) Anterior (left) and posterior (right) ends of adult male worm.

Nematomorphs were once thought to have a persistent blastocoelom, but recent work has shown most of these spaces to be artifacts—thus these worms are generally now regarded as acoelomates. The embryological blastocoel (the coeloblastula) is largely or fully obliterated by the invasion of mesenchyme and organs during development, and neither larvae nor adults have a significant body cavity (although some tiny fluid-filled spaces may remain in some cases, and these might represent remnants of the blastocoelom). In mature animals, the gonads become very spacious and occupy a large volume of the body. The digestive tract is largely nonfunctional, and nematomorphs appear to lack any structural excretory mechanisms. Like nematodes, nematomorphs possess only longitudinal (and no circular) body wall musculature—in contrast, the closely related ecdysozoan phyla Kinorhyncha, Priapula, and Loricifera have both longitudinal and circular musculature in the body wall. There are no functional cilia in these animals.

The larvae of nematomorphs, in both marine and continental species, parasitize mainly arthropods. After emerging from their final host, most adults live in fresh water, among litter and algal mats near the edges of ponds and streams, or in the case of the genus *Nectonema*, are pelagic in coastal marine environments.

NEMATOMORPHA CLASSIFICATION

ORDER NECTONEMATOIDEA Marine, pelagic; with a double row of natatory setae along each side of body; with dorsal and ventral longitudinal epidermal cords and integrated dorsal and ventral nerve cords; small body spaces may be evident, though fluid filled; gonads single; larva parasitizes decapod crustaceans. Monogeneric: *Nectonema* (5 known species).

ORDER GORDIOIDEA Without lateral rows of setae; with a single, ventral epidermal cord in a submuscular position, including the single nerve cord; body cavity largely filled with mesenchyme; older individuals develop spacious gonads; gonads paired. The larva parasitizes aquatic intermediate hosts (primarily arthropods and molluscs), while final hosts are mainly terrestrial arthropods; free-living aquatic adult may be short-lived. About 360 known species. *Chordodes, Gordius, Paragordius*, etc.

The Nematomorph Body Plan

Body Wall, Support, and Locomotion

The general organization of the body wall of nematomorphs is similar in many aspects to that of the nematodes (Figure 19.15A–C). The cuticle of adult specimens, secreted by the epidermis, is very thick (especially in the gordioids) and comprises an outer homogeneous

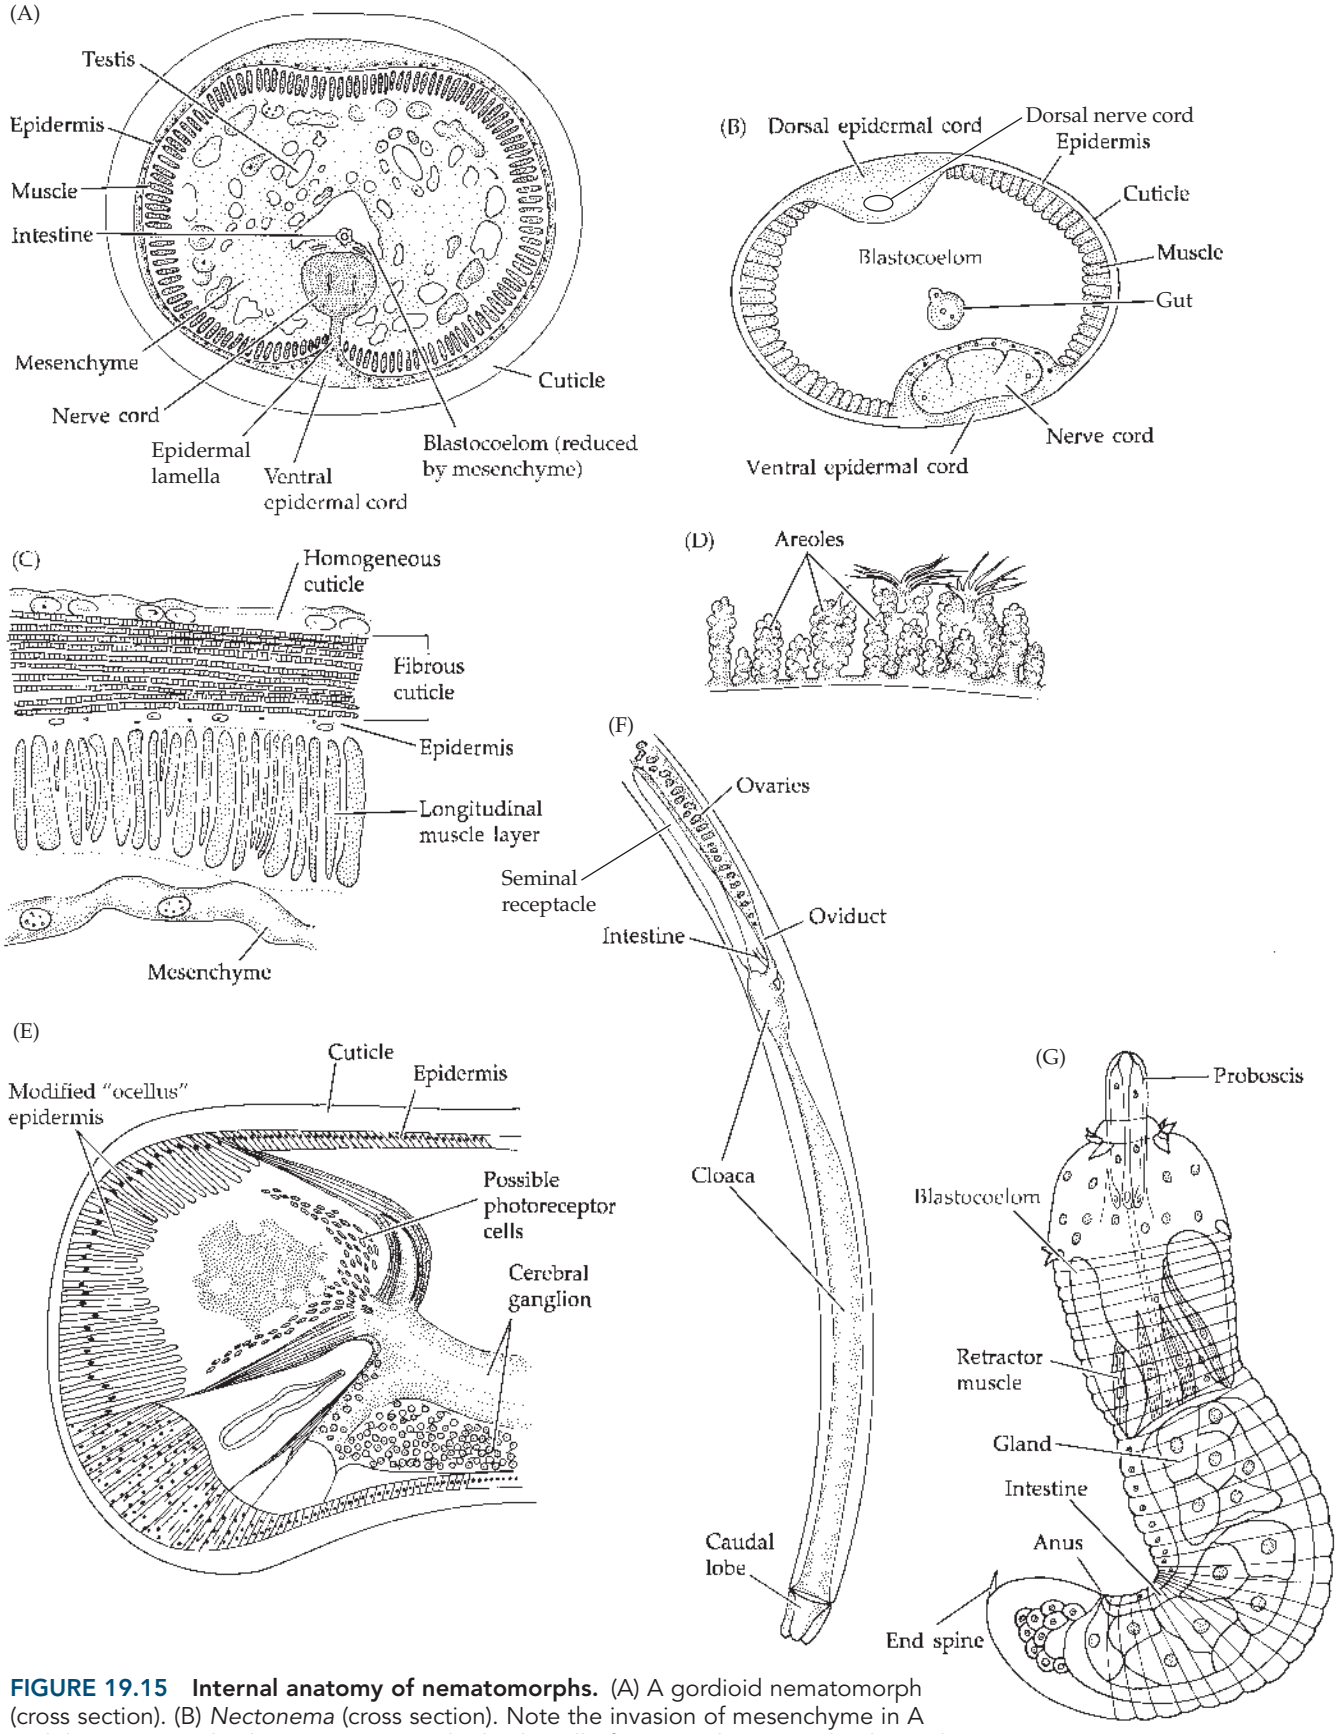

FIGURE 19.15 Internal anatomy of nematomorphs. (A) A gordioid nematomorph (cross section). (B) *Nectonema* (cross section). Note the invasion of mesenchyme in A and the persisting body cavity in B. Meglitsch. 1972. *Invertebrate Zoology*. Oxford University Press, London.)

for more ebook/ testbank/ solution manuals requests email 9601267340@qq.com

layer and an inner, lamellate, fibrous layer. The homogeneous layer often forms bumps, warts, or papillae (collectively called **areoles**; Figure 19.15D), some of which bear apical spines or pores. The function of the areoles is unknown, but spined ones may be touch sensitive, and pore-bearing ones may produce a lubricant. Some species have two or three caudal lobes at the posterior end, and these can be sexually dimorphic.

The unciliated epidermis covers the entire body and rests upon a thin basal lamina. The epidermis forms ventral (Gordioidea) or dorsal and ventral (Nectonematoidea) epidermal cords containing longitudinal nerve tracts. In Gordioidea the ventral cord is in a submuscular position and connected to the epidermis by a thin lamella. Beneath the epidermis is a single layer of longitudinal muscle cells; as in nematodes, there is no layer of circular muscle in the body wall.

The body cavity of nematomorphs is very small and filled with fluid (e.g., *Nectonema*) or altogether absent and filled with mesenchyme (Figure 19.15A,B). Body support comes mainly from the well-developed cuticle. Locomotion in the pelagic *Nectonema* is by undulatory swimming using the body wall muscles and the natatory bristles (Figure 19.16E) or by passive flotation in nearshore currents, aided by the bristles, which provide resistance to sinking. Freshwater nematomorphs use their longitudinal muscles to move by undulations or by coiling and uncoiling movements.

Feeding and Digestion

Nematomorphs might feed only during the parasitic juvenile stage, when they absorb nutrients across their thin body wall from the host's tissue and fluids, leaving adults to rely entirely on nutrients stored during the juvenile parasitic life. There is some evidence that adults of a few species might take in nutrients by absorbing small organic molecules across the body wall, but this seems a remote possibility due to the thickness of the adult cuticle and the reduced state of the intestine. There is growing evidence that parasitism by nematomorphs in insects can alter the host's behavior in ways that cause the insect to ultimately position itself near or in standing water, ensuring that the adults emerge in an appropriate habitat.

The digestive tract of nematomorphs is a simple elongate tube running the length of the body (Figure 19.15A,F,G). In juveniles, the gut is actively involved with uptake and storage of nutrients, transported across the body wall (although possible nutrient uptake through the mouth cannot be excluded). The intestine (midgut) is a thin-walled tube and may serve an excretory function as well as a digestive one. The hindgut is proctodeal (ectodermally derived), functions as a cloaca, and receives the reproductive ducts. In *Nectonema* a tiny mouth leads to a midgut that deteriorates posteriorly and is not connected to the genital opening.

Circulation, Gas Exchange, Excretion, and Osmoregulation

Very little is known about the physiology of nematomorphs. Internal transport is undoubtedly by diffusion through body fluids and mesenchyme and is probably aided by body movement. In the free-living stage gordian worms are presumably obligate aerobes as adults and are restricted to moist environments with ample available oxygen. The threadlike body results in short diffusion distances between the environment and the body organs and tissues.

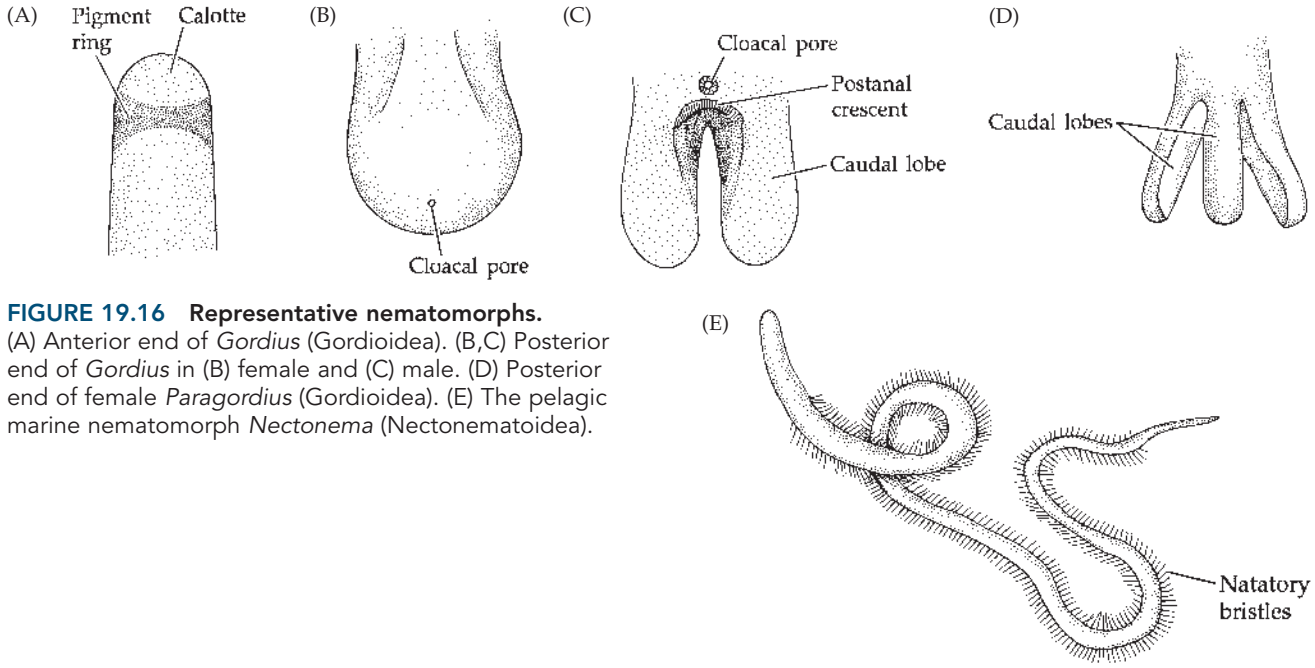

FIGURE 19.16 Representative nematomorphs. (A) Anterior end of *Gordius* (Gordioidea). (B,C) Posterior end of *Gordius* in (B) female and (C) male. (D) Posterior end of female *Paragordius* (Gordioidea). (E) The pelagic marine nematomorph *Nectonema* (Nectonematoidea).

Excretory and osmoregulatory functions probably operate on a strictly cellular level, as there are no protonephridia or other known special structures for these functions. Some workers, however, have speculated that the cells of the midgut may function in the excretion of metabolic wastes and that they may have a structure similar to the Malpighian tubules of insects.

Nervous System and Sense Organs

Like the nervous systems of nematodes and some other small Metazoa, the nervous system of nematomorphs is closely associated with the epidermis. The cerebral ganglion forms a circumesophageal mass of nervous tissue that is mainly subesophageal in gordioids but mainly dorsal in *Nectonema*. This connects to a ventral, longitudinal nerve cord in gordioids but to both dorsal and ventral, intraepidermal cords in *Nectonema* (Figure 19.15A,B). The nerve cords generally extend the length of the body and are attached to the epidermis by a tissue connection called the epidermal lamella (Figure 19.15A,B).

All nematomorphs are touch sensitive, and some are apparently chemosensitive. Adult males are able to detect and track mature females from a distance. However, the structures associated with these sensory functions are a matter of speculation. Presumably, some of the cuticular areoles are tactile, and perhaps others are chemoreceptive. Members of the genus *Paragordius* possess modified epidermal cells in the head region that contain pigment and may be photoreceptors (Figure 19.15E), although this function has not been confirmed. Other possible sensory structures are four "giant cells" near the cerebral ganglion in *Nectonema*.

Reproduction and Development

Nematomorphs are gonochoristic and display some sexual dimorphism (Figure 19.16B–D). The African species *Paragordius obamai* is a notable exception and has been shown to be parthenogenetic in culture. The male reproductive system includes one (in *Nectonema*) or two (in gordioids) testes (Figure 19.15A). Each testis opens to the cloaca via a short sperm duct. The reproductive system of female gordioids is not completely understood. They possess a pair of elongate ovaries with repeated pouches. A seminal receptacle as an extension of the cloaca is present. *Nectonema* contains no discrete ovary; instead, the germinal cells occur as scattered oocytes in the body cavity.

Mating has been studied in some gordioids. The females remain relatively inactive, but males become highly motile during the breeding season and respond to the presence of potential mates in their environment. Once a male locates a receptive female, he wraps his body around her and deposits a drop of sperm near her cloacal pore. The sperm find their way into the seminal receptacle and are stored while the ova mature. The eggs are fertilized internally and laid in gelatinous strings.

Early development has been studied in only a few species of gordioid nematomorphs. Cleavage is holoblastic, but not spiral or radial. A coeloblastula forms, then gastrulates by invagination of the presumptive endoderm. Mesodermal cells proliferate into the blastocoel from the area around the blastopore and in most cases appear to obliterate it. The anus and cloacal chamber also form from the area of the blastopore.

The life cycles of nematomorphs are not fully understood and may differ among species. A nematomorph larva develops and emerges from its egg case. In most cases, the new larva parasitizes an aquatic intermediate (paratenic) host, usually an arthropod or mollusc, and encysts in the host's tissues. Although transmission between intermediate and final host is not well understood, it is suspected that the final host (e.g., grasshopper, cricket, beetle, mantid, occasionally a myriapod or arachnid) consumes the intermediate host, whereupon the larva excysts and becomes a parasitic juvenile. The free-living aquatic adult may be short-lived.

It is likely that metamorphosing insects with aquatic larvae play the most important role as intermediate hosts. Within the definitive host's hemocoel, the larva grows into a juvenile nematomorph, which emerges from the host when it is mature. A single cuticular molt has been reported in some species, taking place shortly before the young worm emerges. Juveniles are nearly full size when they leave their host and do not grow much as adults. For most of the two dozen or so horsehair worms of North America, the hosts are not known.

Chapter Summary

This chapter introduced you to two groups of worms—phyla Nematoda (roundworms, threadworms) and Nematomorpha (horsehair, or gordian, worms)—that constitute a well-supported clade called Nematoida. Nematoida is one of the main lineages of Ecdysozoa (the molting animals), the others being Panarthropoda and Scalidophora, although the latter may also be a grade. The unique cuticle of adult nematoid worms is unusual in lacking chitin, the body is acoelic or blastocoelic, the body wall lacks circular muscles but has two to four unique epidermal cords that carry longitudinal nerves, there are no cilia, and the sperm are aflagellate. The adult stage of all nematomorphs is endoparasitic in pancrustaceans, and many nematodes are endoparasites of plants and animals. The largest species in both phyla can exceed a meter in length, though most species are very small (measured in millimeters). Nematodes are ubiquitous, being found in almost every habitat on Earth—freshwater, marine, terrestrial—on every continent. They have a unique secretory-excretory system composed of one or two renette cells or a bundle of collecting tubules. The cleavage pattern of nematodes is unique (neither radial nor spiral), and they do not produce a larva, but a series of juvenile stages looking like smaller adults. One of the 27,000 species of known nematodes, the tiny (1 mm long) *Caenorhabditis elegans* has been adopted as a model organism in many fields, including neurobiology, developmental biology, toxicology, and genetics, and is perhaps the best-known animal. Human nematode parasites include the whipworm (*Trichuris trichiura*), trichina worm (*Trichinella spiralis*), the filariid worm *Wuchereria bancrofti* (causative agent of elephantiasis), and the filariid worm *Onchocerca volvulus* (which causes river blindness). About 365 species of Nematomorpha have been described from freshwater habitats (and five from the marine environment). Most nematomorph life cycles include a minute, parasitic larva that grows to a large size and lives for a long period once it reaches a definitive host, but reproductive adults are free-living. Future research topics on nematodes and nematomorphs include clarifying their phylogenetic relationships relative to other ecdysozoans, developing better preventives for human and crop-related nematode infections, and better understanding the life cycles of many species with complex life histories. In addition, the field of nematology is in urgent need of a new phylogenetic system, given the conflict between the traditional taxonomy of the group and the phylogenetic history of the clade, making many traditional groups, including the famous Rhabditida, obsolete.

CHAPTER 20

Panarthropoda and the Emergence of the Arthropods

Tardigrades, Onychophorans, and the Arthropod Body Plan

The clade Panarthropoda comprises three phyla: Arthropoda, Onychophora, and Tardigrada. Arthropoda is the largest phylum in the clade Ecdysozoa (and the largest phylum of Metazoa). In fact, with an estimated 1,196,521 named species (995,521 hexapods, 113,000 chelicerates, 72,000 crustaceans, 16,000 myriapods), arthropods are about 82% of all described living animal species. They are so abundant and so diverse and play such vital roles in all of Earth's environments that we devote five chapters to them. The present chapter is divided into four parts. First we introduce two close relatives of the arthropods, the phyla Tardigrada (water bears; 1,300 species) and Onychophora (velvet worms; 200 species). Then we introduce the phylum Arthropoda itself, exploring its general body plan and basic unifying features and how this combination of attributes has led to its preeminent success. Finally, we provide a brief overview of arthropod evolution. Detailed treatments of the living arthropod subphyla—Crustacea and Hexapoda (together, forming the clade Pancrustacea), Myriapoda, Chelicerata—are provided in Chapters 21, 22, 23, and 24.

The close relationship among Tardigrada, Onychophora, and Arthropoda has rarely been questioned—except for a few molecular studies that placed tardigrades with nematodes and/or nematomorphs. Stem group Panarthropoda probably arose in ancient Precambrian seas, as estimated by molecular data, and the phylum Arthropoda in particular has undergone a tremendous evolutionary radiation since its origins in the Fortunian Age of the lowermost Cambrian. For years it was thought that tardigrades were the sister group to the Arthropoda, but recent molecular phylogenies suggest that onychophorans hold that role, and Tardigrada is the sister group to that pairing. The terrestrial subphyla Hexapoda, Arachnida,

and Myriapoda probably all emerged from the sea between the Cambrian and the Silurian.

Defining Panarthropoda morphologically is less straightforward than one might think, as most characters typically used in textbooks are absent in one of the three phyla (Table 20.1). However, they all have muscles isolated in bands, although only weakly so in the tardigrades and onychophorans. They also all have paired ventrolateral segmental appendages with terminal "claws," but the nature of these appendages differs among them. But only the phylum Arthropoda has undergone a full "arthropodization" process, with both the body segmented (and with segmental sclerites) and the appendages segmented (divided into segmental podomeres/articles separated by arthrodial membranes and intrinsic muscles). Onychophorans and arthropods share the same general pattern of gap gene expression along the proximodistal axis of the appendages (these data are not yet known for tardigrades). All three groups have a ganglionic supraesophageal brain, but that of tardigrades is composed of a single ganglion pair, and that of onychophorans is composed of two (protocerebrum and deutocerebrum), while Arthropoda have three (protocerebrum, deutocerebrum, tritocerebrum). The ventral nerve cords of these three groups also differ, with a paired ganglionated nerve cord in tardigrades and arthropods versus a lack of segmental ganglia in onychophorans. Similarly, onychophorans do not express external segments but show an annulated cuticle. Nevertheless, the segment polarity transcription factor protein engrailed is expressed in the posterior ectoderm of developing segments in each of these panarthropod groups, suggesting that it plays a common role in establishing segmental boundaries in the three phyla. While a segmented mesoderm and a mixocoel have been suggested as synapomorphies for Panarthropoda, these are not seen in tardigrades (where they may have been secondarily lost).

(I) Phylum Arthropoda, subphylum Myriapoda. A lithobiomorphan centipede. (J) Phylum Arthropoda, subphylum Hexapoda. A horse lubber grasshopper (*Taeniopoda eques*) from Arizona.

Today, arthropods occur in virtually every environment on Earth, exploiting every imaginable lifestyle (Figure 20.1C–J). Modern forms range in size from microscopic mites and crustaceans less than 1 mm long to Japanese spider crabs (*Macrocheira kaempferi*) with leg spans that reach nearly 4 m. Our inadequate knowledge of Earth's biodiversity is apparent when we consider the estimates of numbers of *undescribed species* of arthropods, which range from 3 million to over 100 million species. Most of this undiscovered diversity resides among the insects and mites on land and the crustaceans in the sea. Whether we lean toward the conservative or the liberal estimates, we are struck by the reality that no other phylum approaches the magnitude of species richness seen in arthropods. One might say, the modern world belongs to the arthropods. Yet, despite their overwhelming diversity, arthropods do share a suite of fundamental similarities and a distinct unifying

TABLE 20.1 A Comparison of the Panarthropod Phyla

Phylum/ subphylum	Number of described species	With segmental mesoderm and a mixocoel	Malpighian tubules	Muscles isolated as bands	Jointed legs	Compound eyes	With arthrodial membranes

body plan that we describe later in this chapter. But first, we begin our discussion with the less diverse, but equally charismatic relatives of the arthropods—the water bears and velvet worms.

Phylum Tardigrada

The first recorded observation of a tardigrade was by Polish theologian Johann Conrad Eichhorn in 1767. Since then, about 1,300 species have been described. Fossil tardigrades are very rare; they include specimens from the middle Cambrian of Siberia with "Orsten"-type preservation, having only three pairs of legs (Box 20A), from North American Cretaceous amber—*Milnesium swolenskyi* from the Late Cretaceous of New Jersey (USA), *Beorn leggi* from the Late Cretaceous of Manitoba (Canada), and *Paradoryphoribius chronocaribbeus* from Miocene age Dominican amber. More recently, rock fossil tardigrades have been discovered from the lower Cambrian Chengjiang deposits of China, but these remain unpublished.

Phylogenomic analyses, as well as neuroanatomical studies, support the traditional view that tardigrades are part of the Panarthropoda clade. Although the phylogenetic position of tardigrades relative to Onychophora is still debated, the most recent evidence suggests Onychophora is the sister group to Arthropoda, while Tardigrada is the sister group to that clade.

Most living tardigrade species are found in semiaquatic habitats, such as the water films on mosses, lichens, liverworts, and certain angiosperms, or in soil and forest litter. Others live in various freshwater and marine benthic habitats, both deep and shallow, often interstitially or among shore algae. A few very interesting species have been reported from hot springs. Some marine species are commensals on the pleopods of isopods or the gills of mussels; others are ectoparasites on the epidermis of holothurians or barnacles. Tardigrades occasionally occur in high densities, up to 300,000 per square meter in soil and more than 2,000,000 per square meter in moss. All are small, usually on the order of 0.1–0.5 mm in length, although some l.3 mm giants have been reported.

Under the microscope, tardigrades resemble miniature eight-legged bears, especially as they move with a lumbering, ursine gait—hence the name Tardigrada (Latin *tardus*, "slow"; *gradus*, "step"). Their locomotion, paunchy body, and clawed legs have earned them the nickname "water bears" (Figures 20.1A and 20.2–20.11).

Most terrestrial tardigrade species are widespread, and many might be cosmopolitan. A major factor in their wide distribution is probably the fact that their eggs, cysts, and tuns are resistant and light enough to be carried great distances either by winds or on soil clinging to insects, birds, and other animals. The minute sizes and precarious habitats of water bears have resulted in numerous traits also seen in some blastocoelomate groups that live in similar habitats.

Tardigrades are well known for their remarkable powers of **anabiosis** (a state of dormancy that involves greatly reduced metabolic activity during unfavorable environmental conditions) and **cryptobiosis** (an extreme state of anabiosis in which all external signs of metabolic activity are absent). Soil and freshwater tardigrades, during dry periods when the ponds or vegetation they inhabit become desiccated, encyst by pulling in their legs, losing body water, and secreting a double-walled cuticular envelope around the shriveled body. Such anabiotic cysts maintain a very low basal metabolism. Further reorganization (or "deorganization") of the body can result in a single-walled **tun** stage, in which body metabolism is undetectable (a cryptobiotic state). The extreme expression of cryptobiosis is the **anhydrobiosis** state, in which terrestrial tardigrades can survive as dry tuns for many years.

The resistant qualities of tardigrade tuns in anhydrobiosis have been demonstrated by experiments in which individuals have recovered after immersion in extremely toxic compounds such as brine, ether,

BOX 20A Characteristics of the Phylum Tardigrada

1. With modified or nonteloblastic segmentation; living species with 4 pairs of legs
2. Malpighian tubules without cuticle (i.e., endodermally derived)
3. With nonjointed, telescopic legs lacking intrinsic musculature
4. With a unique nerve connection between the first brain lobe and first ventral trunk ganglion
5. All sensory structures—cirri (mechanoreceptors) and clavae (chemoreceptors)—similar to those of arthropods
6. Body coelom greatly reduced and functioning as a hemocoel (defined coelomic compartments absent or restricted to gonadal cavities)
7. With thin, uncalcified cuticle, but always very complex—in all heterotardigrades with an outer honeycomb layer, followed with pillars and finally with a procuticle containing α-chitin
8. Muscles in isolated bands; body wall without sheetlike circular muscle layer
9. Cross-striated muscles in the stylet muscles of all tardigrades; cross-striated muscles in all muscles of all arthrotardigrades
10. Mouth terminal or ventral
11. Without circulatory system, gas exchange structures, or metanephridia
12. Cyclomorphosis is known in several marine eutardigrades
13. Capable of pronounced anabiosis/cryptobiosis

The section on Tardigrada was revised by Reinhardt Møbjerg Kristensen.

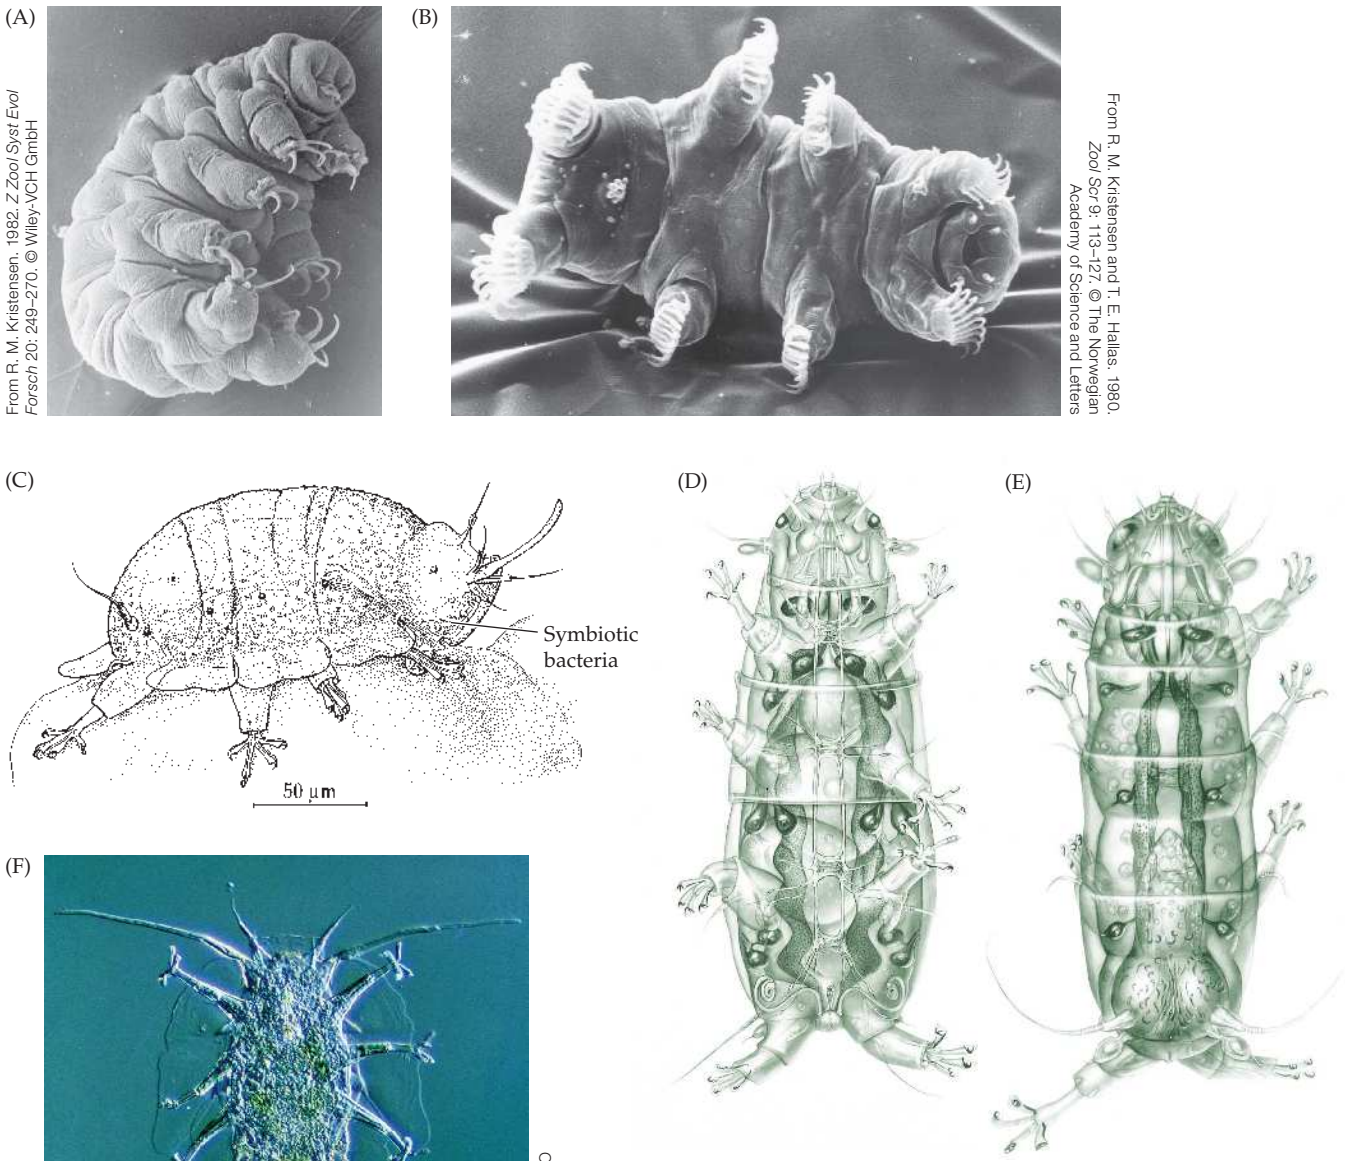

FIGURE 20.2 Representatives of the phylum Tardigrada. (A) *Halobiotus crispae*, a marine species common on brown algae in Greenland. This species undergoes a yearly cyclomorphosis involving a special hibernation stage (the pseudosimplex) during which it overwinters in the icy Greenland littoral zone. (B) *Echiniscoides sigismundi* (ventral view), a littoral species from Denmark. (C) *Wingstrandarctus corallinus* from the Coral Sea (which has symbiotic bacteria in its head). (D,E) *Styraconyx qivitoq* (ventral and dorsal views), a tardigrade that lives on ectoprocts and has been collected only in Greenland. (F) A marine water bear, *Florarctus heimi* (Arthrotardigrada), from coal sand at Heron Island, Australia. A male with extremely long primary clavae (chemoreceptors).

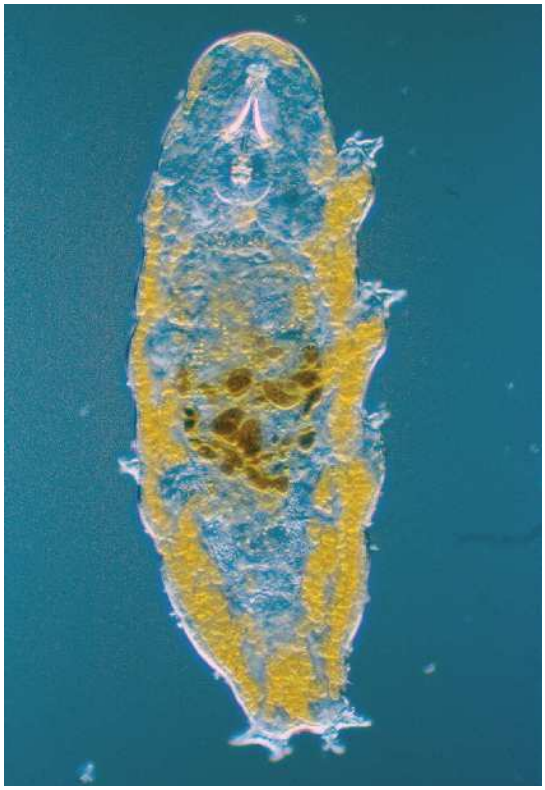
absolute alcohol, and even liquid helium. They have survived temperatures ranging from +149°C to –272°C, on the brink of absolute zero. They have also survived high vacuum, intense ionizing radiation, and long periods with no environmental oxygen whatsoever. Following desiccation, when water is again available, the animals swell and become active within a few hours. Many rotifers, nematodes, mites, and a few insects are also known for their anabiotic powers, and these groups often occur together in the surface water films of plants such as mosses and lichens. Tardigrades are also found on the Greenland ice sheet, in the so-called cryoconite holes formed by stardust and dark terrestrial material such as soot and volcanic dust, where few other metazoans can survive. Experiments with tardigrades in anhydrobiosis have demonstrated they can even survive at least several months in outer space. The BIOPAN 6 experiment in 2007 showed that tardigrades from mosses (Figure 20.3) could survive outside the spacecraft in anhydrobiosis for several months. In the most extreme case, embryos of *Milnesium tardigradum*



Courtesy of R. M. Kristensen

kept for three months in an outer space hatch had 100% survival after rehydration. And in 2019 an Israeli spacecraft carrying tardigrades crash-landed on the moon, leaving them stranded in a state of anhydrobiosis on that satellite's surface.

One marine tardigrade genus (*Echiniscoides*) survives quite well with a life cycle that regularly alternates between active (Figure 20.2B) and tun stages, and it can even survive an experimentally induced cycle forcing it to undergo cryptobiosis every six hours! Evidence indicates that the tardigrade aging process largely ceases during cryptobiosis and that by alternating active and cryptobiotic periods, tardigrades may extend their life spans to several decades. One rather sensational report described a dried Italian museum specimen of moss that yielded living tardigrades when moistened after 120 years on the shelf! However, the tardigrades died shortly later.

Early genomic analyses of tardigrades indicated that this group had incorporated a huge number of foreign genes into its own genome, by way of horizontal gene transfer, from various Eubacteria, Archaea, and even plants and fungi. These adopted genes, which comprised as much as 17.5% of the tardigrades' DNA, were thought to play a role in the ability of water bears to withstand extreme stresses. But this was later shown to be the result of contamination, and although subsequent genome resequencing showed some level of horizontal gene transfer, this was in the order of 1%–2%, similar to many other animals.

In certain areas of extreme environmental conditions, marine tardigrades may undergo an annual cycle of **cyclomorphosis** (rather than the cryptobiosis typical of terrestrial and freshwater forms). During cyclomorphosis, two distinct morphologies alternate. For example, *Halobiotus crispae*, a littoral species first found in Greenland (Figures 20.2A and 20.4), has a summer morph and a winter morph. The latter is a special hibernation stage called the **pseudosimplex** that is resistant to freezing temperatures and perhaps low salinities. In contrast to cryptobiotic tuns, the pseudosimplex is active and motile. Cyclomorphosis is coupled with gonadal development, and in Greenland only the summer morph is sexually mature.

Currently the phylum Tardigrada comprises 31 families in three classes: Heterotardigrada, Apotardigrada, and Eutardigrada. The classes are defined largely on the basis of the details of the head appendages, the nature of the leg claws, and the presence or absence of Malpighian tubules. The former monotypic class Mesotardigrada includes the single species *Thermozodium esakii*, known only from the hot springs of Unzen Park, near Nagasaki, Japan, but it has not been found since the end of the Second World War. Recently, a team of experts looked for this species but could not rediscover it, therefore leaving *T. esakii* a nomen dubium. Heterotardigrades include the orders Arthrotardigrada (nearly all marine) and Echiniscoidea (marine, freshwater, and terrestrial); however, the arthrotardigrades are clearly paraphyletic with respect

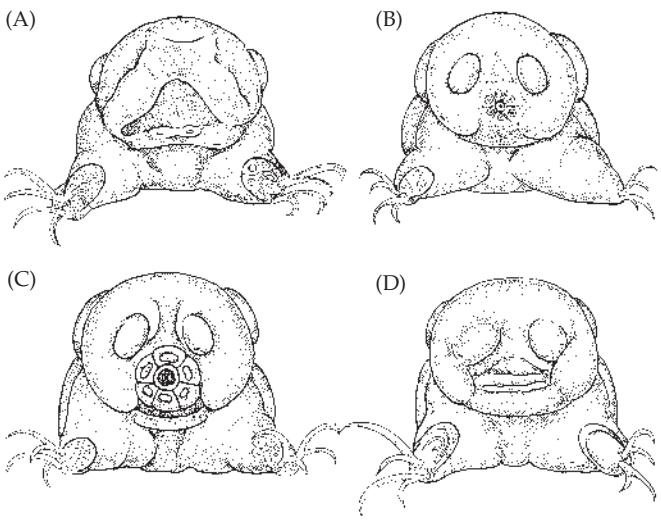

FIGURE 20.4 Cyclomorphosis in a marine tardigrade, *Halobiotus crispae*, from Greenland; frontal views. (A) The hibernation stage, pseudosimplex 1 (winter form, with double cuticle). to the echiniscoids. Apotardigrada and Eutardigrada are freshwater-terrestrial, except for two secondarily marine genera of eutardigrades.

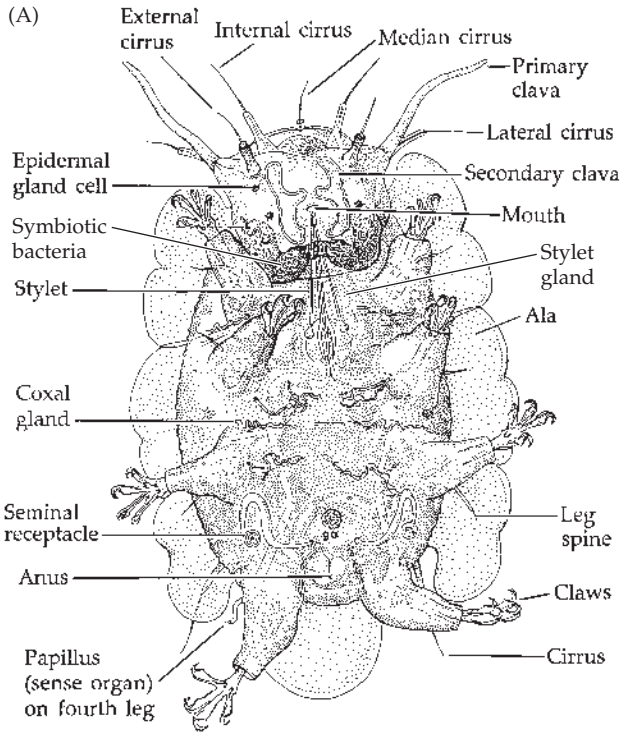
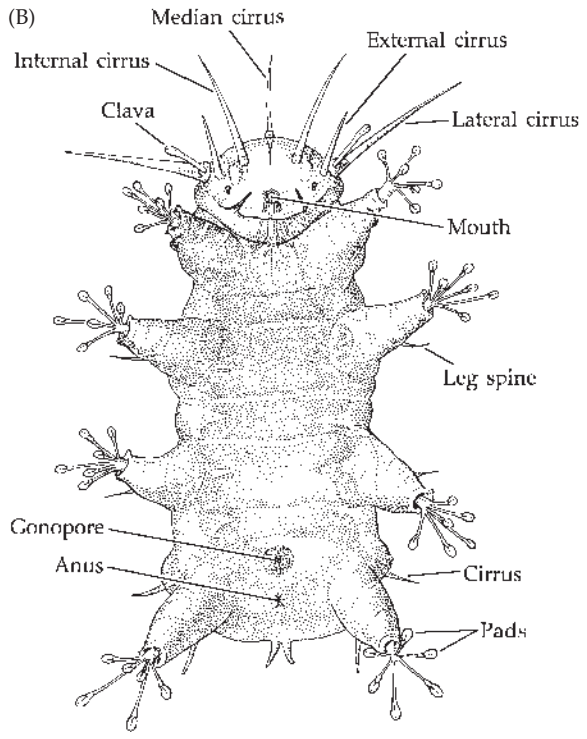
The Tardigrade Body Plan

Tardigrades have four pairs of ventrolateral legs (Figures 20.2, 20.3, 20.4, 20.5, and 20.6). The legs of eutardigrades (Figure 20.2A) are short, hollow extensions of the body wall, essentially lobopodal in design, and similar to the lobopodal legs of onychophorans. Each leg terminates in one or as many as a dozen or so "claws" (Figures 20.4, 20.5, 20.6, and 20.7). The claws may be modified as adhesive pads or discs, or the claws may resemble those of onychophorans. In the marine arthrotardigrades (Figures 20.2C and 20.5A), the legs are telescopic and each consists of a so-called coxa, femur, tibia, and tarsus; however, there is no evidence that these leg "segments" are homologous with those of arthropod legs.

As in onychophorans, the body is covered by a thin, unmineralized cuticle that is periodically molted. It is often ornamented and occasionally divided into symmetrically arranged dorsal and lateral (rarely ventral) plates (Figures 20.2 and 20.5C). These plates may be homologous with the sclerites of arthropods, but this is not certain. The cuticle shares some features with both onychophorans and arthropods, but it is also unique in certain ways—for example, the epicuticle often has support pillars (Figure 20.8). Elsewhere the cuticle comprises up to seven distinguishable layers and contains various sclerotized ("tanned") proteins and always chitin in the procuticle, and it lines the foregut and rectum. The cuticle is secreted by an underlying epidermis, which is composed of a constant cell number in many (but not all) species. Such cell constancy and the phenomenon of eutely are common in minute metazoans, and we have noted several other examples among the blastocoelomate phyla (e.g., some rotifers and nematodes). Growth in tardigrades proceeds by





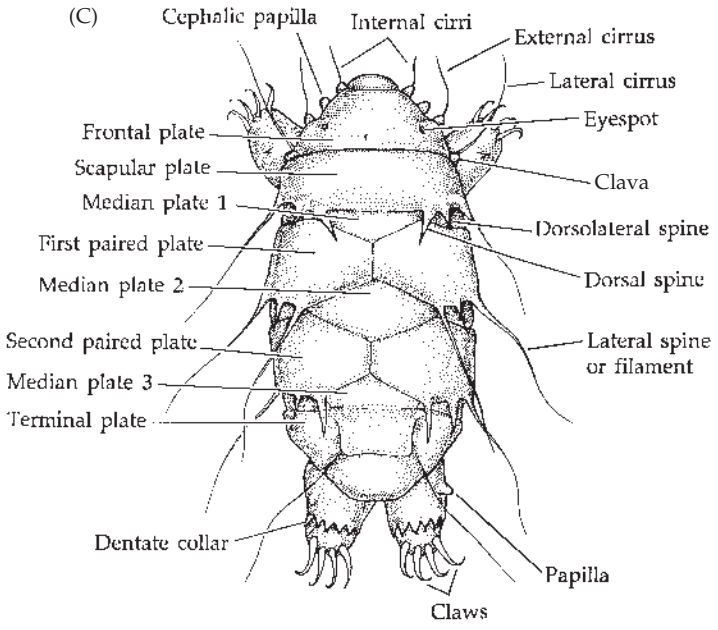


FIGURE 20.5 Tardigrade anatomy. (A) *Wingstrandarctus corallinus* (ventral view), an inhabitant of shallow, sandy marine habitats in Australia and Florida. (B) *Batillipes noerrevangi* (ventral view). (C) Generalized *Echiniscus* (dorsal view).

molts, as in onychophorans and arthropods, with sexual maturity being attained after three to six instars. Not only is the cuticle molted—the buccal canal, the two stylets, the two stylet supports, and the distal part of legs with claws or toes are also re-formed during ecdysis. Both the claws and the stylets are formed in special glands—called **stylet** and **claw glands** (Figures 20.5A and 20.6). During ecdysis the animal cannot eat, and the mouth opening is closed. This stage is called the **simplex stage**.

The body is quite short, segmentation is homonomous, and tardigrades are rather weakly cephalized. Such a compact body seems to be derived from a loss of most of the trunk region, making the tardigrade body basically homologous with the arthropod head. Nonmarine tardigrades are often colorful animals, exhibiting shades of pink, purple, green, red, yellow, gray, and black. Color is determined by cuticular pigments, the color of the food in the gut, or the presence of granular bodies with carotene in the coelomocytes suspended in the hemocoel.

Like the coelom of arthropods and onychophorans, the adult coelom of tardigrades is either greatly reduced and confined largely to the gonadal cavities or absent altogether, depending on the interpretation. The main body cavity is thus a hemocoel, and the colorless body fluid directly bathes the internal organs and body musculature. Furthermore, all Eutardigrada and Apotardigrada have many coelomocytes in this body fluid. The coelomocytes provide nutrition to all the organs in the body. In the Arthrotardigrada the situation is very different, as there is clearly no body cavity (thus they are acoelomate) and the coelomocytes are fixed (e.g., to the brain). Here the coelomocytes are called "amebocytes."

The musculature of tardigrades is quite different from that of onychophorans, in which the body wall muscles are in sheetlike layers; in tardigrades there is no circular muscle layer in the body wall, and the muscles occur in separate bands extending between subcuticular attachment points, as they do in arthropods (Figure 20.6).

It was long thought that tardigrades possessed only smooth muscle, in contrast to the striated muscles of arthropods, and in the past this feature was used as an argument against a close relationship between these two phyla. However, we now know that both smooth and striated muscles occur in all tardigrades, the latter predominantly in the order Arthrotardigrada. The striated muscles are of the arthropod type, being cross-striated rather than obliquely-striated like those of onychophorans. Numerous fine structural details of the muscle attachment regions are also shared between tardigrades and arthropods. Furthermore, in all tardigrades the stylet muscles always are cross-striated. It has been suggested that a partial shift from arthropod-like striated muscle to smooth muscle in some tardigrades might have accompanied a transition from the marine to the terrestrial environment, and it might be functionally tied to the phenomenon of cryptobiosis. Furthermore, both slow and fast nerve fibers occur in tardigrades, the former predominating in the somatic musculature and the latter in the leg musculature. However, the leg musculature appears to be entirely extrinsic, like that of onychophorans, with one muscle attachment near the tip of the leg and the other within the body proper. Many of the muscle bands in tardigrades consist of only a single muscle cell or a few large muscle cells each.

Locomotion

The concentration of muscles as discrete units and the thick cuticle in tardigrades demand a different locomotory strategy than the primarily hydrostatic system seen in onychophorans. Instead, tardigrades use a step-by-step gait controlled by independent antagonistic sets of muscles or by flexor muscles that work against hemocoelic pressure. The claws, pads, or discs at the ends of the legs are used for purchase and for clinging to objects, such as strands of vegetation or sediment particles (Figure 20.7). And, at least one marine species, *Tholoarctus natans*, is capable of limited jellyfish-like swimming by use of a bell-shaped expansion of the cuticle margin to keep it suspended just above the sediment.

(D) The feet of *Orzeliscus* (left) and *Batillipes* (right), showing adhesive discs or pads on the claws. (After C. I. Morgan and P. E. King. 1976. *British Tardigrades*. Academic Press, London.)

Feeding, Digestion, and Excretion

Tardigrades usually feed on the fluids inside plant or animal cells by piercing the cell walls with a pair of **oral stylets**. Soil-dwelling species feed on bacteria, algae, and decaying plant matter or are predators on small invertebrates. Carnivorous and omnivorous tardigrades have a terminal mouth; herbivorous and detritivorous ones have a ventral mouth.

The mouth opens into a short stomodeal buccal tube, which leads to a bulbous, muscular pharynx (Figure 20.6). A pair of large salivary glands flank the esophagus and produce digestive secretions that empty into the mouth cavity; these glands also are responsible for the production of a new pair of oral stylets with each molt, hence they are often referred to as **stylet glands** (Figures 20.5A and 20.6). The muscular pharynx produces suction that attaches the mouth tightly to a prey item during feeding and pumps the cell fluids out of the prey and into the gut. In many species there is a characteristic arrangement of chitinous rods, or **placoids**, within an expanded region of the pharynx. These rods provide support for the musculature of that region and may contribute to masticating action. The pharynx empties into an esophagus, which in turn opens into a large intestine (midgut), where digestion and absorption take place. The short hindgut (the cloaca or rectum) leads to a terminal anus. In some species defecation accompanies molting, with the feces and cuticle being abandoned together. Several marine arthrotardigrades have symbiotic bacteria in cephalic vesicles (Figures 20.2C and 20.5A). In *Wingstrandarctus* these bacteria may be used when the tardigrades are starving. The vesicles can be empty when the tardigrades have a full, green gut content, indicating they have been feeding on plant material.

At the intestine-hindgut junction in freshwater and terrestrial species of eutardigrades there are three large glandular structures called **Malpighian tubules** (Figure 20.6), each consisting of only about nine cells. The precise nature of these organs is not well understood, but they are probably not homologous with the Malpighian tubules of arthropods. In at least one marine eutardigrade genus (*Halobiotus*), the Malpighian tubules are greatly enlarged and have an osmoregulatory function. It is probable that some excretory products are absorbed through the gut wall and eliminated with the feces; other waste products may be deposited in the old cuticle prior to molting. In terrestrial heterotardigrades, excretory and ion/osmoregulatory structures are found between the second and third pairs of legs. However, in several marine arthrotardigrades segmental trunk glands open at the base of the legs and a single pair of these segmental glands is located in the head. These glands may be homologous with the coxal glands of arthropods.

Circulation and Gas Exchange

Perhaps because of their small size and moist habitats, tardigrades have no traces of discrete blood vessels, gas exchange structures, or metanephridia; consequently, they rely on diffusion through the body wall and the extensive body cavity. The body fluid contains numerous cells (sometimes called coelomocytes) credited with a storage function.

Nervous System and Sense Organs

The nervous system of tardigrades is built on the arthropod plan and is distinctly metameric. A large dorsal cerebral ganglion is connected to a subpharyngeal ganglion by a pair of commissures surrounding the buccal tube (Figure 20.6). From the subpharyngeal ganglion, a pair of ventral nerve cords extends posteriorly, connecting a chain of four pairs of ganglia that serve the four pairs of legs. As a unique apomorphy for all tardigrades, there exists a nerve connective between the first brain lobe and the first ventral trunk ganglion. Sensory bristles or spines occur on the body, particularly in the anterior and ventral region and on the legs. The structure of these bristles is essentially homologous with that of arthropod setae (Figure 20.8). A pair of sensory eyespots is often present inside the dorsal brain. Each eyespot consists of five cells, one of which

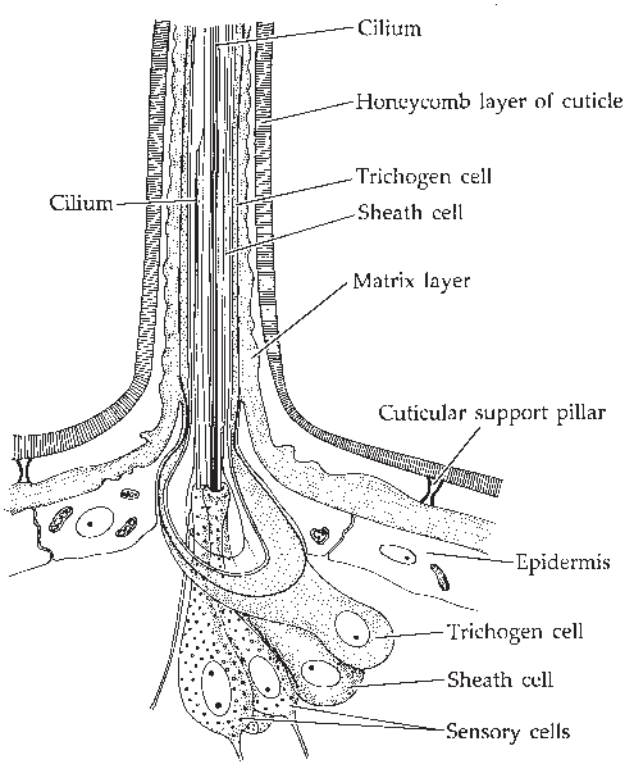

FIGURE 20.8 **Base of an external bristle of *Batillipes noerrevangi* (longitudinal section), showing the relationship between the various cells and the cuticle.**

for more ebook/ testbank/ solution manuals Request: email 9601267340@qq.com

is a pigmented light-sensitive cell with both microvilli and modified ciliary structure.

The anterior end of many heterotardigrades bears long sensory **cirri**, and most of these species also have one to three pairs of hollow anterior sensory structures called **clavae** that are probably chemosensory in nature (Figures 20.2C and 20.5). The clava appears structurally similar to the olfactory seta of many arthropods. Many males have longer clavae than females.

Reproduction and Development

Many tardigrades are gonochoristic, with both sexes possessing a single saclike gonad lying above the gut. In males, the gonad terminates as two sperm ducts, suggesting that the single gonad is derived from an ancestral paired condition (Figure 20.9). The ducts extend to a single gonopore, which opens just in front of the anus or into the rectum. In females a single oviduct (right or left) opens either through a gonopore anterior to the anus or into the rectum (which in this case is called a cloaca) (Figure 20.6). There are two complex seminal receptacles (e.g., Arthrotardigrada) that open separately (Figure 20.5A) or a single small seminal receptacle (e.g., some Eutardigrada) that opens into the rectum near the cloaca (Figure 20.6).

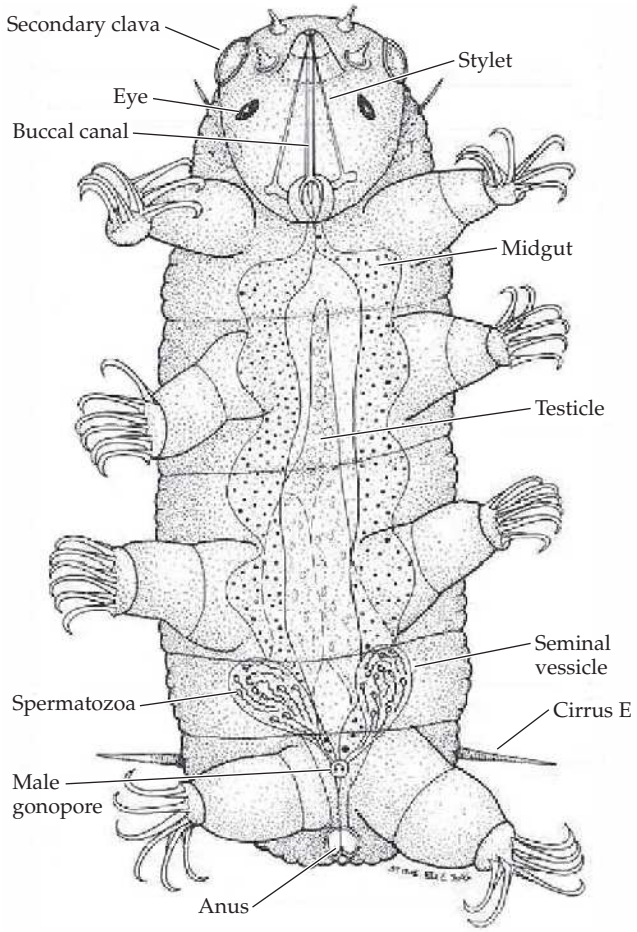

FIGURE 20.9 Reproductive system of a male tardigrade. Ventral drawing of *Isoechiniscoides sifae*, a marine heterotardigrade with six claws on each leg. (Illustration by Stine B. Elle from N. Møbjerg et al. 2016. *Zool J Linn Soc* 178: 804–818.)

Males are unknown in some terrestrial genera, but most tardigrades that have been studied copulate and lay eggs, and copulation is amazingly diverse among these little water bears. Parthenogenesis may be common in some terrestrial species, notably those in which males are unknown. Hermaphroditism has also been reported in a few genera. Dwarf males have been recently discovered in several marine genera. In some tardigrades the male deposits sperm directly into the female's seminal receptacles (or cloaca) or into the body cavity by cuticular penetration. In the latter case fertilization takes place in the ovary. In other tardigrades, a wonderfully curious form of indirect fertilization takes place: the male deposits sperm beneath the cuticle of the female prior to her molt, and fertilization occurs when she later deposits eggs in the shed cuticular cast (Figure 20.10). Several studies have shown tardigrade sperm to be uniflagellate. In at least a few marine species, a primitive courtship behavior exists, wherein the male strokes the female with his cirri. Thus stimulated, the female deposits her eggs on a sand grain, upon which the male then spreads his sperm.

Females lay from 1 to 30 eggs at a time, depending on the species. In strictly aquatic species the fertilized eggs are either left in the shed cuticle or glued to a submerged object. The eggs of many terrestrial species bear thick, sculptured shells that resist drying (Figures 20.10 and 20.11). Some species alternate between thin-walled and thick-walled eggs, depending on environmental conditions.

There have been only a few studies on tardigrade embryology. Development appears to be direct and rapid, but indeterminate. Cleavage has been described as holoblastic and always radial. A blastula develops, with a small blastocoel; eventually it proliferates an inner mass of endoderm that later hollows to form the archenteron. Stomodeal and proctodeal invaginations develop, completing the digestive tube. Subsequent to gut formation, five pairs of archenteric coelomic pouches are said to appear off the gut, reminiscent of the enterocoelic development of many deuterostomes. The first pair arises from the stomodeum (ectoderm) and forms the stylet glands and stylets, and the last four pairs from the midgut (endoderm). The two posterior pouches fuse to form the gonad; the others disappear as their cells disperse to form the body musculature.

Tardigrades were long thought to have typical teloblastic segmentation, a type of development where there is a growth zone from which the new body segments arise. However, recent work has shown that

tardigrades develop all four pairs of legs and the coelomic pouches very early in embryogenesis, and the legs are present when they hatch. So, teloblastic segmentation may be modified in living species. However, extinct Cambrian tardigrades from Siberian limestone may have had teloblastic growth—the smallest specimens have only three pairs of legs, and larger specimens have limb buds for the fourth pair of legs. Development in living species is typically completed in 14 days or less, whereupon the young use their stylets to break out of the shell (Figure 20.11C).

Juveniles lack adult coloration, have fewer lateral and dorsal spines and cirri, and may have reduced numbers of claws, when compared to adults. At birth, the number of cells in the body is relatively fixed, and growth is primarily by increases in cell size rather than in cell number. In nature, these remarkable animals may live only a few months or may survive for a great many years.

Phylum Onychophora

The first living onychophoran (Greek *onycho*, "talon"; *phora*, "bearer") was described by the Reverend Lansdown Guilding in 1826 as a leg-bearing slug (a mollusc). Since that initial discovery, 220 or so species of onychophorans have been described, 200 of which are considered valid, and probably at least that many more remain to be discovered (Figures 20.1B and 20.12). All the living species are terrestrial, constituting the only animal phylum that is entirely land-bound. We now know that onychophoran relatives, probably part of the stem group, known as lobopodians, were part of the explosive marine diversification in the lower Cambrian (see Chapter 1). Their fossils have been found in middle Cambrian marine faunas at several localities (e.g., *Aysheaia pedunculata* from the famous middle Cambrian Burgess Shale deposits of British Columbia, Canada, and *Aysheaia prolata* from a similar deposit in Utah), in the remarkable Chengjiang lower Cambrian (520–530 Ma) deposits of China, and in the equally stunning Swedish upper Cambrian Orsten fauna. Perhaps the most famous lobopodian fossil is the Cambrian genus *Hallucigenia*, long a mystery because it was originally interpreted in an upside-down orientation but later turned right side up and discovered to possess long dorsal spines (Figure 20.13A). The fossil record of crown group Onychophora is, however, restricted to a Carboniferous deposit from the Stephanian deposits of Montceau-les-Mines (France) (Figure 20.12G) and to a few amber deposits from the Cretaceous of Myanmar (Figure 20.13E).

Onychophora constitutes an old group that has changed very little over the past 310 million years. At some point in its long history, prior to the Carboniferous Period (when the first unambiguous crown-group onychophorans appear in the fossil record), they successfully invaded the terrestrial environment. Like arthropods and tardigrades, onychophorans are segmented animals, and they have features that are somewhat intermediate between those of tardigrades and arthropods. The three phyla together comprise the clade called Panarthropoda. Due to their special type of segmentation, in the past, workers regarded onychophorans as "living fossils," or "missing links" between other segmented soft-bodied animals, such as annelids, and the arthropods. However, molecular phylogenetic studies now place the annelids in the Spiralia, quite distant from the Panarthropoda, which are ecdysozoans. Their close relationship to arthropods has triggered a great deal of research on onychophorans, aimed at understanding the early steps in the evolution of Earth's most diverse animal phylum. Indeed, research on velvet worms has undergone a revival in the twenty-first century with a plethora of studies focusing on their development, the nervous system, and segmentation, as well as taxonomic and biogeographic treatments.

Living onychophorans comprise two families, Peripatidae and Peripatopsidae (Figure 20.12). The former is circumtropical in distribution (with multiple species in the Neotropics, one in western Africa, and a few in Southeast Asia), whereas the latter is circumaustral (confined to the more temperate Southern Hemisphere), with species in Chile, South Africa, New Zealand, and Tasmania but also in the tropical regions of New Guinea and Australia. During dry periods, velvet worms retire to protective burrows or other retreats where they can preserve moisture and become inactive. During wet periods they can be found actively hunting at night, inside damp fallen tree logs, or in leaf litter. Onychophorans live for several years, during which time periodic molting takes place, as often as every two weeks in some species (Box 20B).

BOX 20B Characteristics of the Phylum Onychophora

1. Segmentation probably teloblastic; 13–43 pairs of legs
2. Muscles in isolated bands
3. With superficially annulated, nonjointed, telescopic, lobopodal legs lacking intrinsic musculature; legs with terminal claw (or hooks)
4. Cerebral ganglion (brain) lying dorsal to pharynx, probably with only two pairs of ganglia; protocerebrum innervating eyes and antennae; deutocerebrum innervating jaws
5. With jaws, probably homologous with chelicerae of Chelicerata, or antennae of myriapods and hexapods (first antennae of crustaceans)
6. Paired ventral nerve cords different from those of tardigrades and arthropods, with no relationship between arrangement of median or ring commissures and position of legs; cell bodies of serotonergic neurons not arranged in the segmentally repeated and bilaterally symmetrical pattern characteristic of arthropods (instead, scattered in an apparently random fashion along the length of the nerve cord)
7. With slime papillae, possibly from modified nephridia (innervated by ventral nerve cords)
8. Embryonic coelomic cavities fused with spaces of primary body cavity (blastocoel); adult body thus a mixocoel/hemocoel; with unique subcutaneous vascular channels (hemal channels)
9. Body wall with sheetlike muscle layer
10. Gas exchange by tracheae and spiracles (probably not homologous with arthropod trachea)
11. Gonochoristic

CLASSIFICATION OF ONYCHOPHORA

FAMILY PERIPATIDAE 19 to 43 leg pairs, genital opening between the penultimate pair of legs; with a diastema on the inner blades of the jaws. Tropical distribution, 75 species in 10 genera: *Eoperipatus* and *Typhloperipatus* (Southeast Asia), *Mesoperipatus* (West Africa), and a series of poorly characterized genera from the Neotropics, e.g., *Epiperipatus*, *Heteroperipatus*, *Macroperipatus*, *Oroperipatus*, *Peripatus*, *Plicatoperipatus*.

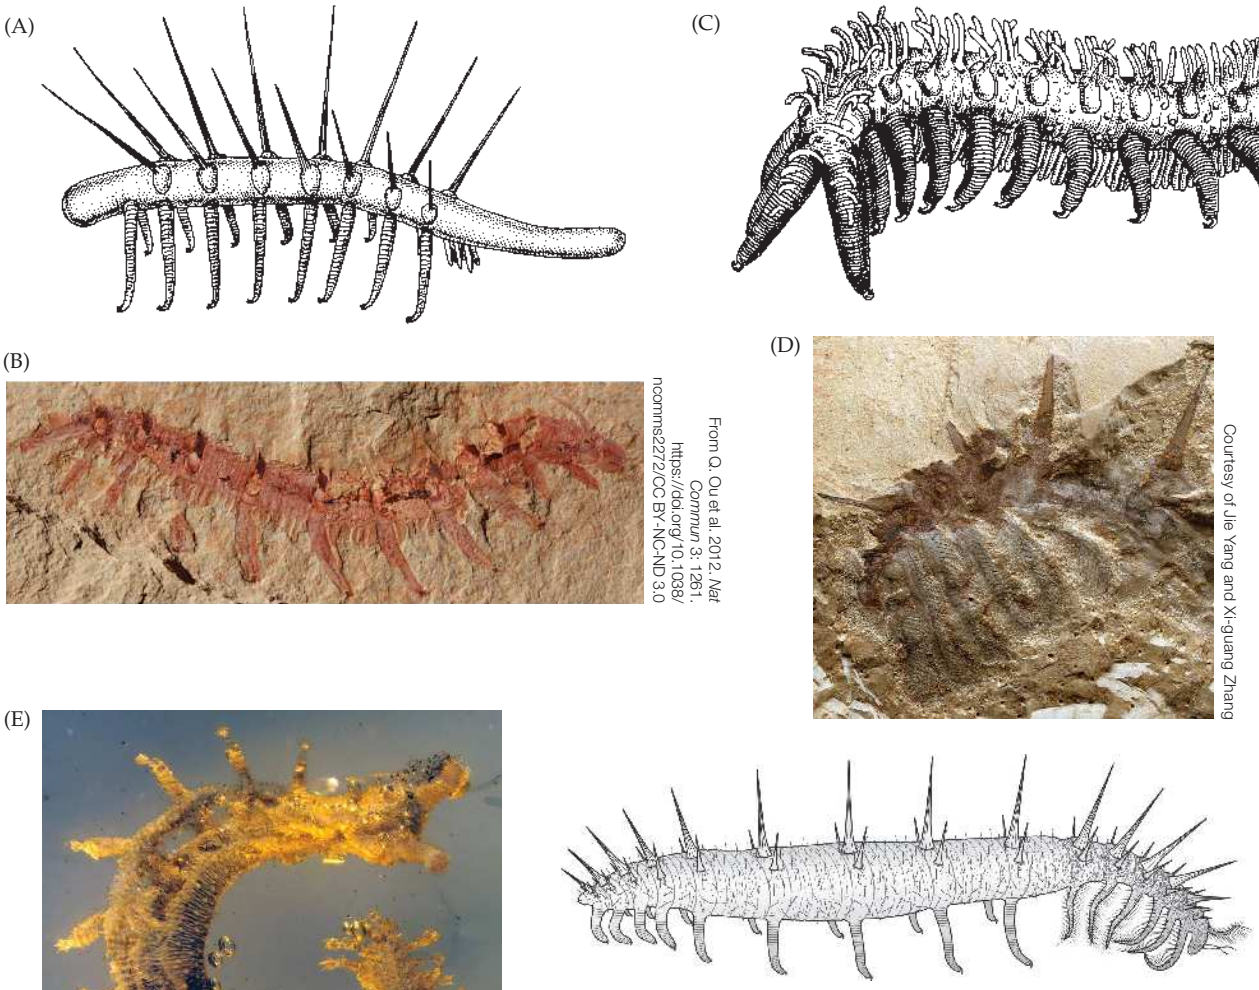

FIGURE 20.13 Reconstructions of Cambrian marine lobopodians and a fossil crown group onychophoran. (A) The enigmatic *Hallucigenia sparsa*, with two rows of long dorsal spines. (B) *Onychodictyon ferox* from the lower Cambrian Chengjiang deposits of China, with dorsal spines and papillae. (C) *Aysheaia pedunculata*, from middle Cambrian Burgess Shale deposits. (D, photo and drawing) In 2015 the remarkable lobopodian fossil *Collinsium ciliosum* was described from the Cambrian Xiaoshiba deposit in southern China (not far from the famous Chengjiang deposit). Like *Hallucigenia*, its dorsum is covered with long hard spines, but with many more than seen in *Hallucigenia*—up to 72 in fact. It also differs from *Hallucigenia* in having distinctly different anterior and posterior legs; the front legs being brushlike and probably functioning as feeding appendages, the rear legs being clawed and likely adapted for clinging to a sponge or cnidarian or other substratum. Being one of the earliest animals to develop armor, and reaching lengths of nearly 10 cm, this species would have been a striking and formidable Cambrian marine creature. It is further evidence that the ancestors to modern Onychophora were far more morphologically and ecologically diverse than today's velvet worms. A reconstruction of *C. ciliosum* is shown below the photograph of the actual fossil. (E) *Cretoperipatus burmiticus*, in amber, from the Cretaceous of Myanmar. (A,C after L. Ramsköld and X.-G. Hou. 1991. *Nature* 351: 225–228. https://www.nature.com/articles/351225a0)

FAMILY PERIPATOPSIDAE 13 to 29 leg pairs, genital opening between the last pair of legs; without a diastema on the inner blades of the jaws. Temperate to tropical in the Southern Hemisphere, 125 species in 39 genera, e.g., *Austroperipatus*, *Cephalofovea*, *Euperipatoides*, *Kumbadjena*, *Nodocapitus*, *Occiperipatoides*, *Ooperipatellus*, *Ooperipatus*, *Opisthopatus*, *Paraperipatus*, *Peripatoides*, *Peripatopsis*, *Phallocephale*, *Planipapillus*, *Tasmanipatus*.

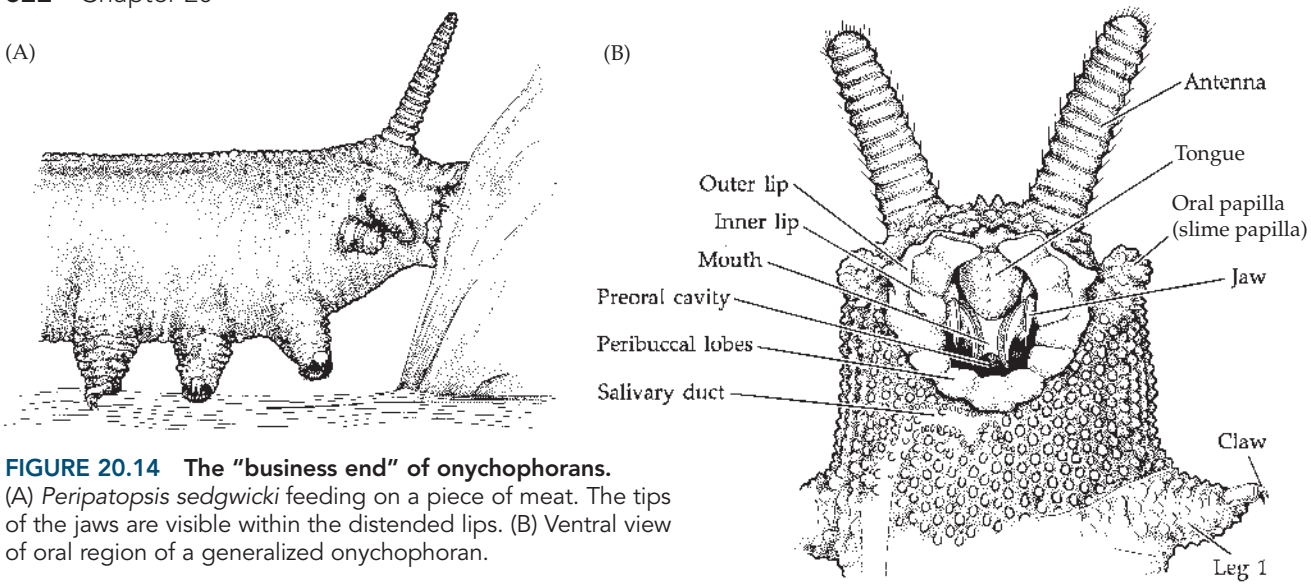

FIGURE 20.14 The "business end" of onychophorans. (A) *Peripatopsis sedgwicki* feeding on a piece of meat. The tips of the jaws are visible within the distended lips. (B) Ventral view of oral region of a generalized onychophoran.

The Onychophoran Body Plan

Modern onychophorans loosely resemble caterpillars, ranging from 5 mm to 15 cm in adult length. Within a given species, males are smaller than females and normally have fewer legs. Little cephalization is externally visible, and body segmentation is homonomous, where all legs differ little. Three paired appendages are found on the head: one pair of fleshy annulated antennae, a single pair of jaws, and a pair of fleshy **oral papillae** ("**slime papillae**"), resembling a small leg, lying posterior to the mouth (Figure 20.14). Circular lips surround the jaws. Beady eyes are located at the base of the antennae in most species (Figure 20.15), but a few species are eyeless (Figure 20.12F). The anterior head appendages are followed by 13–43 pairs of simple **lobopodal (saclike) walking legs**. A series of **ventral and preventral organs** is common among onychophorans and serves as an attachment site for segmental limb depressor muscles. The origin of these structures can be traced back in the embryo as lateroventral segmental, ectodermal thickenings *not* associated with the development of the nervous system. Although the head appendages and lobopods are superficially annulated, they are not jointed or segmented, nor do they possess intrinsic musculature (i.e., all appendage muscles attach at one end to the body proper).

The homology of onychophoran head structures with those of arthropods has long been a matter of debate, but the issue now seems resolved, in part thanks to the use of DNA labeling, immunocytochemistry, and neuronal tracing techniques in developing embryos. The eyes and antennae are innervated by the protocerebrum, unlike in any living arthropod, where the protocerebrum innervates only the eyes. The jaws are homologous with the chelicerae of chelicerates, or to the (first) antennae of myriapods, crustaceans, and hexapods, and are innervated by the deutocerebrum. Although the slime papillae align with the pedipalps of chelicerates and the second antennae of crustaceans, they are innervated by the ventral nerve cords, and not by the tritocerebrum as in arthropods, as the brain of velvet worms seems to comprise only two pairs of ganglia.

Similarly, the paired ventral nerve cords are very different from those of tardigrades and arthropods, as there is no relationship between the arrangement of median or ring commissures and the position of the legs. In addition, the cell bodies of serotonergic neurons are not arranged in the segmentally repeated and bilaterally symmetrical pattern characteristic of arthropods. Rather, these neurons are scattered in an apparently random fashion along the length of the onychophoran nerve cord. In summary, the overall arrangement of nerve pathways in the onychophoran nerve cord differs markedly from the rope-ladder arrangement in arthropods. In fact, it is more similar to the arrangement of orthogonally crossing nerve pathways found in the nervous systems of various wormlike protostomes than to those of tardigrades or arthropods.

Externally, the unjointed, fleshy nature of the head appendages, the structure of the jaws, and the legs appear quite different from those of arthropods. The serially arranged, clawed lobopodal appendages of onychophorans (including certain enigmatic fossil forms) have no clear counterpart in the animal kingdom.

The body is covered by a thin chitinous cuticle (containing α-chitin, as in arthropods) that is molted, as is in all other ecdysozoans. However, unlike that of arthropods, the cuticle of onychophorans is soft, thin, flexible, very permeable, and not divided into articulating plates or sclerites, but instead annulated like that of priapulans, and exhibiting multiple plicae per segment. Beneath the cuticle is a thin epidermis, which overlies a connective tissue dermis and layers of circular, diagonal, and longitudinal muscles (Figure 20.16). The body surface of onychophorans is covered with wartlike papillae of multiple kinds, usually arranged in rings or bands around

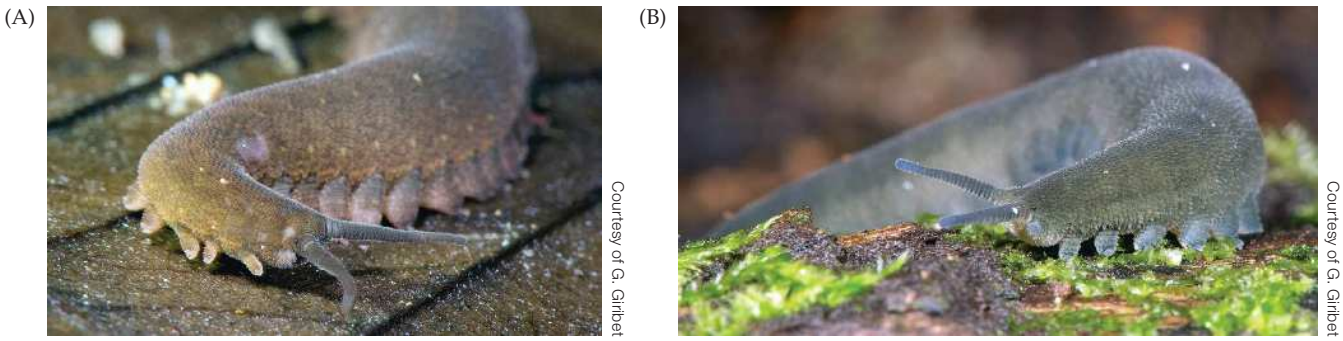

FIGURE 20.15 Although a few species of onychophorans are blind, most have small beady eyes that are homologous with the simple eyes of arthropods. (A) *Peripatus* sp. from Reserva Ducke, Manaus, Amazonia, Brazil. (B) *Peripatopsis moseleyi*, Karkloof Nature Reserve, Kwazulu-Natal, South Africa.

the trunk and appendages. These are classified as primary and secondary papillae, and they are of taxonomic importance. The papillae are covered with minute scales. Most onychophorans are distinctly colored blue, green, orange, or black, and the papillae, sometimes quite colorful, and scales give the body surface a velvety sheen—hence the common name "velvet worms."

The coelom formation in relation to that of arthropods has received considerable attention and is restricted almost entirely to the gonadal cavities in the adult onychophoran. In the Neotropical species *Epiperipatus biolleyi* the fate of the embryonic coelomic cavities has been studied in detail, providing evidence that embryonic coelomic cavities fuse with spaces of the primary body cavity (blastocoel). During embryogenesis, the somatic and splanchnic portions of the mesoderm separate, and the former coelomic linings are transformed into mesenchymatous tissue. The resulting body cavity therefore represents a mixture of primary and secondary (coelomic) body cavities, that is, the "mixocoel," but the homology of the segmental coeloms and nephridia in onychophorans and arthropods is not supported from the point of view of comparative anatomy. The hemocoel is also arthropod-like, being partitioned into sinuses, including a dorsal pericardial sinus.

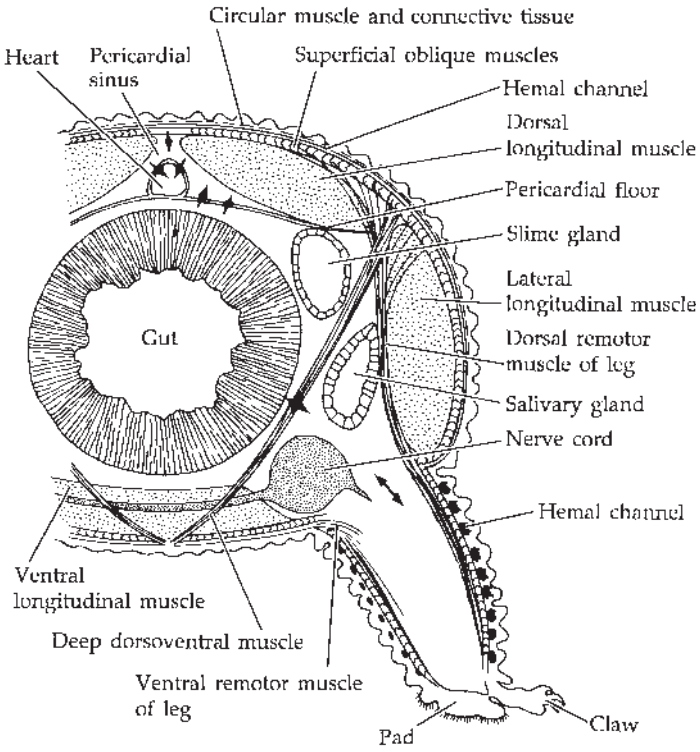

FIGURE 20.16 Body segment and leg of Peripatopsis (transverse section). Arrows indicate direction of blood flow.

Locomotion

The segmentally paired walking legs of onychophorans are conical, unjointed, ventrolateral lobes with a multispined terminal claw (sometimes called hooks). When the animal is standing or walking, each leg rests on three to six distal transverse pads (Figure 20.16). These lobopodal legs are filled with hemocoelic fluid and contain only extrinsic muscle insertions. Walking is accomplished by leg mechanics governed by a complex interplay of 15 muscles, including one promotor, one remotor, one levator, one retractor, two depressors, two rotators, one flexor, and two constrictors, as well as muscles for stabilization and by hydrostatic forces exerted via the hemocoel. Waves of contraction pass from anterior to posterior. When a segment is elongated, the legs are lifted from the ground and moved forward. When a segment contracts, a pulling force is exerted and the more anterior legs are held against the substratum. The overall effect is reminiscent of some types of annelid locomotion, wherein the parapodia are used mainly for purchase rather than as legs or paddles.

The body muscles are a combination of smooth and obliquely striated fibers and are arranged similarly to those of annelids. The thin cuticle, soft body, and hydrostatic body plan allow

onychophorans to crawl and force their way through narrow passages in their environment. As we saw in the annelids, the efficiency of a hydrostatic skeleton is enhanced by internal longitudinal communication of body fluids. The ancestors of the onychophorans apparently expanded the blood vascular system to achieve a hemocoelic hydrostatic skeleton.

Feeding and Digestion

Onychophorans occupy a niche similar to that of medium-sized centipedes. They are carnivores that prey on small invertebrates such as snails, worms, termites, and other insects, which they pursue into cracks and crevices. Special **slime glands**, thought to be modified nephridia, open at the ends of the oral papillae (Figure 20.18); through these openings an adhesive is discharged in two powerful disorganized jets, sometimes to a distance of 30 cm. The glue hardens quickly, entangling prey (or would-be predators) for subsequent leisurely dining.

The jaws are used to grasp and cut up prey. Paired salivary glands, also thought to be modified nephridia, open into a median dorsal groove on the jaws (Figure 20.14). Salivary secretions pass into the body of the prey and partly digest it; onychophorans then suck the semiliquid tissues into their mouth, after they ingest their own glue. The mouth opens into a chitin-lined foregut, composed of a pharynx and esophagus. A large, straight intestine is the principal site of digestion and absorption. The hindgut (rectum) usually loops forward over the intestine before passing posteriorly to the anus, which is located ventrally or terminally on the last body segment.

Circulation and Gas Exchange

The circulatory system of onychophorans is arthropod-like and linked to their hemocoelic body plan. A tubular heart is open at each end and bears a pair of lateral ostia in each segment. The heart lies within a pericardial sinus. Blood leaves the heart anteriorly and then flows posteriorly within the large hemocoel via body sinuses, eventually reentering the heart by way of the ostia. The blood is colorless, containing no oxygen-binding pigments. Onychophorans possess a unique system of subcutaneous vascular channels, called **hemal channels** (Figure 20.16 and 20.17C). These channels are situated beneath the transverse rings, or ridges, of the cuticle. A bulge in the layer of circular

muscle forms the outer wall of each channel, and the oblique muscle layer forms the inner wall. The hemal channels may be important in the functioning of the hydrostatic skeleton. Thus the superficial annulations of the onychophoran body are external manifestations of the subcutaneous hemal channels, as may be true of some Cambrian lobopodians.

Gas exchange is by tracheae that open to the outside through the many small spiracles located between the bands of body papillae. Each tracheal unit is small and supplies only the immediate tissue near its spiracle (Figure 20.17B). Anatomical data suggest that the tracheal system is not homologous with those of insects, arachnids, or terrestrial isopods but has been independently derived in each of these terrestrial groups, including in Onychophora.

Excretion and Osmoregulation

A pair of nephridia lies in each leg-bearing body segment, except the one possessing the genital opening (Figures 20.17A and 20.18). The nephridiopores are situated next to the base of each leg, except at the fourth and fifth legs, where the nephridia open through distal nephridiopores on the transverse pads of the legs

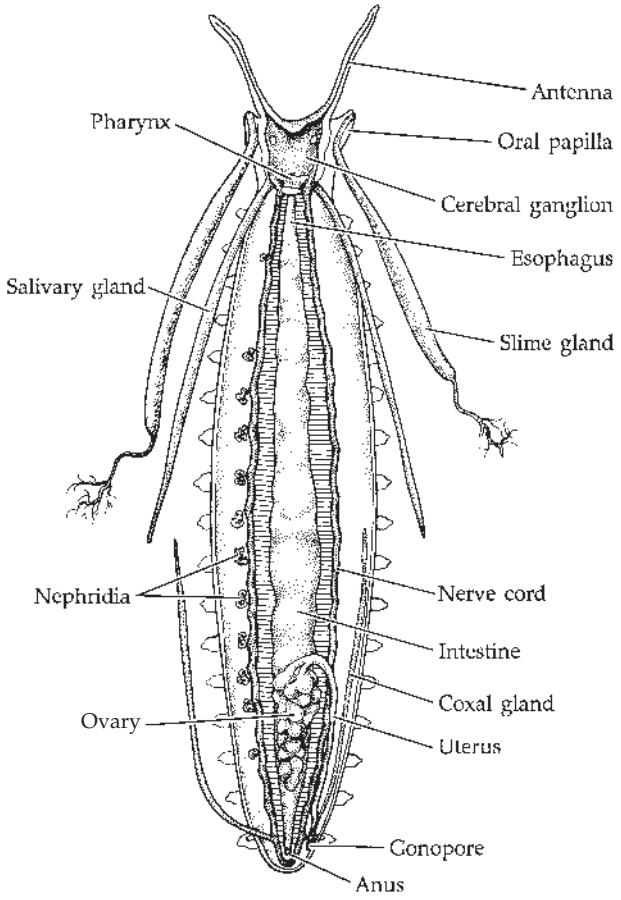

FIGURE 20.18 Internal anatomy of a generalized onychophoran.

themselves. The nephridial anlagen develops by reorganization of the lateral portion of the embryonic coelomic wall that initially gives rise to a ciliated canal. All other structural components, including the **sacculus**, merge after the nephridial anlagen has been separated from the remaining mesodermal tissue. The nephridial sacculus thus does not represent a persisting coelomic cavity, as previously thought, since it arises de novo during embryogenesis. There is no evidence for "nephridioblast" cells participating in the nephridiogenesis of Onychophora, which is in contrast to the general mode of nephridial formation in Annelida. Each set of sacculus + nephridioduct together is called a **segmental gland**. The nephridioduct, or tubule, enlarges to form a contractile bladder just before opening to the outside via the nephridiopore. The nature of the excretory wastes is not known. The anterior nephridia are thought to be modified as the salivary glands and slime glands, in addition to the nephridial anlagen in the antennal segment, and the posterior ones form the gonoducts in females.

The legs of some onychophorans, such as *Peripatus*, bear thin-walled eversible sacs or vesicles that open to the exterior near the nephridiopores by way of minute pores or slits. These vesicles may function in taking up moisture, as do the coxal glands of many myriapods, hexapods, and arachnids. They are everted by hemocoelic pressure and pulled back into the body by retractor muscles.

Nervous System, Sense Organs, and Behavior

The nervous system of onychophorans is ladderlike in structure but differs considerably from that of arthropods and tardigrades. A large bilobed cerebral ganglion ("brain") lies dorsal to the pharynx. A pair of ventral nerve cords, without segmental ganglia, is connected by nonsegmental ring commissures, which are also connected to multiple longitudinal nerve tracts. The protocerebrum innervates the eyes and antennae; the deutocerebrum innervates the jaws. The paired leg nerves are the only segmental structures in the onychophoran nerve cords, and the somata of serotonin-like immunoreactive neurons do not show any ordered arrangement but are instead scattered throughout the entire length of each nerve cord, showing neither a serially iterated nor a bilaterally symmetric pattern, in contrast to the strictly segmental arrangement of serotonergic neurons in arthropods (Figure 20.19). The general body surface, especially the larger papillae, is supplied with sensillae that might be homologous with those of tardigrades and arthropods.

Onychophorans are nocturnal animals and photophobic. With the exception of some cave-adapted species, there is a small dorsolateral eye at the base of each antenna. The eyes are of the direct rhabdomeric type, with a large chitinous lens and a relatively well-developed retinal layer (Figure 20.17D).

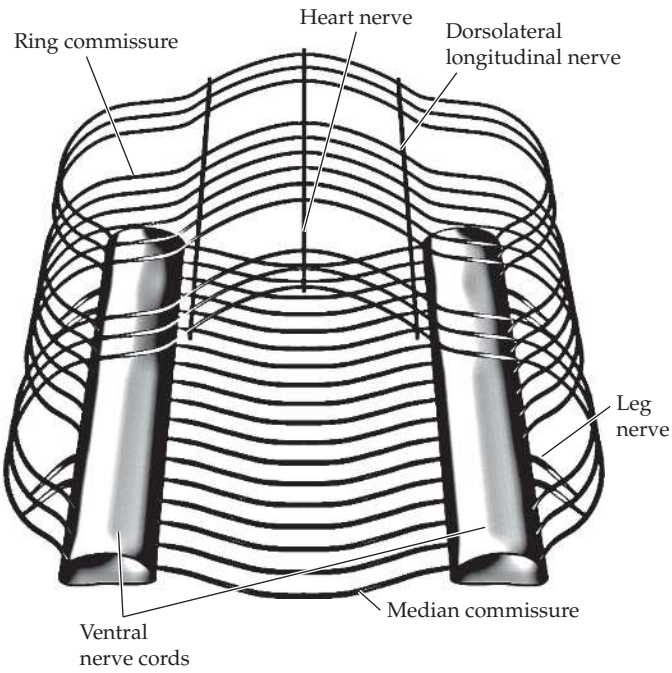

FIGURE 20.19 Schematic diagram of the arrangement of the main serotonin-like immunoreactive nerve tracts in the onychophoran trunk. Innervation of gut, various fiber networks, nephridial nerves, and ventral and lateral branches contributing to the subepidermal network are not shown.

The presence in onychophorans of only one optic neuropil and the development of the eye from an ectodermal groove correspond with the median ocelli rather than the compound eyes of arthropods. In addition, there are some parallels in innervation patterns between onychophoran eyes and the median ocelli of arthropods, since both are associated with the central (rather than lateral) part of the brain. These similarities have been interpreted to mean that there may be particular correspondences between the eyes of Onychophora, median ocelli of Chelicerata, and nauplius eyes of Malacostraca since in all these taxa there is a visual input to the central body.

Males of onychophorans have segmental **crural glands**, a type of exocrine gland that opens on the ventral surface at the base of the legs. These glands have been shown to secrete a pheromone that attracts conspecific females.

Reproduction and Development

With the exception of one known parthenogenetic population from Trinidad (often assigned to the mainland species *Epiperipatus imthurni*), all onychophorans are gonochoristic. Most females have a pair of largely fused ovaries in the posterior region of the body (Figure 20.18). Each ovary connects to a gonoduct (oviduct), and each gonoduct to a uterus. The uteri open through a posteroventral gonopore. Males are smaller than females and have a pair of elongate, separate testes. Paired sperm ducts join to form a single tube in which sperm are packaged into spermatophores up to 1 mm in length. The male gonopore is also located posteroventrally.

Copulation has been observed in a few onychophorans. In the South African genus *Peripatopsis* the male deposits spermatophores seemingly at random on the general body surface of the female (Figure 20.15B). The presence of the spermatophores stimulates special amebocytes in her blood to bring about a localized breakdown of the integument beneath the spermatophore. Sperm then pass from her body surface into her hemolymph, through which they eventually reach the ovaries, where fertilization takes place. In some onychophorans a portion of the uterus is expanded as a seminal receptacle, but sperm transfer in these species is not well understood. Insemination can also be vaginal or facultative between vaginal and dermal. Several Eastern Australian species present a diversity of male extragenital sexual structures in the form of organs on the dorsal surface of the head, which are highly elaborate in some species and may be involved in the mechanics of sperm transfer.

Embryological work on onychophorans has revealed some unusual features. For example, onychophorans may be oviparous, viviparous, or ovoviviparous. Females of oviparous species (e.g., *Ooperipatus*) have an ovipositor and produce large, oval, yolky eggs with chitinous shells. It is believed that this is the primitive onychophoran condition, even though living oviparous species are rare and deeply nested in the phylogeny of the group. The eggs of oviparous onychophorans contain so much yolk that early, superficial, intralecithal cleavage takes place, with the eventual formation of a germinal disc similar to that seen in many terrestrial arthropods. Most living onychophorans, however, are viviparous and have evolved a highly specialized mode of development associated with small, spherical, nonyolky eggs. Interestingly, most Old World viviparous species, although developing at the expense of maternal nutrients, lack a placenta, whereas most New World viviparous species have a placental attachment to the oviducal wall (Figure 20.20A). Placental development is viewed as the most advanced condition in onychophorans.

The yolky eggs of lecithotrophic species have a typical centrolecithal organization. Cleavage is by intralecithal nuclear divisions, similar to that seen in many groups of arthropods. Some of the nuclei migrate to the surface and form a small disc of blastomeres that eventually spreads to cover the embryo as a blastoderm, thus producing a periblastula. Simultaneously, the yolk mass divides into a number of anucleate "yolk spheres" (Figure 20.20B–D).

Nonyolky and yolk-poor eggs are initially spherical, but once within the oviduct, they swell to become ovate. As cleavage ensues, the cytoplasm breaks up into a number of spheres. The nucleate spheres are the blastomeres, and the anucleate ones are called

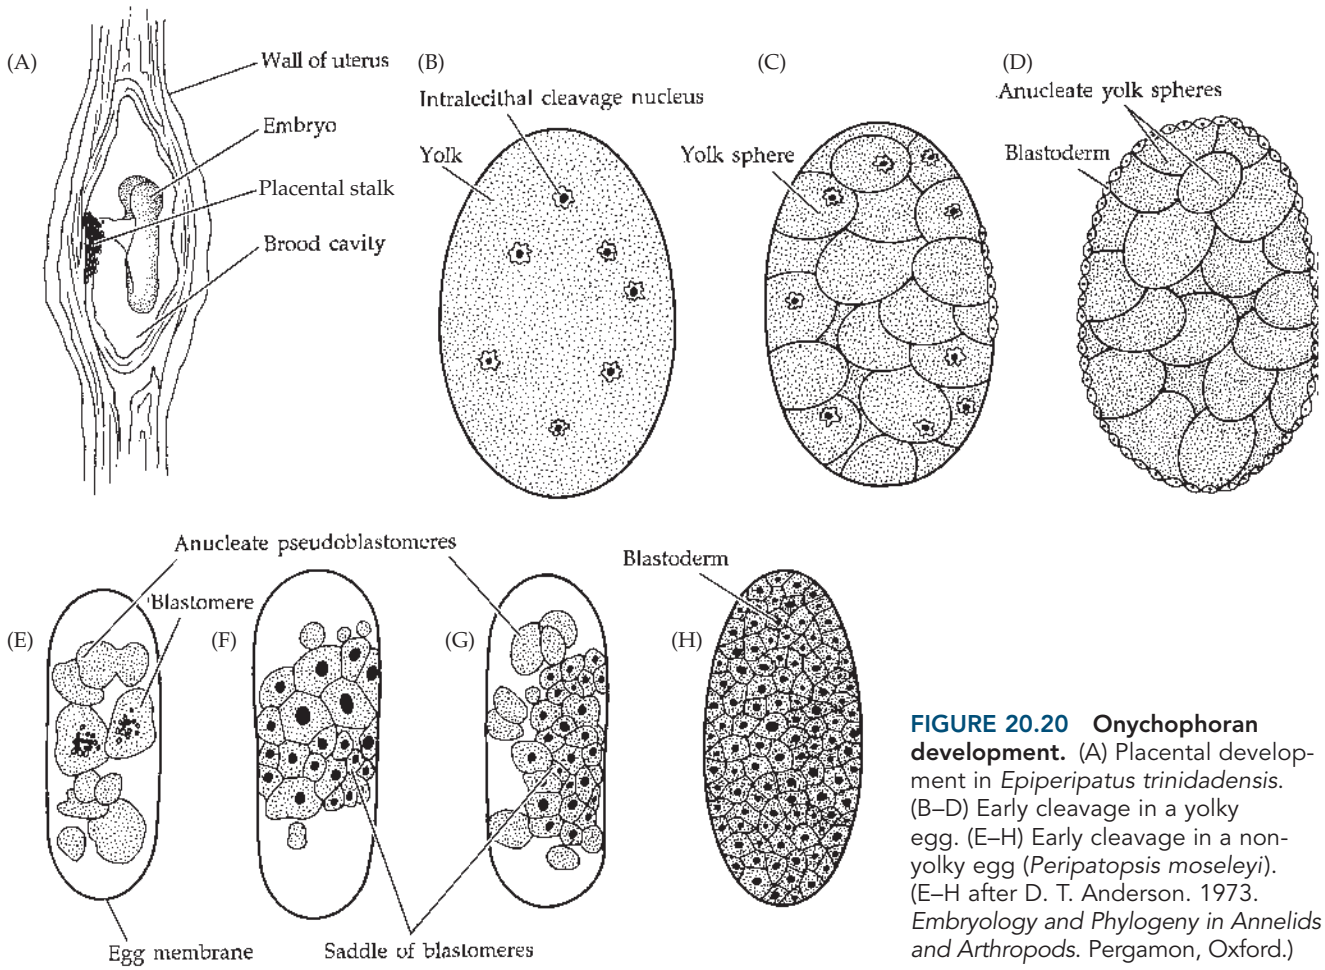

FIGURE 20.20 Onychophoran development. (A) Placental development in *Epiperipatus trinidadensis*. (B–D) Early cleavage in a yolky egg. (E–H) Early cleavage in a nonyolky egg (*Peripatopsis moseleyi*). (E–H after D. T. Anderson. 1973. *Embryology and Phylogeny in Annelids and Arthropods*. Pergamon, Oxford.)

pseudoblastomeres (Figure 20.20E–G). The blastomeres divide and form a saddle of cells on one side of the embryo (Figure 20.20G). The pseudoblastomeres disintegrate and are absorbed by the dividing blastomeres. The saddle expands to cover the embryo with a one-cell-thick blastoderm around a fluid-filled center.

Placental oviparous species have even smaller eggs than do nonplacental species, and the eggs do not swell after release from the ovary. Further, these eggs are not enclosed in membranes. Cleavage is total and equal, yielding a coeloblastula. The embryo then attaches to the oviducal wall and proliferates as a flat placental plate. As development proceeds, the embryo moves progressively down the oviduct and eventually attaches in the uterus. Sperm can remain motile in the seminal receptacle for up to 6 months. Gestation may be quite long, up to 15 months, and the oviduct/uterus often contains a series of developing embryos of different ages. Although gastrulation is still not fully understood in onychophorans, in several species a slitlike ventral furrow has been seen to form on the anterior–posterior axis. It was long thought that this slit underwent a median closure; the remaining ends giving rise to the mouth and anus. However, gene expression studies in *Euperipatoides kanangrensis* suggest that this groove does not correspond to the blastopore, even though both the mouth and anus do develop from it. Rather, a posterior pit on the developing embryo appears to be the blastopore; the posterior of the ventral groove at some point fuses with it to form the definitive anus. This has been called a case of "concealed" deuterostomy.

Development after the formation of the blastula is remarkably similar among the few species of onychophorans that have been studied. Gastrulation in onychophorans involves very little actual cell migration. Cells of the presumptive areas undergo immediate organogenesis by direct proliferation. This process involves the proliferation of small cells into the interior of the embryo through and around the yolk mass or fluid-filled center and the production by surface cells of the germinal centers of limb buds and other external structures. All onychophorans have direct development. In all species that have been studied, the full complement of segments and adult organ systems is attained before they hatch.

Onychophorans are also unusual in that neither a presegmental acron nor a postsegmental pygidium or telson can be distinguished. In onychophorans, even though growth is teloblastic, the growth zone from which the

trunk segments arise appears to be postanal. When the last mesoderm has been formed, the growth-zone ectoderm apparently develops directly into the anal somite with no postsegmental ectoderm remaining. Onychophorans thus have the last pair of legs in subterminal position, as opposed to tardigrades, with the fourth pair of legs being terminal—a character that seems to differentiate them from the Cambrian lobopodians.

Systematics and Biogeography

The phylogenetic relationships of onychophorans have received recent attention, when the use of DNA sequence data has been generalized and used in many evolutionary studies at multiple hierarchical levels, illustrating in several cases the existence of cryptic species. DNA markers have shown strong evidence for the division of Onychophora into Peripatidae and Peripatopsidae, with both families diverging around the Carboniferous–Permian Periods, before the breakup of Pangaea. Peripatidae, with their tropical distribution, have a species-poor lineage in Southeast Asia, a monotypic genus in western Africa, and most of their diversity in the Neotropics, including many Caribbean islands (this Neotropical clade is called Neopatida). Peripatidae has been diversifying since around the Triassic Period. Peripatopsidae, restricted to the former circum-Antarctic Gondwanan landmasses, divides into a South African/Chilean clade (West Gondwana) and into an Australian/New Guinea/New Zealand clade (East Gondwana), diversifying initially around the Jurassic Period, long after its divergence from Peripatidae.

An Introduction to the Phylum Arthropoda

With over a million described living species, and 3–100 times that many estimated still to be described, the phylum Arthropoda is unprecedented in its diversity. There are four clearly distinguished groups of extant arthropods, which are usually recognized as subphyla: Crustacea (crabs, shrimps, etc.), Hexapoda (insects and their kin), Myriapoda (centipedes, millipedes, etc.), and Chelicerata (horseshoe crabs, arachnids, and pycnogonids). However, we now know that the hexapods arose from among the Crustacea, leaving the latter as a paraphyletic taxon (the two groups together comprise the clade Pancrustacea). Among the several lineages of fossil arthropods that have been identified are the Trilobita (trilobites and their kin), which have left a fossil record from the early Cambrian to the end of the Permian. After 150 years of debate over the evolutionary relationships of arthropods, molecular systematics has finally allowed us to largely resolve the phylogeny among these groups (see Figure 20.39). We now know with a high degree of certainty, based on genomic and transcriptomic analyses, that extant arthropods split into two clades, chelicerates and mandibulates, the latter comprising the myriapods and the pancrustaceans (Crustacea + Hexapoda). The basic features of the arthropod body plan are listed in Box 20C. Some of these features are unique to the phylum Arthropoda and thus represent defining synapomorphies; others also occur in closely related taxa, such as the onychophorans and tardigrades.

BOX 20C Characteristics of the Phylum Arthropoda

1. Body segmented, both internally and externally; segments arising by teloblastic growth (showing *engrailed* gene expression)
2. Minimally, body divided into head (cephalon) and trunk; commonly with further regional body specialization or tagmosis; typically with a head shield or carapace covering fused head segments
3. Head with labrum (or clypeolabrum) (showing *Distal-less* gene expression) and with presegmental acron
4. Cuticle forming well-developed exoskeleton, generally with thick sclerotized plates (sclerites) consisting of dorsal tergites, lateral pleurites, and ventral sternites; cuticle of exoskeleton consists of chitin and protein (including resilin), with or without varying degrees of calcification; without collagen
5. Each true body segment primitively with a pair of segmented (jointed), ventrally attached appendages, showing a great range of specialization among the various taxa; appendages composed of a proximal protopod and a distal telopod (both multiarticulate); some protopodal articles bearing medial endites or lateral exites
6. Cephalon with a pair of lateral faceted (compound) eyes and one to several simple median ocelli; compound eyes, ocelli, or both lost in several groups
7. Coelom reduced to portions of the reproductive and excretory systems; main body cavity an open hemocoel (= mixocoel); circulatory system largely open; dorsal heart a muscular pump with lateral ostia for blood return
8. Gut complex and highly regionalized, with well-developed stomodeum and proctodeum; digestive material (and often also the feces) encapsulated in a chitinous peritrophic membrane
9. Nervous system with dorsal (supraenteric) ganglia (= cerebral ganglia), circumenteric (circumesophageal) connectives, and paired, ganglionated ventral nerve cords, the latter often fused to some extent
10. Growth by ecdysone-mediated molting (ecdysis); with cephalic ecdysial glands
11. Muscles metamerically arranged, striated, and grouped in isolated, intersegmental bands; dorsal and ventral longitudinal muscles present; intersegmental tendon system present; without circular somatic musculature
12. Most gonochoristic, with direct, indirect, or mixed development; some species parthenogenetic

Taxonomic History and Classification

The great Swedish naturalist Carl Linnaeus, in the first half of the eighteenth century, recognized six major groups of animals (Vermes, Insecta, Pisces, Amphibia, Aves, Mammalia), placing all of the invertebrates except the insects in Vermes. In the early nineteenth century, such famous zoologists as Lamarck and Cuvier presented substantial reorganizations of Linnaeus's earlier scheme, and it was during this period that the various arthropod taxa began to emerge. Lamarck recognized four basic arthropod groups: Cirripedia (barnacles), Crustacea, Arachnida, and Insecta. He placed the ostracods with the brachiopods and, of course, did not realize the crustacean nature of the barnacles. Cuvier joined the arthropods and annelids in his Articulata (referring to the segmented nature of these animals), and Lankester also classified them together with rotifers in his Appendiculata. The great zoologists Hatschek, Haeckel, Beklemishev, Snodgrass, Tiegs, Sharov, and Remane all viewed the Articulata as a discrete phylum, including in it at various times the groups Echiura, Sipuncula, Onychophora, Tardigrada, and Pentastomida. It was Leuckart who, in 1848, separated out the arthropods as the distinct phylum we recognize today; Von Siebold coined the name Arthropoda in the same year, noting the jointed legs (Greek *arthro*, "jointed"; *pod*, "foot") as the group's principal distinguishing attribute, but he also included Tardigrada as mites. Haeckel published the first evolutionary tree of the arthropods in 1866. And, beginning in 1997 with the benchmark study by Anna Marie Aguinaldo and colleagues, molecular phylogenetics began to reveal that annelids and arthropods are not at all as closely related as long thought, the former now being placed in the clade Spiralia, with arthropods being in the clade Ecdysozoa. Brief diagnoses of the four living arthropod subphyla are provided below, and detailed treatments of these groups are presented in Chapters 21, 22, 23, and 24.

It is important to offer a word of caution about the use of terminology among the various groups of arthropods. Because the lineage of Arthropoda is so vast and diverse, specialists usually concentrate on only one or a few subgroups. Thus, over time, slightly different terminologies have evolved. Students sometimes feel overwhelmed by arthropod terminology—for example, the hindmost region of the body may be called an abdomen or pleon (as in insects and crustaceans), an opisthosoma (in chelicerates), or a pygidium (in trilobites). But there is a greater, though more subtle danger to this mixed terminology. Different terms for similar parts or regions in different taxa do not necessarily imply nonhomology; conversely, the same term applied to similar parts of different arthropods does not always imply homology. To deal with these problems in this text, we have made an effort to achieve consistency in terminology as much as possible, to simplify word use and spelling, and to indicate homologies (and nonhomologies) where known.

Of all fossil invertebrates, trilobites are perhaps the most symbolic of ancient and exotic faunas. The subphylum Trilobita, or Trilobitomorpha (Latin *trilobito*, "three-lobed"; Greek *morph*, "form"), includes over 20,000 species of arthropods known only from the fossil record (see Figures 20.37 and 20.38. They were restricted to (and characteristic of) Paleozoic seas. Trilobites dominate the fossil record of the Cambrian and Ordovician Periods (541 to 443.8 Ma) and continued to be important components of marine communities until the Permo-Triassic mass extinction that marked the end of the Paleozoic Era. Because of their hard molting exoskeletons (made of chitin and calcium carbonate, as in modern crustaceans and horseshoe crabs), great abundances, and broad distributions, the trilobites left a rich fossil record, and more is known about them than about most other extinct taxa. Most of the present world's land areas were submerged during various parts of the Paleozoic, so trilobite fossils are found in marine sedimentary rocks worldwide.

The trilobite body was divided into three tagmata: cephalon, thorax, and pygidium (abdomen). The segments of the cephalon and pygidium were fused, while those of the thorax were free and articulating. The body was demarcated by two longitudinal grooves into a median and two lateral lobes ("tri-lobite"). The cephalon had one pair of preoral antennae; all other appendages were postoral and more or less similar to one another, with a robust locomotory telopod to which was attached at the base a long filamentous branch (thought to be a protopodal exite). Most seem to have had compound eyes (an apomorphy of Arthropoda), including both appositional and nonappositional eyes.

Although trilobites were exclusively marine, they exploited a variety of habitats and lifestyles. Most were benthic, either crawling about over the bottom or plowing through the top layer of sediment. Most benthic species were a few centimeters long, although some giants reached lengths of 60–70 cm. A few trilobites appear to have been planktonic; they were mostly small forms, less than 1 cm long and equipped with spines that presumably aided in flotation. Most of the benthic trilobites were probably scavengers or direct deposit feeders, although some species may have been predators that lay partially burrowed in soft sediments and grabbed passing prey. Some workers speculate that at least some trilobites may have suspension fed by using the filamentous parts of their appendages. One group of Olenidae may have had symbiotic relationships with sulfur-oxidizing bacteria; these late Cambrian–Lower Ordovician trilobites had vestigial mouthparts and large "gill filaments" (epipods) that might have been sites for bacterial cultivation.

In addition to trilobites, the Cambrian seas saw a great diversity of stem arthropods and stem panarthropods that had undergone arthrodization (sclerotization and jointing of the exoskeleton) but not complete arthropodization, as well as many other groups

of arthropods that cannot be assigned to any of the extant groups and that are thus considered stem chelicerates, stem mandibulates, stem myriapods, or stem crustaceans.

SYNOPSES OF THE LIVING ARTHROPOD SUBPHYLA

SUBPHYLUM CRUSTACEA Crabs, lobsters, shrimps, beach hoppers, pillbugs, etc. About 72,000 described living species. Body usually divided into 3 tagmata: head (cephalon), thorax, and abdomen (the notable exception being the class Remipedia, which has only head + trunk); appendages uniramous or biramous; 5 pairs of cephalic appendages—the preoral first antennae (antennules) and 4 pairs of postoral appendages: second antennae (which migrate to a "preoral position" in adults), mandibles, first maxillae (maxillules), and second maxillae; with compound eyes usually having tetrapartite crystalline cones; gonopores located posteriorly on thorax or anteriorly on abdomen. Crustacea is now known to be a paraphyletic group, because the Hexapoda arose from within it (see Chapter 21).

SUBPHYLUM HEXAPODA Insects and their kin; monophyletic. Close to a million described living species. Body divided into 3 tagmata: head (cephalon), thorax, and abdomen; with 4 pairs of cephalic appendages: antennae, mandibles, maxillae, and labium (fused second maxillae); 3-segmented thorax with uniramous legs and often 2 pairs of wings; with compound eyes having tetrapartite crystalline cones; gas exchange by spiracles and tracheae; with ectodermally derived (proctodeal) Malpighian tubules; gonopores open on abdominal segment 7, 8, or 9 (see Chapter 22).

SUBPHYLUM MYRIAPODA Millipedes, centipedes, etc.; monophyletic. Over 16,000 described living species. Body divided into 2 tagmata: head (cephalon) and long, homonomous, many-segmented trunk; with 3–4 pairs of cephalic appendages (antennae, mandibles, first maxillae, and sometimes second maxillae); first maxillae free or coalesced; second maxillae often absent or partly (or wholly) fused; all appendages uniramous; living species mostly lack compound eyes (but they are present in Scutigeromorpha); with ectodermally derived (proctodeal) Malpighian tubules; gonopores on third or last trunk somite (see Chapter 23).

SUBPHYLUM CHELICERATA Horseshoe crabs, scorpions, spiders, mites, daddy longlegs, sea spiders, etc.; monophyletic. Over 113,000 described species. Body divided into two tagmata, anterior prosoma (cephalothorax) and posterior opisthosoma (abdomen); opisthosoma with up to 12 segments (plus telson); prosoma of 6 somites, each with a pair of uniramous appendages (chelicerae, pedipalps, 4 pairs of legs); gas exchange by gill books, book lungs, tracheae, or cuticular; excretion by coxal glands and/or endodermally derived (midgut) Malpighian tubules; with simple median eyes and lateral compound eyes (see Chapter 24).

The Arthropod Body Plan and Arthropodization

If we are to grasp the "essence of arthropod," we must first understand the effects of one of the major synapomorphies of this phylum—the hard, jointed exoskeleton. Just imagine living your life encased in a rigid exoskeleton, a permanent suit of armor, if you will. What kinds of structural and functional problems would have to be solved in order for such an animal to survive? The approach arthropods evolved to live in their hard casing comprises a suite of adaptations collectively known as arthropodization. Arthropodization has some of its roots in the Onychophora and Tardigrada but came to full fruition in the phylum Arthropoda itself.

Being encased in an exoskeleton resulted in some obvious constraints on growth and locomotion. The fundamental problem of locomotion was solved by the evolution of body and appendage joints and highly regionalized muscles. Flexibility was provided by thin intersegmental areas (joints) in the otherwise rigid exoskeleton, imbued with a unique and highly elastic protein called **resilin**. As the muscles became concentrated into intersegmental bands associated with the individual body segments and appendage joints (intrinsic appendage muscles), the circular muscles were lost almost entirely.

With the loss of peristaltic capabilities resulting from body rigidity, and the loss of circular muscles, the coelom became nearly useless as a hydrostatic skeleton. The ancestral body coelom was lost, and an open circulatory system evolved—the body cavity became a **hemocoel**, or blood chamber, in which the internal organs could be bathed directly in body fluids.[1] But the large bodies of these animals still required some way of moving the blood around through the hemocoel, hence a highly muscularized dorsal vessel was developed as a pumping structure—a heart. The excretory organs became closed internally, thereby preventing the blood from being drained from the body. Surface sense organs (the "arthropod setae") differentiated, becoming numerous and specialized and acquiring various devices for transmitting sensory impulses to the nervous system in spite of the hard exoskeleton. Gas exchange structures evolved in various ways that overcame the barrier of the exoskeleton.

For these animals, now encased in a rigid outer covering, growth was no longer a simple process of gradual increase in body size. Thus the complex

[1] The hemocoel is not a true coelom, either evolutionarily or ontogenetically, but it may be viewed as a persistent blastocoelic remnant. Thus, one might at first reason that the arthropods technically are blastocoelomates. However, the absence of a large body coelom in arthropods is probably a secondary condition resulting from a loss/reduction of the ancestral coelomic body cavity during the evolution of the arthropod body plan, not a primary condition like that seen in the true blastocoelomates, most of which probably never have had a true coelom in their ancestry. A similar secondary loss of the coelom has occurred, in a different way, in the molluscs (see Chapter 13).

for more ebook/ testbank/ solution manuals Requests: email me 9601267340@qq.com

process of **ecdysis**, a specific hormone-mediated form of molting or cuticular shedding, was "perfected." As we have already seen, some form of ecdysis occurs in all eight phyla belonging to the clade Ecdysozoa. In arthropods, it is also through this process of ecdysis (molting) that the exoskeleton is periodically shed to allow for an increase in real body size. If we add to this suite of events the notion of arthropods invading terrestrial and freshwater environments, the evolutionary challenges become compounded by osmotic and ionic stresses, the necessity for aerial gas exchange, and the need for structural support and effective reproductive strategies.

While the origin of the exoskeleton demanded a host of coincidental changes to overcome the constraints it placed on arthropods, it clearly endowed these animals with great selective advantages, as evinced by their enormous success. One of the key advantages is the protection it provides. Arthropods are armored not only against predation and physical injury, but also against physiological stress. In many cases the cuticle is an effective barrier against osmotic and ionic gradients, and as such it is a major means of homeostatic control. It also provides the strength needed for segmental muscle attachment and for predation on other shelled invertebrates.

If we start with a generalized, rather homonomous arthropod prototype with a fairly high number of segments, and with paired appendages on each of those segments, we can set the stage for arthropod diversification. The diversity seen today has resulted largely from the differential specialization of various segments, regions, and appendages. The arthropod body has itself undergone various forms of regional specialization, or **tagmosis**, to produce segment groups specialized for different functions. These specialized body regions (e.g., the head, thorax, and abdomen of insects) are called **tagmata**. Tagmosis is mediated by Hox genes and the other developmental genes they influence. Our emerging understanding of Hox genes tells us that the most fundamental aspects of animal design arise from spatially restricted expression of these "master developmental genes." However, tagmosis varies among the arthropod groups (see the Synopsis of the Living Arthropod Subphyla section). The genetic and evolutionary plasticity of regional specialization, like limb variation, has been of paramount importance in establishing the diversity of the arthropods and their dominant position in the animal world.

One of the best examples of arthropod tagmosis is revealed by the expression pattern of the segment polarity gene *engrailed* (*en*) in the head, or cephalon, of Crustacea, Hexapoda, and Myriapoda, three arthropod subphyla comprising the clade known as Mandibulata. In each of these subphyla, the same six head regions emerge during embryogenesis. The most anterior region is usually called the **acron**, and it is often regarded as presegmental. The acron is also known as the protocerebral, or ocular segment because it contains the protocerebrum and eyes; it lacks appendages (Table 20.2). Next come the first and second antennal segments, the mandibular segment, and the first and second maxillary segments.

While segmentation in the various arthropod lineages likely shares a common developmental origin, the way it is described and interpreted can differ between

TABLE 20.2 Homologies of Arthropod (and Onychophoran) Anterior/Head Appendages[a]

Segment	Onychophora	Pycnogonida	Chelicerata	Myriapoda	Crustacea	Hexapoda
1 Protocerebral segment, or ocular segment	Antennae	–	–	–	–	–
2 Deutocerebral segment	Jaws	Chelifores	Chelicerae	Antennae	First antennae (= antennules)	Antennae
3 Tritocerebral segment)	Slime papillae (Note: Onychophorans may not have a tritocerebrum)	Palps	Pedipalps	–	Second antennae	–
4	Leg pair	Leg pair	Leg pair	Mandibles	Mandibles	Mandibles
5	Leg pair	Leg pair	Leg pair	First maxillae	First maxillae (= maxillules)	Maxillae
6	Leg pair	Leg pair	Leg pair	Second maxillae (or without appendages)	Second maxillae	Labium (= second maxillae)

[a]Gene expression studies have revealed the likelihood that the anterior-most appendages (the "protocerebral appendages") have been lost in all modern arthropods. A labrum (or "upper lip") occurs in all arthropod subphyla and also in Onychophora; its function is thought to be to prevent food particles from escaping ingestion. The evolutionary origin of the labrum has long been a mystery, and most workers have not regarded it as a true appendage of the head. However, recent gene expression studies suggest it might represent the remnant of a pair of ancient fused appendages. In insects and spiders, the labrum has been shown to arise from two primordia that fuse during embryogeny, controlled by the genes *decapentaplegic* (*dpp*) and *wingless* (*wg*), the same gene expressions as seen in the buds of regular appendages in arthropods.

groups and the nature of each fundamental segment is not always obvious. In centipedes, for instance, the composition of the trunk is usually reported in terms of the number of leg bearing segments, excluding one anterior segment that bears a pair of maxillipeds, and a posterior ano-genital region of uncertain segmental composition (possibly 2–3 segments plus the telson). In notostracan crustaceans, uncertainty about segment identity led to a recommendation that the term "segment" be replaced with "ring" for the units of the dorsal segmental series (and "leg pair" for the ventral ones).

In a similar vein, an evolutionary-developmental understanding of the head of panarthropods has been one of the greatest challenges to biologists, and we have only recently begun to understand head homologies across major lineages. One of the biggest challenges is the nature of the anteriormost "segment" in Arthropoda, or what has traditionally been called the acron. As we have noted, this anterior piece has no appendages in extant arthropods but houses the protocerebrum and the eyes—hence it might better be called the protocerebral segment or ocular segment. "Acron" is a term borrowed from annelid development when the two phyla were thought to be very closely related (i.e., the Articulata hypothesis), as the larval episphere in annelids is of pre-segmental origin and gives rise to the adult prostomium. As in annelids, the arthropod acron (and telson/pygidium) have been considered not to be "true" segments—the acron being viewed as presegmental and the telson as postsegmental. However, the demise of the Articulata hypothesis, and the realization that arthropods are ecdysozoans (and annelids are spiralians), undermined the concept of acron (and telson) homology between the two phyla. Further, unlike the arthropod acron/ocular segment, the acron in annelids (usually called the prostomium) commonly bears both eyes and antennae, as well as a variety of palps, tentacles, and sense organs. Within the Panarthropoda (Onychophora, Tardigrada, Chelicerata, Mandibulata), however, the acron/ocular segment appears homologous. In Onychophora, the protocerebrum also innervates a pair of antennae on this first segment, as also seems to be the case of several Cambrian taxa with "great appendages," such as *Anomalocaris*.

As we discuss the various aspects of the arthropod body plan here and in subsequent chapters, do not lose sight of the "whole animal" and the "essence of arthropod" described in this section.

The Body Wall

A cross section through a body segment of an arthropod reveals a good deal about its overall architecture (Figure 20.21). As noted, the body cavity is an open hemocoel, and the organs are bathed directly in the hemocoelic fluid, or blood (although discrete blood vessels do occur, notably in Crustacea and Chelicerata). The body wall is composed of a complex, layered **cuticle** secreted by the underlying epidermis (Figure 20.22). The epidermis, often referred to in arthropods as the **hypodermis**, is typically a simple cuboidal epithelium. In general, each body segment (or **somite**) is "boxed" by skeletal plates called **sclerites**. Each somite typically has a large dorsal and ventral sclerite, the **tergite** and **sternite** respectively.[2] The side regions, or **pleura**, are flexible unsclerotized areas in which are embedded various minute, "floating" sclerites, the origins of which are hotly debated. The legs (and wings) of arthropods articulate in this pleural region. Numerous secondary deviations from this plan exist, such as fusion or loss of adjacent sclerites. Muscle bands are attached at points where the inner surfaces of sclerites project inward as ridges or tubercles, called **apodemes**.

The structure of the multilayered arthropod cuticle is similar to that of other ecdysozoans, although the layers can have different names in different phyla. Figure 20.22

[2]The terms *tergum, sternum,* and *pleuron* are often used interchangeably with *tergite, sternite,* and *pleurite*. However, the term *tergum* refers more precisely to the dorsal, or tergal, region, and sternum to the ventral, or sternal, region. Thus we restrict the use of the terms *tergite* (pl., *tergites*) and *sternite* (pl., *sternites*) to the specific skeletal plates, or sclerites. In some cases, the sternum is formed of multiple fused sternites.

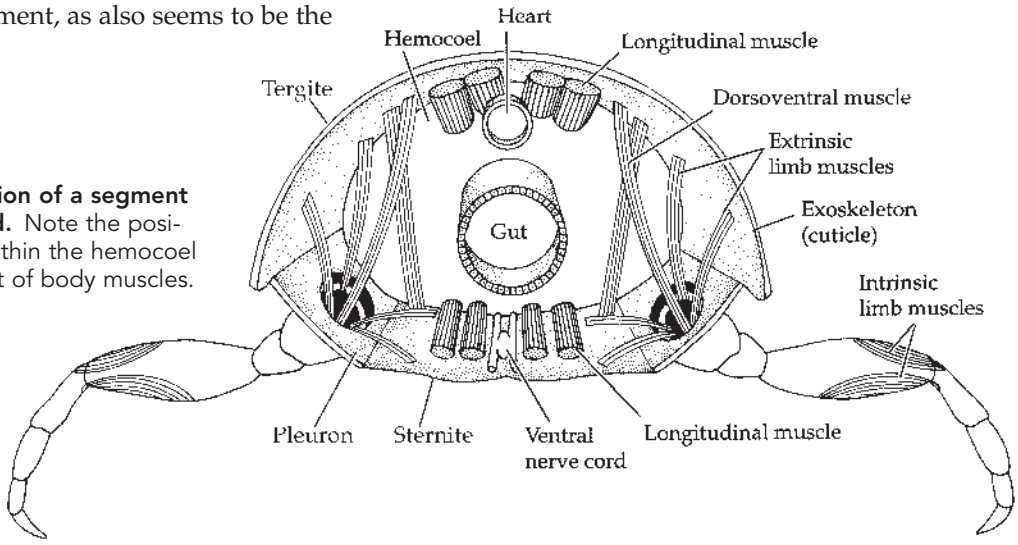

FIGURE 20.21 Cross section of a segment of a generalized arthropod. Note the positions of the major organs within the hemocoel and the typical arrangement of body muscles.

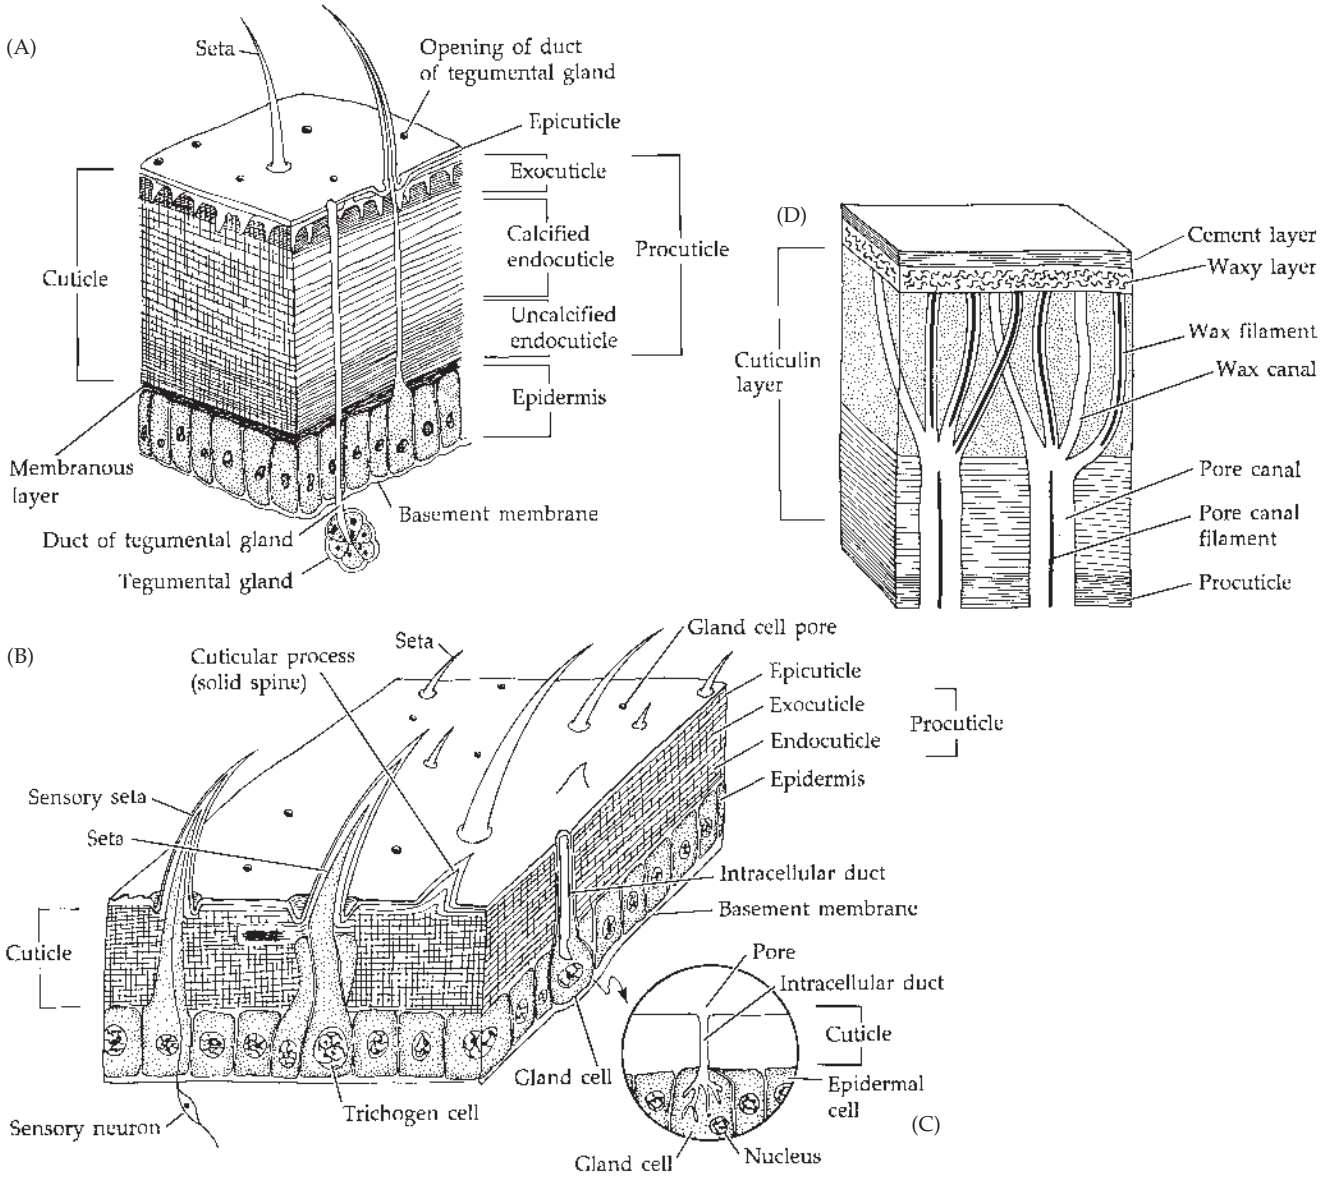

FIGURE 20.22 Arthropod cuticles. (A,B) The cuticle and epidermis of (A) a crustacean and (B) an insect. (C) A simple unicellular arthropod gland. (D) The epicuticle of an insect. (A after R. Dennell. 1960. In T. H. Waterman [Ed.], *The Physiology of Crustacea, Vol. 1*, pp. 449–472. Academic Press, New York.)

illustrates the cuticles of an insect and a marine crustacean. The outermost layer is the **epicuticle**, which is itself multilayered (Figure 20.22D). The external surface of the epicuticle is a protective lipoprotein layer—sometimes called the cement layer. Beneath this is a waxy layer that is especially well developed in terrestrial arachnids and insects. The waxes in this layer, which are long-chain hydrocarbons and the esters of fatty acids and alcohols, provide an effective barrier to water loss and, coupled with the outer lipoprotein layer, protection against bacterial invasion. These outermost two layers of the epicuticle largely isolate the arthropod's internal milieu from the external environment. No doubt, the development of the epicuticle was critical to the invasion of land and fresh water by various arthropod lineages. The innermost layer of the epicuticle is a **cuticulin layer**, which consists primarily of proteins and is particularly well developed in insects. The cuticulin layer usually has two components: a thin but dense outer layer and a thicker, somewhat less dense inner layer. The cuticulin layer is involved in the hardening of the exoskeleton and contains canals through which waxes reach the waxy layer.

Beneath the epicuticle is the relatively thick **procuticle**, which may be subdivided into an outer **exocuticle** and an inner **endocuticle** (Figure 20.22A,B).[3] The procuticle consists primarily of layers of protein and chitin (but no collagen). It is intrinsically tough, but flexible. In fact, certain arthropods possess rather soft and pliable exoskeletons (e.g., many insect larvae, parts of spiders,

[3]Caution: Some authors use the term *endocuticle* to refer to the entire procuticle of crustaceans, and they use the two subdivision terms only when referring to insects.

some small crustaceans and arachnids). However, in most arthropods, the cuticle is hard and inflexible except at the joints, a condition brought about by one or both of two processes: sclerotization and mineralization.

Cuticular hardening by **sclerotization** (a process known as **tanning**) occurs to various degrees in all arthropods. The layered arrangement of untanned proteins yields a flexible structure. To produce a rigid sclerotized structure, the protein molecules are cross-bonded to one another by orthoquinone linkages. Sclerotization generally begins in the cuticulin layer of the epicuticle and progresses to various degrees into the procuticle, where it is associated with a distinct darkening in color. The relationship between cuticular hardening, joints, and molting is discussed in more detail below. **Mineralization** of the skeleton is largely a phenomenon of some crustaceans, millipedes, and horseshoe crabs and is accomplished by the deposition of calcium carbonate in the outer region of the procuticle.

The epidermis is responsible for the secretion of the cuticle, which it does with various unicellular glands (Figure 20.22C), some of which bear ducts to the surface of the cuticle. Because the cuticle is secreted by the epidermal cells, it often bears their impressions in the form of microscopic geometric patterns. The epidermis is underlain by a distinct basement membrane that forms the outer boundary of the body cavity or hemocoel.

Arthropod Appendages

Appendage anatomy In an evolutionary sense, one might be tempted to say "arthropods are all legs." Certainly, much of arthropod evolution has been about the appendages, modified in myriad ways over the 521-million-year fossil history of this group. The unique combination of body segmentation and serially homologous appendages, in combination with the evolutionary potential of developmental genes, has allowed arthropods to develop modes of locomotion, feeding, and body region/appendage specialization that have been unavailable to the other metazoan phyla. The enormous variety of limb designs in arthropods has, unfortunately, also driven zoologists to create a plethora of terms to describe them. Read on, and we will try to guide you through this terminological jungle in the clearest fashion we can.

Primitively, every true body somite, or segment, probably bore a pair of appendages, or limbs, as found in the other panarthropods, in the fossil trilobites, and in some extant arthropod groups like centipedes or remipedes. Arthropod appendages are articulated outgrowths of the body wall, equipped with sets of extrinsic muscles (connecting the limb to the body) and intrinsic muscles (wholly within the limb). The limbs of the other panarthropod phyla (Tardigrada and Onychophora) do not have intrinsic musculature and thus must rely strongly on hydraulics for movement. In the arthropods, muscles move the various limb segments or pieces, which are called **articles** (or podites).[4] The limb articles are organized into two groups, the basal-most group constituting the **protopod** (= sympod) and the distal-most group constituting the **telopod** (Figure 20.23). Whether the protopod is composed of one or more articles, the basal-most article is always called the **coxa** (in living arthropods). The telopod arises from the distal-most protopodite, or protopodal article. Sometimes the exoskeleton of the telopodites becomes annulated, forming a flagellum, as in the antennae of many arthropods, but these annuli should not be confused with true articles.

A great variety of additional structures can arise from articles of the protopod (the protopodites), either laterally (collectively called **exites**) or medially (collectively called **endites**) (Figure 20.23A). Evolutionary creativity among the protopodal exites has been exceptional among arthropods. In crustaceans and trilobites they form a diversity of structures such as gills, gill cleaners, and swimming paddles. Broad or elongate exites that function as gills or gill cleaners are often called **epipods**. Exites may become annulated, like the flagella of some antennae. Protopodal endites, on the other hand, often form grinding surfaces, or "jaws," usually termed **gnathobases**. Figure 20.23 illustrates some arthropod appendage types and the terms applied to their parts.[5]

Appendages with large exites, such as gills, gill cleaners, or swimming paddles (the last often developed in combination with a paddlelike telopod) are

[4] Although some authors refer to the articles of the appendages as "segments," we attempt to restrict the use of the latter term to the true body segments, or somites, reserving the term *articles* for the separate "segments" of the limb.

[5] A basic morphological view of arthropod limb evolution is rooted in 30 years of detailed comparative morphology by Jarmila Kukalová-Peck, who studies both fossil and living arthropod limbs. In the Kukalová-Peck model, the ancestral arthropod appendage comprised a series of 11 articles (4 protopodites, 7 telopodites), each of which could theoretically bear an articulated endite or exite. The number of articles in her arthropod limb ground plan is not so important as her concept of a single series of articles, with endites and exites that specialized to become the diversity of structures seen in modern taxa. Over evolutionary time, so her theory goes, the basal-most protopodites fused with the pleural region of the body to form pleural sclerites in various taxa. On the thoracic segments of hexapods, the exite of the first protopodite (the epicoxa) migrated dorsally and gave rise to insect wings (see Chapter 22). On the other hand, many of the earliest known arthropod fossils (including trilobites) have protopods of a single article, as do many living arthropods, suggesting to some workers that multiarticulate protopods might be derived conditions. Kukalová-Peck's hypothesis, however, holds that such uniarticulate protopods represent cases in which protopodal articles have fused together (e.g., in trilobites) or migrated onto the pleural region of the body somites. The number of articles in the telopods of living arthropods varies greatly, reflecting, in Kukalová-Peck's view, various kinds of loss or fusion of articles. The elegance of Kukalová-Peck's theory is that it simply explains the origin of all arthropod limb structures. Viewing the arthropod limb ground plan as a series of articles from which endites and exites were modified in a variety of ways eliminates 100 years of confusion over the nature of uniramous, biramous, and polyramous limbs (these terms now having little phylogenetic significance).

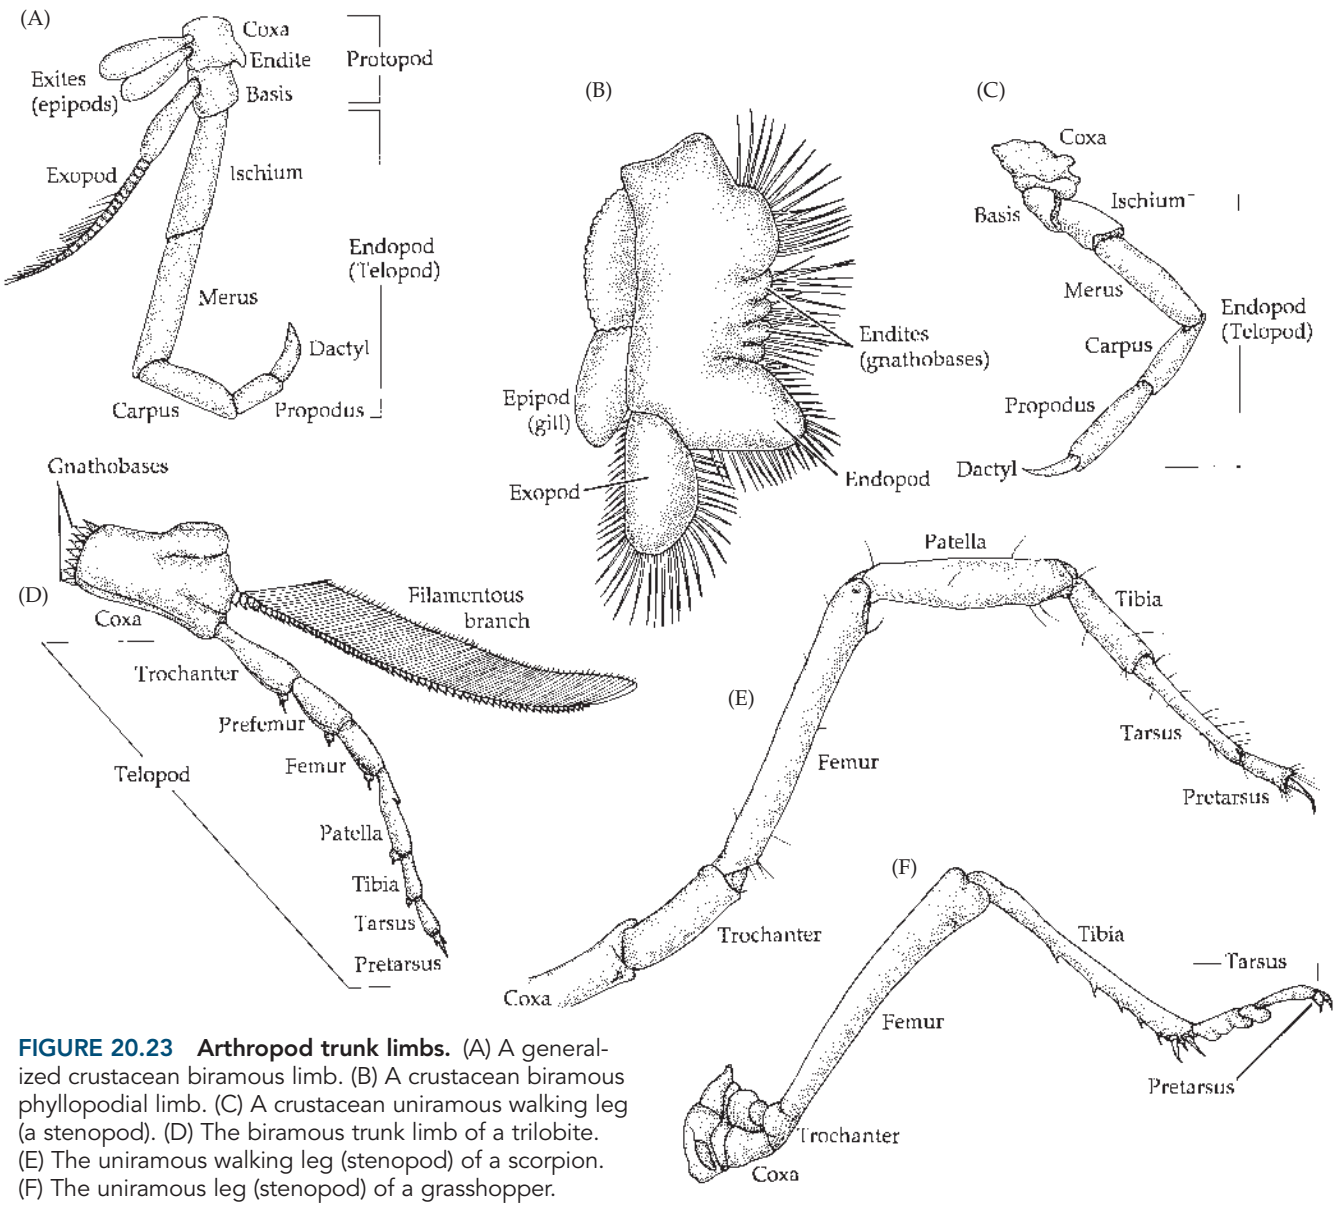

FIGURE 20.23 Arthropod trunk limbs. (A) A generalized crustacean biramous limb. (B) A crustacean biramous phyllopodial limb. (C) A crustacean uniramous walking leg (a stenopod). (D) The biramous trunk limb of a trilobite. (E) The uniramous walking leg (stenopod) of a scorpion. (F) The uniramous leg (stenopod) of a grasshopper.

often called **biramous limbs** (or, sometimes, triramous or polyramous limbs). Biramous limbs occur only in crustaceans and trilobites, although their ancestral occurrence in chelicerates is suggested by the gills and other structures that may be derivatives of early limb exites. In crustaceans, the exite on the last protopodite can be as large as the telopod itself, and in these cases it is termed an **exopod**, the telopod then being called the **endopod** (Figure 20.23A). Biramous limbs are commonly associated with swimming arthropods, and in crustaceans in which they are greatly expanded and flattened (e.g., Cephalocarida, Branchiopoda, Phyllocarida), they may also be called foliacious limbs, or **phyllopodia** (Greek *phyllo*, "leaf-shaped"; *podia*, "feet") (Figure 20.23B).

Appendages without large exites are called **uniramous limbs** (or **stenopods**; Greek *steno*, "narrow"; *podia*, "feet") (Figure 20.23C,E,F). Uniramous limbs are characteristic of the chelicerates, hexapods, myriapods, and some crustaceans, although these appendages were probably secondarily derived from biramous limbs on more than one occasion. Uniramous legs are typically ambulatory (walking legs).

The combination of protopodal and telopodal articles, and their evolutionarily "plastic" endites and exites, has created in arthropods a veritable "Swiss army knife" of appendages. This diversity has no equal in the animal kingdom, and it has played a pivotal role in the evolutionary success of the phylum. As you peruse the following chapters, be sure to notice the phenomenal array of limb morphologies and adaptations among the arthropods.

Appendage Evolution The amazing diversity seen in arthropod limbs has come about through the unique potential of homeobox (Hox) genes and other

developmental genes and the downstream genes they regulate, which are conserved and yet flexible in their expression. We are just beginning to understand how these genes work, and new information in this field is appearing so fast that we hesitate to go into great detail—our understanding of arthropod developmental biology is literally changing from one month to the next! We now know that the fates of arthropod appendages are largely under the ultimate control of Hox genes, which dictate where body appendages form and the general types of appendages that form. Hox genes can either suppress limb development or modify it to create alternative appendage morphologies. These unique genes have played major roles in the evolution of new body plans among arthropods (and other phyla).

A good example of the evolutionary potential of Hox genes is seen in the abdominal limbs of insects. Abdominal limbs (prolegs) occur on the larvae (but not the adults) of various insects in several orders, and they are ubiquitous in the order Lepidoptera (i.e., caterpillars). Abdominal limbs were almost certainly present in the crustacean ancestry of insects. Hence, prolegs may have reappeared in groups such as the Lepidoptera through something as simple as the de-repression of an ancestral limb development program (i.e., they are a Hox gene–mediated atavism). We have learned that proleg formation is initiated during embryogenesis by a change in the regulation and expression of the bithorax gene complex (which includes the Hox genes *Ubx*, *abdA*, and *AbdB*).

Molecular developmental biology has also begun to unravel the origins of arthropod appendages themselves. We now know that appendage development is orchestrated by a complex of developmental genes, in particular the genes *Distal-less* (*Dll*) and *Extradenticle* (*Exd*). Evidence suggests that *Exd* is necessary for the development of the proximal region of arthropod limbs (the protopod), whereas *Dll* is expressed in the distal region of developing appendages (the telopod). Thus the protopod and the telopod of arthropod appendages are somewhat distinct, each under its own genetic control and each, presumably, free to respond to the whims and processes of evolution. So, whether an arthropod mandible is a "telomeric," or "whole-limb," appendage (i.e., built of all, or most, of the full complement of articles) or a "gnathobasic" appendage (i.e., built of only the basal-most, or protopodal, articles) depends on whether or not (or how much) the gene *Dll* is expressed.

Dll is expressed throughout the development of the multiarticulate, telomeric chelicerae and the pedipalps of chelicerates, but it is only transiently expressed in myriapod mandibles and in crustacean mandibles lacking palps. It is expressed throughout embryogeny in the mandibular palp of crustaceans, but not at all in the mandibles of hexapods. This expression pattern suggests that only the chelicerae and pedipalps of chelicerates are fully telomeric appendages, although the palp of the crustacean mandible represents the telopod of that limb. It also suggests that the development of a telopod is an evolutionarily flexible feature that can easily show homoplasy (i.e., parallelism). *Dll* is also expressed in the endites of arthropod limbs (e.g., in the phyllopodous limbs of Branchiopoda). In fact, *Dll* is an ancient gene that occurs in many animal phyla, where it is expressed at the tips of ectodermal body outgrowths in such different structures as the limbs of vertebrates, the parapodia and antennae of polychaete worms, the tube feet of echinoderms, and the siphons of tunicates.

So, we see that despite their considerable diversity, all arthropod limbs have a common ground plan and similar genetic mechanisms in their development. For example, developmental biology has now identified the appendage homologies of the head region for the major arthropod groups. A good example of developmental gene potential is revealed in Table 20.2, where we see the diversity of homologous head appendages across the onychophoran–arthropod spectrum. Imagine the jaws of velvet worms, chelicerae of scorpions, and antennae of insects all being derived from the same ancestral appendage! Evidence now suggests that the uniramous legs of hexapods arose from the biramous (or uniramous) appendages of crustacean ancestors. And elegant new research in gene patterning, using knockout methodology, backs 100 years of comparative anatomy and embryology in support of the idea that insect wings arose from crustacean leg segments that fused with the body wall in the evolutionary past (crustacean proximal leg-segment exites evolved into body wall lobes, then into wings). Although morphologists have struggled to establish homologies among the specific articles, or podites, of arthropod legs, considerable debate still exists on that issue. But we are beginning to acquire the developmental genetic toolkit needed to resolve this and other issues across the arthropod subphyla.

Support and Locomotion

Arthropods rely on the exoskeleton for support and maintenance of body shape. Their muscles are arranged as short bands that extend from one body segment to the next, or across the joints of appendages and other regions of articulation. An understanding of the nature of these articulation points—the areas where the cuticle is notably thin and flexible—is crucial to an understanding of the action of the muscles and hence of locomotion. In contrast to most of the exoskeleton, the articulations (joints) between body and limb segments are bridged by areas of very thin, flexible cuticle in which the procuticle is much reduced and unhardened (Figure 20.24). These thin areas are called **arthrodial or articular membranes**. Generally, each articulation is bridged by one or more pairs of antagonistic muscles.

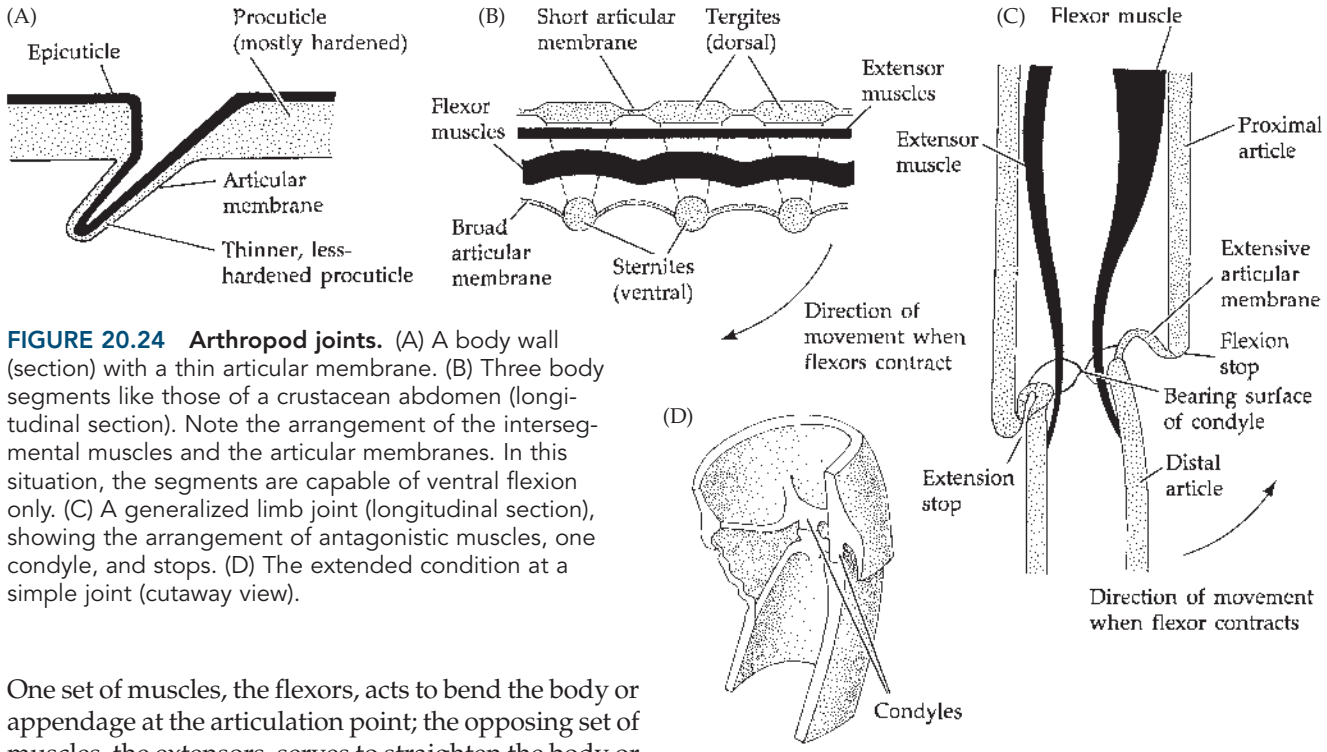

FIGURE 20.24 Arthropod joints. (A) A body wall (section) with a thin articular membrane. (B) Three body segments like those of a crustacean abdomen (longitudinal section). Note the arrangement of the intersegmental muscles and the articular membranes. In this situation, the segments are capable of ventral flexion only. (C) A generalized limb joint (longitudinal section), showing the arrangement of antagonistic muscles, one condyle, and stops. (D) The extended condition at a simple joint (cutaway view).

One set of muscles, the flexors, acts to bend the body or appendage at the articulation point; the opposing set of muscles, the extensors, serves to straighten the body or appendage. The same principles apply in the opposing sets of muscles of our own arms and legs.

Joints that operate as just described generally articulate in only a single plane (much like your own knee or elbow joints). Such movement is limited not only by the placement of the antagonistic muscle sets, but also by the structure of the hard parts of the cuticle that border the articular membrane. In such cases the articular membrane may not form a complete ring of flexible material, but will be interrupted by points of contact between hard cuticle on either side of the joint. These contact points, or bearing surfaces, are called **condyles** and serve as the fulcrum for the lever system formed by the joint. A dicondylic joint allows movement in one plane, but not at angles to that plane. The motion at a joint is also usually limited by hard cuticular processes called locks or stops, which prevent overextension and overflexion (Figure 20.24C,D).

Some joints are constructed to allow movement in more than one plane, much like a ball-and-socket joint. For example, in most arthropods the joints between walking legs and the body (the coxal-pleural joints) lack large condyles, and the articular membranes form complete bands around the joints. In other cases, two adjacent dicondylic limb joints articulate at 90° to one another, forming a gimbal-like arrangement that facilitates movement in two opposing planes.

Arthropods have evolved a plethora of locomotor devices for movement in water, on land, and in the air. Only the vertebrates can boast a similar range of abilities, albeit utilizing a far less diverse set of mechanisms. Like so many other aspects of arthropod biology, their methods of movement reflect the extreme evolutionary plasticity and adaptive qualities associated with the segmented body and appendages.

Movement through water involves various patterns of swimming that include smooth paddling by shrimps, jerky stroking by certain insects and small crustaceans, and startling backward propulsion by tail flexion in lobsters and crayfish. Aerial locomotion has been mastered by the pterygote (winged) insects but is also practiced by certain spiders that drift on threads of silk. Many arthropods burrow or bore into various substrata (e.g., ants, bees, termites, burrowing crustaceans). Some terrestrial arthropods that are normally associated with the ground engage in short-term aerial movements that serve as escape responses. Some, like fleas, simply jump, whereas others jump and glide, giving us possible clues to the evolutionary origin of flight. Some crustaceans jump as well, such as the familiar beach hoppers (amphipods) that bound away over the sand when disturbed. Arthropods that move in contact with the surface of the substratum, under water or on land, by various forms of walking, creeping, crawling, or running are referred to as pedestrian or reptant.

All of the common forms of arthropod locomotion except flight depend on the use of typical appendages and thus are based on the principles of joint articulation just described, coupled with specialized architecture of the appendages. Next we discuss some aspects of two fundamental types of appendage-dependent locomotion in arthropods, swimming and pedestrian locomotion, exploring variations on these methods and others in subsequent chapters.

Many examples of swimming arthropods are found among the crustaceans. Most swimming crustaceans (e.g., anostracans and shrimps) and even those that swim only infrequently (e.g., isopods and amphipods) employ ventral, flaplike setose appendages as paddles (Figure 20.23B). The appendages used for swimming may be restricted to particular body regions (e.g., the abdominal swimmerets of shrimps, stomatopods, and isopods; the metasomal limbs of swimming copepods) or may occur along much of the trunk (e.g., the appendages of anostracans, remipedes, and cephalocarids) (Figure 20.25). These appendages engage in a backward power (propulsive) stroke and a forward recovery stroke. In all cases, the appendages are constructed in such a way that on the recovery stroke, they are flexed and the flaps and marginal setae passively "collapse" to reduce the coefficient of friction (drag). On the power stroke the limbs are held erect, with their largest surface facing the direction of limb movement, thus increasing thrust efficiency (by increasing the coefficient of friction and the distance through which the limb travels). These swimming appendages typically articulate with the body only on a plane parallel to the body axis. Less sophisticated swimming is accomplished in other arthropods by use of various other appendages, including the antennae of many minute crustaceans and larvae and the thoracic stenopods of many aquatic insects.

Pedestrian locomotion in arthropods is highly variable, both among different groups and even in individual animals. With the exception of a few strongly homonomous "vermiform" types (e.g., centipedes and millipedes), most arthropods are incapable of lateral body undulations. Thus, they cannot amplify the stride length of their appendages by body waves (as many polychaetes do, for example). Walking arthropods depend almost entirely on the mobility of specialized groups of appendages. The structure of these ambulatory legs is quite different from that of paddle-like swimming appendages, and their action is much more complex and variable.

Consider the general movement of an ambulatory leg as it passes through its power and recovery strokes (Figure 20.26). At the completion of the power stroke, the appendage is extended posteriorly and its tip is in contact with the substratum. The recovery stroke involves lifting the limb, swinging it forward, and placing it back down on the substratum; by then the limb is extended anterolaterally. The power stroke is accomplished by first flexing and then extending the leg while the tip is held in place against the substratum. Thus the body is first pulled and then pushed forward by each limb.

These complicated movements obviously would not be possible if all of the limb joints and limb-body joints were dicondylic articulations in the same plane, parallel to the body axis. The leg must be able to move up and down as well as forward and backward, and the action at each joint must be coordinated with the actions of all the others. In general, the distal limb joints are dicondylic, with articulation (and movement) planes parallel to the limb axis. They allow the appendage to flex and extend, that is, to move the tip closer to (adduction) or farther from (abduction) the point of limb origin. The actions of these joints typically involve the usual sets of antagonistic flexor and extensor muscles described earlier. In some arachnids and a few crustaceans, however, certain limb joints lack extensor muscles, and the limbs are extended by an increase in blood pressure. Raising and lowering of the limb are also accomplished by extensor and flexor muscles, which thus serve as levators and depressors, respectively; the muscles in the proximal leg joints usually serve these purposes.

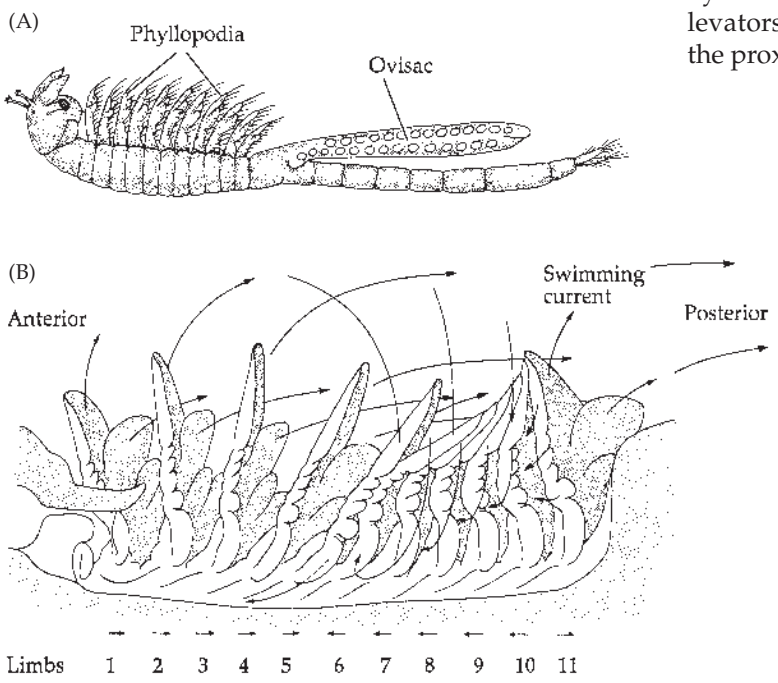

FIGURE 20.25 Swimming motions in a branchiopod crustacean. (A) A fairy shrimp (Anostraca) on its back in its normal swimming posture. (B) The appendages "in motion," producing a posteriorly directed flow of water that propels the animal forward. Arrows near the bases of the appendages indicate feeding currents. The small arrows below the drawing indicate the direction of movement of each numbered appendage at this moment in the anterior progression of the metachronal wave. Water is drawn into the interlimb spaces as adjacent appendages move away from one another, and water is pressed out of the spaces as adjacent limbs move together. The lateral articles of these phyllopodial appendages are hinged in such a way that they extend on the power stroke to present a large surface area and collapse on the recovery stroke, thereby producing less drag.

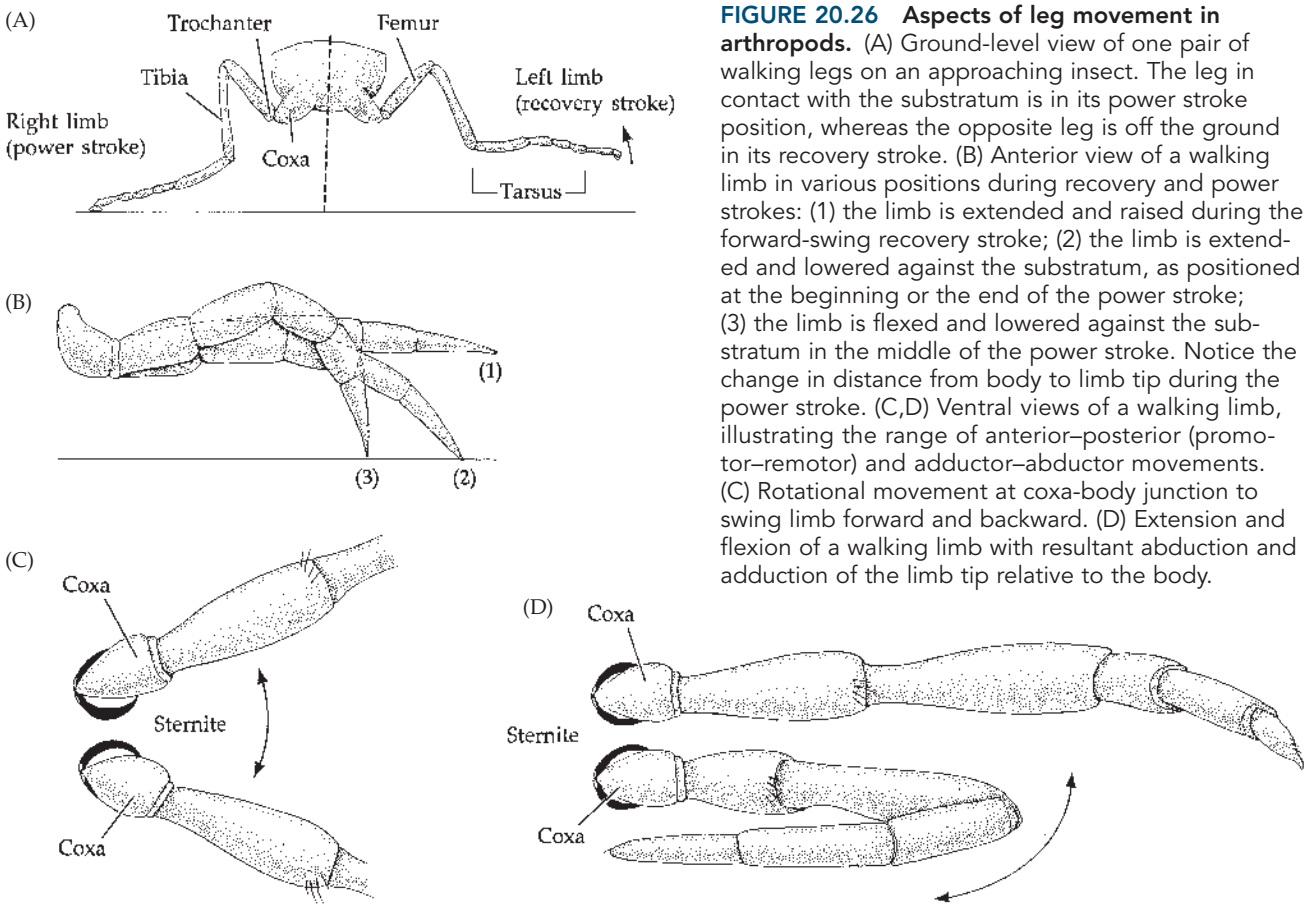

FIGURE 20.26 Aspects of leg movement in arthropods. (A) Ground-level view of one pair of walking legs on an approaching insect. The leg in contact with the substratum is in its power stroke position, whereas the opposite leg is off the ground in its recovery stroke. (B) Anterior view of a walking limb in various positions during recovery and power strokes: (1) the limb is extended and raised during the forward-swing recovery stroke; (2) the limb is extended and lowered against the substratum, as positioned at the beginning or the end of the power stroke; (3) the limb is flexed and lowered against the substratum in the middle of the power stroke. Notice the change in distance from body to limb tip during the power stroke. (C,D) Ventral views of a walking limb, illustrating the range of anterior–posterior (promotor–remotor) and adductor–abductor movements. (C) Rotational movement at coxa-body junction to swing limb forward and backward. (D) Extension and flexion of a walking limb with resultant abduction and adduction of the limb tip relative to the body.

Anterior–posterior limb movements are accomplished in two basic ways. First, the ball-and-socket type of joint at the point of limb-body articulation typically carries out these actions in most crustaceans, insects, and myriapods. Promotor and remotor muscles that are associated with these joints rotate the limb forward and backward, respectively. Second, many arachnids accomplish multidirectional limb movements by using only uniplanar dicondylic joints. In these arthropods, one or more of the proximal joints articulate perpendicular to the limb axis, and thus to the rest of the limb joints, providing forward and backward movement.

Understanding how a single limb moves does not, of course, describe the locomotion of the whole animal. The various patterns of pedestrian locomotion in arthropods, called gaits, are the result of many factors (e.g., leg number, leg movement sequences, stride lengths, speed). The number of patterns is great, but it is limited by certain biological and physical constraints. Speed is limited by rates of muscle contraction and the necessity for coordinating leg movements to avoid tangling. Furthermore, the animal must maintain an appropriate distribution of legs at all times in various phases of power and recovery strokes so that its weight is fully supported.

The gaits of insects have been more extensively studied than those of other arthropods. Studies on insects and myriapods led to an attempt to establish principles under which all pedestrian arthropod locomotion could be unified. The most frequently used descriptions of arthropod walking, crawling, and running are based on the "metachronal model." The basic idea of this model is that the legs on each side of the body move in metachronal (repeated) waves from back to front and that the waves overlap to various degrees, depending on the speed of movement. This model does work for some arthropods, some of the time, but things are not so simple, and attempts to overgeneralize have been misleading. A good deal of the work on crustaceans and arachnids (and even insects) indicates that leg movement sequences, stepping patterns, stride lengths, and other characteristics are extremely variable, even within individuals, and depend on a host of factors other than speed. The actions of the joints are coordinated by information supplied to the central nervous system by proprioceptors in the joints themselves.

Growth

The imposition of a rigid exoskeleton on the arthropods precludes growth by means of a gradual increase in external body size. Rather, an overall increase in body size takes place in staggered increments associated with the periodic loss of the old exoskeleton and

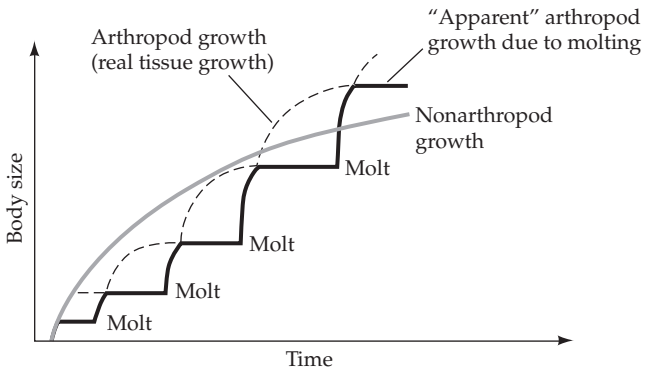

FIGURE 20.27 Arthropod versus nonarthropod growth. The heavy solid line indicates the incremental ("stair-step") growth pattern of an arthropod as measured by changes in external body size associated with molts. The dotted line depicts real tissue growth in the same arthropod. The gray line depicts the typical growth of a nonarthropod.

the deposition of a new, larger one (Figure 20.27). The process of shedding the exoskeleton is called **molting**, and it is a phenomenon characteristic of arthropods and all other ecdysozoans. The molting process varies in detail even among the arthropods. It has been best studied in certain insects and crustaceans, and the description here is based primarily on those two groups. We first outline the basic steps in the arthropod molt cycle and then briefly discuss the hormonal control of those events. In all arthropods (and probably all ecdysozoans) molting is regulated by a hormone called **ecdysone**; thus, the entire molting process in these groups is also known as **ecdysis**.

The stages between molts are called **intermolts** (or **instars**, in insects). It is during these intermolt stages that real tissue growth occurs, although with no increase in external size. When such tissue growth reaches the point at which the body "fills" its exoskeletal case, the animal usually enters a physiological state known as **premolt or proecdysis**. During this stage there is active preparation for the molt, including accelerated growth of any regenerating parts. Certain epidermal glands secrete enzymes that begin digesting the old endocuticle, thus separating the exoskeleton from the epidermis. In many crustaceans, some of the calcium is removed from the cuticle during this period and stored within the body for later redeposition. As the old cuticle is loosened and thinned, the epidermis begins secreting a soft new cuticle. Figure 20.28 depicts some of these events.

Once the old cuticle has been substantially loosened and a new cuticle formed, actual molting occurs. The old cuticle splits in such a way that the animal can wriggle free and pull itself out. The lines along which the cuticle splits vary among the arthropods but are consistent within particular groups. It is important to remember that all cuticular linings are lost during ecdysis, including the linings of the foregut and hindgut, the eye surfaces, and the cuticle that lines every pit, groove, spine, and seta on the body surface. When you see a cast-off intact exoskeleton, or **exuvium**, of an arthropod, you are bound to be impressed with its wonderfully perfect detail. It is at first difficult to imagine how the animal could extricate itself from each and every tiny part of the old cuticle (Figure 20.28C,D). The ability to do so depends, of course, on the great flexibility of the body within its new and unhardened exoskeleton.

As soon as the arthropod emerges from its old cuticle, and while the new cuticle is still soft and pliable, its body swells rapidly by taking up air or water. Once the new cuticle is thus enlarged, the animal enters a postmolt period (**postecdysis**), during which the cuticle is hardened by sclerotization and/or the redeposition of calcium salts. The excess water (or air) is then actively pumped from the body, and real tissue growth occurs during the subsequent **intermolt** period. During the sclerotization process, the cuticle becomes drier, stiffer, and resistant to chemical and physical degradation through the molecular cross-linking process in the protein-chitin matrix described earlier.

We have stressed the adaptive significance of the arthropod exoskeleton in terms of its protective and supportive qualities. However, during the **postmolt period**, before the new exoskeleton is hardened, the animal is quite vulnerable to injury, predation, and osmotic stress. Many arthropods become reclusive at this time, hiding in protective nooks and crannies and not even feeding when in this "soft-shell" condition. The time required for hardening of the new exoskeleton varies greatly among arthropods, generally being longer in larger animals. The well-known and delectable "soft-shell crabs" of the eastern United States are simply blue crabs (*Callinectes sapidus*) caught during their postmolt period.

Many genes and a complex hormonal system regulate the molt cycle (Figure 20.29). Several models have been proposed to explain the hormonal pathways involved in molting in insects and crustaceans, but the picture is still somewhat incomplete, despite having whole genomes available for so many arthropods. The hormonal activities of the crustacean ecdysial cycle have been most extensively studied in decapods. In some (e.g., lobsters and crayfish), molting occurs periodically throughout the animal's life, but in many others (e.g., copepods and some crabs), molting, and therefore growth, ceases at some point, and a maximum size is attained. Animals that have engaged in their final molt are said to have entered a state of **anecdysis**, or permanent intermolt—they are in their final instar. Among insects, molting is largely associated with metamorphosis from one developmental stage to the next (e.g., pupa to adult), and except for the most primitive hexapods, adults do not molt (i.e., they are in anecdysis).

In both crustaceans and hexapods (and probably all arthropods), the initiation of molting, beginning with the events of proecdysis, is brought about by the

action of a molting hormone called ecdysone. Apparently, however, the pathways controlling the secretion of ecdysone are different in insects and crustaceans, as diagrammed in Figure 20.29. In crustaceans ecdysone is secreted by an endocrine gland called the Y-organ located at the base of the antennae or near the mouthparts. The action of the Y-organ is controlled by a complex neurosecretory apparatus located near the eyes or in the eyestalks. During the intermolt period, a **molt-inhibiting hormone (MIH)** is produced by neurosecretory cells of the X-organ, located in a region of the eyestalk nerve (or ganglion) called the medulla terminalis (Figure 20.29A). MIH is carried by axonal transport to a storage area called the sinus gland, which appears to control MIH release into the blood. As long as sufficient levels of MIH are present in the blood, the production of ecdysone by the Y-organ is inhibited.

The active premolt and subsequent molt phases are initiated by sensory input to the central nervous system. The stimulus is external for some crustaceans (e.g., day length or photoperiod for certain crayfishes) and internal for others (e.g., growth of soft tissues in certain crabs). External stimuli are transmitted via the central nervous system to the medulla terminalis and X-organ (Figure 20.29B). Appropriate stimuli inhibit the secretion of MIH, ultimately resulting in the production of ecdysone and the initiation of a new molt cycle.

The sequence of events in insects is somewhat different from that in crustaceans in that a molt inhibitor is apparently not involved. When an appropriate stimulus is introduced to the central nervous system, certain neurosecretory cells in the cerebral ganglia are activated. These cells, which are located in the pars intercerebralis, secrete **ecdysiotropin**. This hormone is carried by axonal transport to the corpora cardiaca, paired neural masses associated with the cerebral ganglia. Here, thoracotropic hormone is produced and carried to the prothoracic glands, stimulating them to produce and release ecdysone (Figure 20.29C).

The Digestive System

It will come as no surprise that the great diversity among arthropods is reflected in their expression of nearly every feeding method imaginable. As a group, the only real constraint on arthropods in this regard is the absence of external (as well as internal), functional cilia. Evolutionarily, many arthropods have overcome even this limitation and suspension feed by other means. So varied are arthropod feeding strategies that we postpone discussion of them to the sections and chapters on particular taxa, and here we simply generalize about the basic structure and function of arthropod digestive systems.

The digestive tract of arthropods is complete (a through gut) and generally straight, extending from a ventral mouth on the head to a posterior anus. Various appendages (the mouthparts and other associated appendages) may be associated with processing food and moving it to the mouth. Regional specialization of the gut occurs in most taxa. In almost all cases there is a well-developed, cuticle-lined, stomodeal foregut and proctodeal hindgut (both derived from embryonic ectoderm), connected by an endodermally derived midgut (Figure 20.30). In general, the foregut serves for ingestion, transport, storage, and mechanical digestion of food; the midgut for enzyme production, chemical digestion, and absorption; and the hindgut for water absorption and the preparation of fecal material. The midgut typically bears one or more evaginations in the

form of **digestive ceca** (often referred to as the "digestive gland," "liver," or "hepatopancreas"). The number of ceca and the arrangement of the other gut regions vary among the different taxa. In almost all arthropods, the inner layer of midgut epithelium is typically coated with a **peritrophic matrix**—a very thin but complex chitinous sheet that is continuously formed by delamination from the epithelium such that the inner surface of

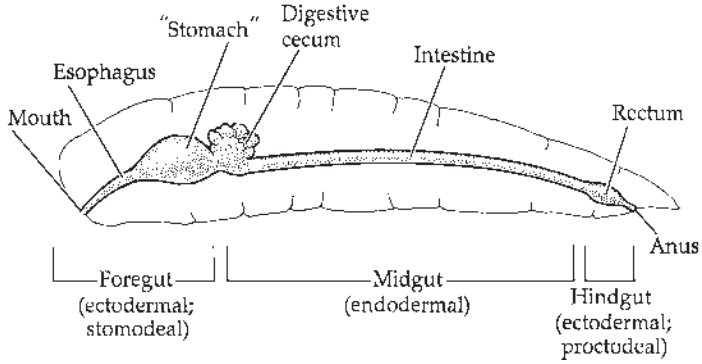

FIGURE 20.30 The major gut regions of arthropods. The myriad variations on this theme are discussed in subsequent chapters on particular taxa.

the midgut is constantly being "cleaned." As this layer lifts off the epithelium, it surrounds ingested materials as a **peritrophic membrane**, including microbes and food particles, wrapping and compartmentalizing them as "pellets." This membrane protects the gut epithelium from damage by food particles and pathogens; it can also play a role in the accumulation and metabolism of certain elements (e.g., calcium, copper) as well as the inactivation of potentially toxic metals. Microscopic pores in the membrane allow passage of enzymes and digested nutrients. Arthropod feces are thus typically "packaged" in the remains of the peritrophic membrane.

The various terrestrial arthropods have convergently evolved many similar features as adaptations to life on land. Many of these convergent structures are associated with (although not necessarily derived from) the gut. For example, excretory structures called **Malpighian tubules** that develop from the midgut or hindgut of insects, arachnids, myriapods, and tardigrades appear to be convergences (i.e., nonhomologous structures). The excretory structures of onychophorans also used to be called Malpighian tubules, but they have recently been shown to be complex metanephridia with secondarily derived, closed end sacs. Many unrelated terrestrial taxa have special **repugnatorial glands**, which may or may not be associated with the gut and which produce noxious substances used to deter predators.

Many different groups of terrestrial arthropods also have evolved the ability to produce silks or silklike substances for use outside their bodies. These silklike fibers are produced by nonhomologous structures among different arthropods. Although they vary greatly in chemical composition, all share a common molecular feature that gives them strength and elasticity; they are composed of regular assemblies of long-chain macromolecules (most being fibrous proteins), and many also incorporate collagens. Modified salivary glands are common silk-producing organs, but silks are also secreted by the digestive tract, Malpighian tubules, accessory reproductive glands, and assorted dermal glands. Silk production occurs in chelicerates (false scorpions, spiders, and mites), many insect orders (such as adult webspinners, or Embioptera, and the larvae of commercial silkworm moths *Bombyx* and *Anaphe*), some myriapods, and some crustaceans (e.g., amphipods). Arthropod silks are used in the production of cocoons, egg cases, webs, larval "houses," flotation rafts, prey entrapment threads, draglines, spermatophore receptacles, intraspecific recognition devices, and other sundry items. The truly spectacular array of silk uses by spiders is discussed in Chapter 24. Silk production and use provide one of the more impressive examples of evolutionary convergence seen in the arthropods.

A number of arthropod groups are capable of digesting plant material and produce their own cellulase, although in most cases digestion is enhanced by symbiotic microbes (bacteria and fungi) in the gut. Some herbivorous crabs (e.g., many Gecarcinidae) and isopods (e.g., Valvifera, Sphaeromatidae, Limnoriidea) appear to use only endogenously produced cellulases to break down plant tissues. In other herbivorous isopod species (Oniscidea, the terrestrial isopods) there is a mix of endogenous cellulases and microbial symbiont-produced cellulases, and this is also the case for termites and herbivorous beetles. Over a dozen endogenous lignocellulose-degrading enzymes have been identified in the common land isopod *Armadillidium vulgare*, attesting to the complexity of the process. In these cases, there is a complementary and synergistic action of the lignocellulose-degrading enzyme repertoire from the host and its microbial symbionts. In marine species, hemocyanins in the gut appear to modify lignin and thus facilitate digestion.

Circulation and Gas Exchange

A major aspect of the arthropod body plan is reflected in the nature of the circulatory system. The largely open hemocoelic system is in part a result of the imposition of the rigid exoskeleton and the loss of an internally segmented and fluid-filled coelom. We have seen that isolated coelomic spaces (such as the segments of annelids) require a closed circulatory system to service them, but this requirement is not present in arthropods. Furthermore, without a muscular, flexible body wall to augment blood movement, a pumping mechanism becomes necessary, resulting in the elaboration of a muscular heart. The result is a system wherein the blood is driven from the heart chamber through short vessels and into the hemocoel, where it bathes the internal organs. The blood returns to the heart via a noncoelomic pericardial sinus and perforations in the heart wall called ostia (Figure 20.31). The blood flows back to the heart along a decreasing pressure gradient resulting from lowered pressure within the pericardial sinus as the heart contracts. The complexity of the circulatory system varies greatly among arthropods, the differences being dependent in large part on body size and shape. These differences include variations in the size and shape of the heart (Figure 20.31B–D), the number of ostia, the length and number of vessels, the arrangement of hemocoelic sinuses, and the circulatory structures associated with gas exchange.

Arthropod blood, or **hemolymph**, serves to transport nutrients, wastes, and usually gases. It includes a variety of types of amebocytes and, in some groups, clotting agents. The blood of many kinds of small arthropods is colorless, simply carrying gases in solution. Most of the larger forms, however, contain

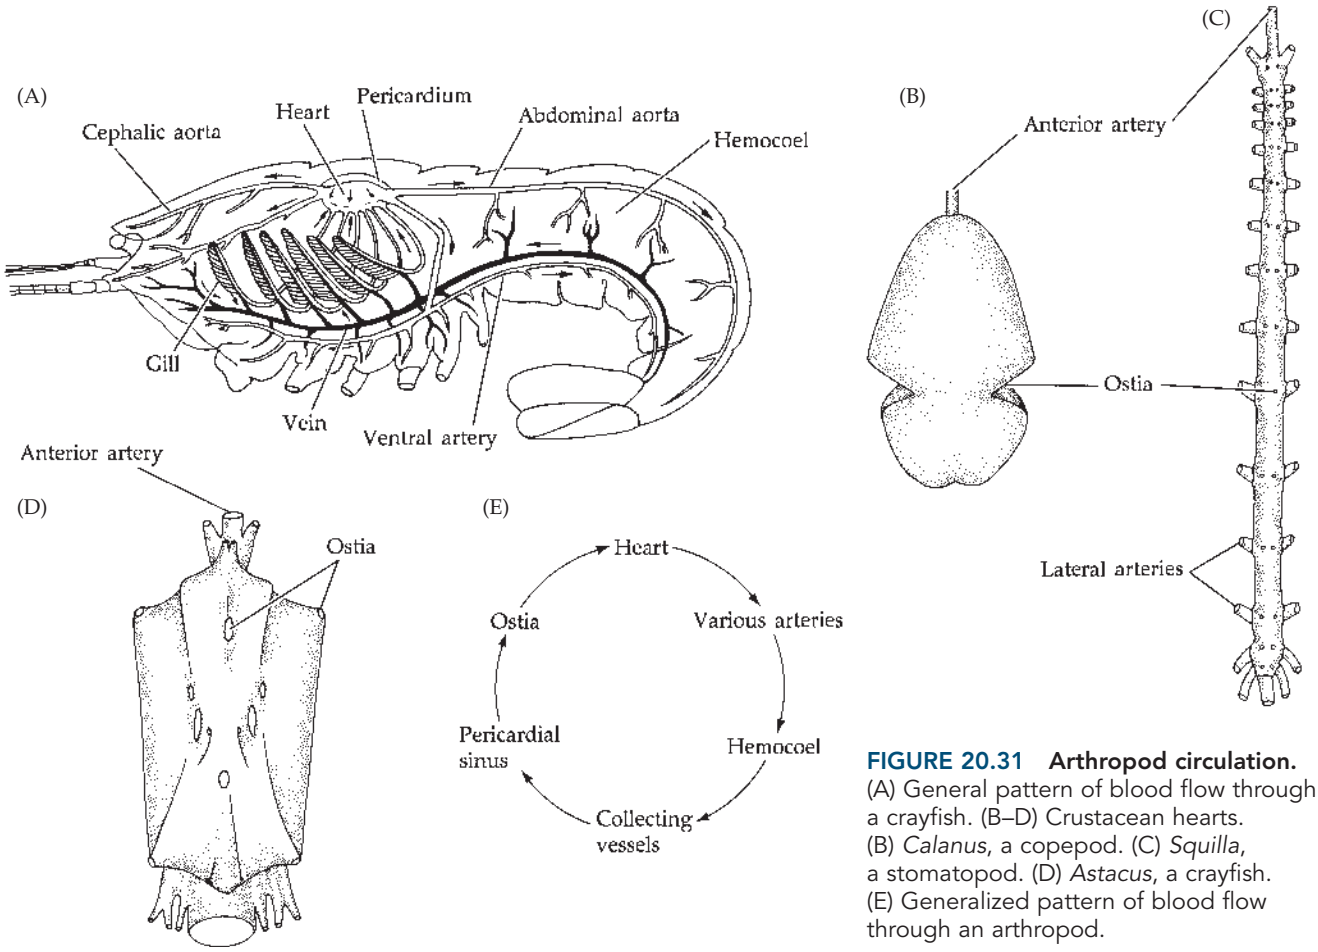

FIGURE 20.31 Arthropod circulation. (A) General pattern of blood flow through a crayfish. (B–D) Crustacean hearts. (B) *Calanus*, a copepod. (C) *Squilla*, a stomatopod. (D) *Astacus*, a crayfish. (E) Generalized pattern of blood flow through an arthropod.

hemocyanin, and a few contain hemoglobin. Both pigments are always dissolved in the hemolymph rather than contained within cells. In most groups of arthropods, the circulatory route takes at least some of the blood past the gas exchange surfaces (e.g., gills) before returning to the heart.

One of the major evolutionary problems arising from the acquisition of a relatively impermeable exoskeleton involves gas exchange, particularly for terrestrial arthropods. On land, any increase in cuticular permeability to facilitate gas exchange also increases the threat of water loss. Remember that gas exchange surfaces not only must be permeable but also must be kept moist (see Chapter 3). Evolutionarily, the challenge for the arthropods becomes one of disrupting the integrity of the exoskeleton in such a way as to allow gas exchange without seriously jeopardizing the survival of the animal by abandoning the principal benefits of the exoskeleton.

The design of arthropod gas exchange structures has taken one form in aquatic groups and quite another in terrestrial taxa (Figure 20.32). The former is best exemplified by the crustaceans and the latter by the insects and terrestrial chelicerates. Some very tiny crustaceans (e.g., copepods) with a low surface-area-to-volume ratio exchange gases cutaneously across the general body surface or at thin cuticular areas such as articulating membranes. However, most of the larger aquatic crustaceans have evolved various types of gills in the form of thin-walled, hemolymph-filled cuticular evaginations. Gills are commonly branched or folded, providing large surface areas (Figure 20.32A). The gills of some crustaceans (e.g., euphausiacians) are exposed, unprotected, to the surrounding medium, whereas in others (e.g., crabs and lobsters) the gills are carried beneath protective extensions of the exoskeleton.

Terrestrial arthropods—the insects, myriapods, and arachnids, but also some terrestrial crustaceans—have evolved gas exchange structures in the form of invaginations of the cuticle, rather than the evaginations seen in aquatic crustaceans. Obviously, external gills would be unacceptable in dry conditions, but placed internally, these gas exchange structures remain moist and act as humidity chambers, allowing oxygen to enter solution for uptake. Many arachnids possess invaginations called **book lungs**, which are sacciform pockets with thin, highly folded walls called lamellae (Figure 20.32C). Hexapods, myriapods, and many arachnids possess inwardly directed branching tubules called **tracheae**, which open externally through pores called **spiracles** (Figure 20.32B). In insect tracheal systems

the inner ends of the tubules lie in the hemocoel or are embedded in organ tissues, allowing direct gas exchange between the air and the blood and internal organs. The tracheae of arachnids are probably not directly homologous with those of insects. Some terrestrial crustaceans (isopods) have **pseudotracheae** on the abdominal appendages; these structures are short, branching tubes that bring air close to the blood-filled spaces in these appendages (Figure 20.32D).

Excretion and Osmoregulation

With the evolution of a hemocoelic circulatory system in arthropods, nephridia with open nephrostomes became functionally untenable. It simply would not do to drain the blood directly from an open hemocoel to the outside. Arthropods have evolved a variety of highly efficient excretory structures that share a common adaptive feature in that they are internally closed. In addition to this major difference between the nephridia of arthropods and those of other coelomate protostomes, there has been a reduction in the overall number of excretory units.

In most adult crustaceans a single pair of nephridia (nephromixia) persists, usually associated with a particular segment of the head (i.e., as antennal glands or maxillary glands) (Figure 20.33A). In arachnids there may be as many as four pairs of nephridia (and in onychophorans, many more) opening at the bases of the walking legs (i.e., coxal glands).

A second type of excretory structure occurs in four terrestrial panarthropod taxa: arachnids, myriapods, insects, and tardigrades. These structures, known as **Malpighian tubules**, arise as blind tubules extending into the hemocoel from the gut wall (Figure 20.33C). However, anatomical and developmental evidence suggest that these Malpighian tubules may have evolved independently in each of these groups, representing yet another exemplary case of convergent evolution among the Arthropoda.

The excretory physiology of arthropods is a complex and extensively studied topic, and we present only a very general summary here. The various nephridial types of coelomic origin are functionally much more complex and efficient than open metanephridia. The uptake of materials from the hemocoel by the inner ends of these nephridia apparently involves passive movement in response to filtration pressure, as well as active transport. The fluid entering the nephridium is generally similar in composition to the hemolymph itself, but as it passes along the plumbing system of the nephridium, a good deal of selective reabsorption occurs, particularly of salts and nutrients such as glucose. Thus, the urine exiting the nephridial pores is markedly different from the hemolymph and represents a concentration of nitrogenous waste products (Figure 20.33B).

Malpighian tubules accomplish the same process, but they must rely on assistance from the gut.

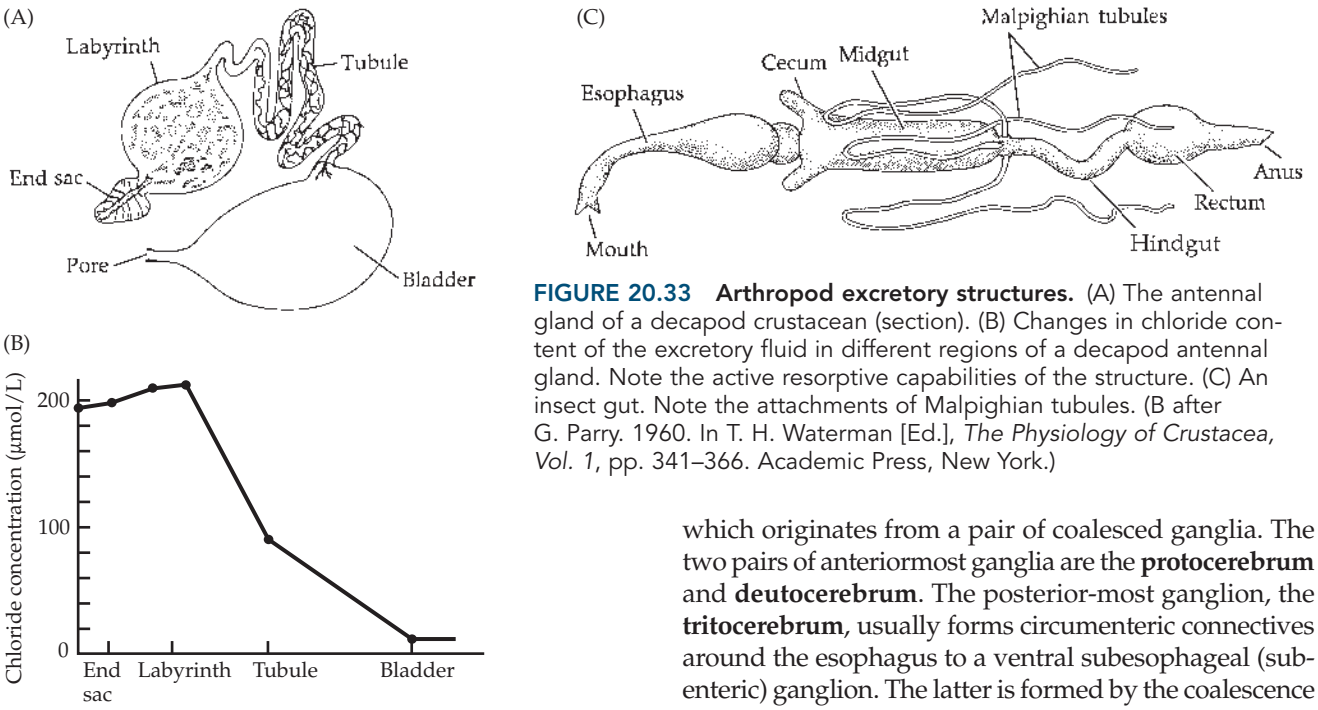

FIGURE 20.33 Arthropod excretory structures. (A) The antennal gland of a decapod crustacean (section). (B) Changes in chloride content of the excretory fluid in different regions of a decapod antennal gland. Note the active resorptive capabilities of the structure. (C) An insect gut. Note the attachments of Malpighian tubules. (B after G. Parry. 1960. In T. H. Waterman [Ed.], *The Physiology of Crustacea, Vol. 1*, pp. 341–366. Academic Press, New York.)

Malpighian tubule uptake from the hemocoel is relatively nonselective, and the resulting "primary urine" (containing nutrients, water, salts, and so on) is emptied directly into the gut. Very little reabsorption of non-waste material occurs along the length of the tubule itself. The hindgut is mostly responsible for concentrating the urine by reabsorbing the non-waste fractions. The ability of the gut to reabsorb water plays a critical role in osmoregulation in terrestrial and freshwater arthropods. Like most aquatic invertebrates, marine crustaceans excrete most (about 70%–90%) of their nitrogenous waste as ammonia; the remainder is excreted in the forms of urea, uric acid, amino acids, and some other compounds. Terrestrial arachnids, myriapods, and insects excrete predominantly uric acid (via the hindgut and anus). In Chapter 3 we reviewed some of the relationships between excretory products and osmoregulation in terms of adaptation to terrestrial habitats. The ability to produce large quantities of uric acid, and thus conserve water, has doubtless contributed significantly to the success of arachnids and insects on land. The crustaceans, on the other hand, have not been able to make a major shift from ammonotelism to uricotelism. Only the terrestrial crustaceans (i.e., isopods—woodlice and pillbugs) show a slight increase in uric acid excretion over that of their marine counterparts.

Nervous System and Sense Organs

The general plan of the arthropod nervous system is similar to that seen in many other protostomes, and many obvious homologies exist (Figure 20.34A). The arthropod brain (**cerebral ganglia**) comprises three regions, each of which originates from a pair of coalesced ganglia. The two pairs of anteriormost ganglia are the **protocerebrum** and **deutocerebrum**. The posterior-most ganglion, the **tritocerebrum**, usually forms circumenteric connectives around the esophagus to a ventral subesophageal (subenteric) ganglion. The latter is formed by the coalescence of several other head ganglia, usually those associated with the mandibles and maxillae in mandibulates. A double or single, ganglionated ventral nerve cord extends through some or all of the body segments. Each of these regions gives rise to a major pair of nerves to particular head appendages (Figure 20.34B,C). The regions have been used as the key landmarks to establish homology of the head appendages across arthropods—the famous "arthropod head problem." In extant arthropods, the protocerebrum innervates the eyes, whereas the deutocerebrum innervates the antennae (only the first antennae in Crustacea), the chelifores of pycnogonids, and the cheliceres of chelicerates. Recall that in onychophorans the protocerebrum innervates both the eyes and the antennae, and the deutocerebrum innervates the jaws.[6]

The segmental ganglia of the ventral nerve cord show various degrees of linear fusion with one another in different groups of arthropods. Hence, just as tagmosis is reflected in the joining of body segments externally, it is also apparent in the union of groups of ganglia along the ventral nerve cord. This pattern has been found in the oldest arthropod fossils. Modifications of the central nervous system are examined more closely in the following chapters on the arthropod subphyla.

Although the presence of an exoskeleton has had little evolutionary effect on the structure of the cerebral ganglia and nerve cord, it has had a major effect on the nature of sensory receptors. Unmodified, the exoskeleton would impose an effective barrier

[6] The concentration of nervous tissue in the arthropod head has been called a brain, cerebrum, cerebral ganglion, and cerebral ganglionic mass. Some of these terms may seem vertebrate derived, or might suggest the presence of a single head ganglion. In fact, the cerebral ganglia comprise a cluster of associated ganglia (concentrations of nervous tissue composed primarily of neuronal cell bodies)—hence the term *cerebral ganglia* is probably the most accurate.

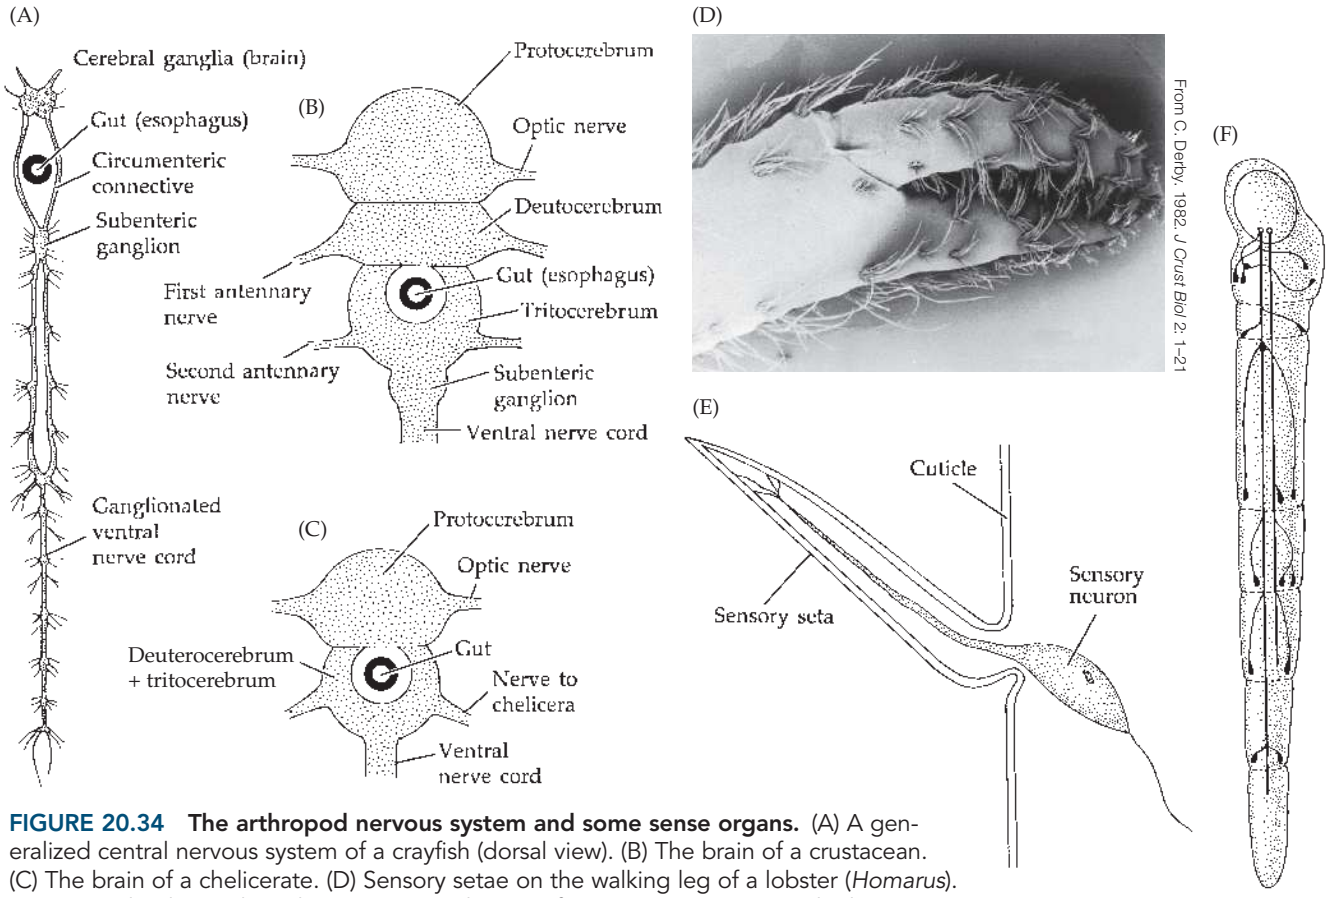

FIGURE 20.34 The arthropod nervous system and some sense organs. (A) A generalized central nervous system of a crayfish (dorsal view). (B) The brain of a crustacean. (C) The brain of a chelicerate. (D) Sensory setae on the walking leg of a lobster (*Homarus*). (E) A typical arthropod tactile seta. (F) Distribution of proprioceptors in a spider leg.

between the environment and the epidermal sensory nerve endings. Hence, most of the external mechanoreceptors and chemoreceptors are actually cuticular processes (setae, hairs, bristles), pores, or slits, collectively called sensilla.

Most arthropod tactile receptors (mechanoreceptors) are cuticular projections in the form of movable bristles or setae, the inner ends of which are associated with sensory neurons (Figure 20.34D,E). When the cuticular projections are touched, that movement is translated into a deformation of the nerve ending, thereby initiating a nerve impulse. Sensitivity to environmental vibrations is similar to tactile reception. Sensilla in the form of fine "hairs" or setae are mechanically moved by external vibrations and impart that movement to underlying sensory neurons. Some terrestrial arthropods bear thin, membranous cuticular windows overlying chambers lined with sensory nerves. When struck by airborne vibrations (e.g., sound), these windows vibrate in turn and impart the stimulus to the chamber and thence to the nerves below.

We have seen in soft-bodied invertebrates that chemoreception is usually associated with ciliated epithelial structures (e.g., nuchal organs, ciliated pits), across which dissolved chemicals diffuse to nerve endings. In arthropods, in the presence of a relatively impermeable cuticle and in the absence of free cilia, such arrangements are obviously not possible. Thus, many arthropods possess special thin or hollow setae, often associated with the head appendages, with permeable cuticular coverings or minute pores that bring the environment into contact with chemoreceptor neurons.

Proprioception is of particular importance to animals with jointed appendages, such as arthropods and vertebrates. The way in which these stretch receptors span the joints enables them to convey information to the central nervous system about the relative positions of appendage articles or body segments (Figure 20.34F). Through this system, an arthropod (or vertebrate) knows where its appendages are, even without seeing them. Arthropod versions of these "strain gauges" are called **campaniform sensilla** in hexapods, **slit sensilla** in arachnids, and **force-sensitive organs** in most crustaceans. Despite subtle differences in their anatomy, all are linked to the central nervous system in similar ways, and all record exoskeletal strain by means of neuronal stretching or deformation.

Arthropods possess three basic kinds of photoreceptors, including simple ocelli, complex lensed ocelli, and faceted or compound eyes. Ocelli were described in Chapter 3; although they vary in anatomical detail, their basic structure and operation is consistent in all invertebrates. Compound eyes, though found in all arthropod subphyla, have been lost or modified in various groups throughout the phylum. Because of their unique structure and function, compound eyes are described here in some detail. Importantly, the origin of compound eyes dates back at least to the lower

for more ebook/ testbank/ solution manuals requests, email me@qq.com

Cambrian, and a number of fossils from the early arthropod stem lineage had compound eyes.

As their name indicates, **compound eyes** comprise from a few to many distinct photoreceptive units, called **ommatidia**. Each ommatidium is supplied with its own nerve tracts leading to the major optic nerve, and each has its own field of vision through square or hexagonal cuticular facets on the eye surface. The visual fields of neighboring ommatidia overlap to some extent, such that a shift in the position of an object within the visual field generates impulses from several ommatidia; hence compound eyes are especially suitable for detecting movement. However, visual acuity is affected by the degree of overlap among the fields of vision of neighboring ommatidia—the greater the overlap, the poorer the visual acuity. In general, compound eyes with many small facets probably produce higher-resolution images than eyes with fewer, larger facets. Note that the function of an ommatidium is to concentrate light from a reasonably narrow direction into a receptor area, and an individual ommatidium cannot "focus" in the sense of image formation. Image formation is the result of multiple signals from multiple ommatidia.

Among living arthropods, two major types of compound eyes are known. In some mandibulates (crustaceans, hexapods, some myriapods) the ommatidia have a dioptric apparatus comprising a cuticular lens and a cellular crystalline cone usually made up of four cone cells. In the chelicerate horseshoe crabs, the cuticular lens has a conelike extension that serves to collect light and guide it to the **retinula** (= retinular element) cells.

The following discussion describes the structure and function of compound eyes, using the crustacean-hexapod (pancrustacean) model (Figure 20.35). Each ommatidium is covered by a modified portion of the cuticle called the **cornea** (= corneal lens); the special epidermal cells that produce the corneal elements are called **corneagen cells**. The corneagen cells may later withdraw to the sides of the ommatidium to form (usually two) **primary pigment cells** (= iris cells). When viewed externally, the facets on the surface of each cornea produce the characteristic mosaic pattern so frequently photographed by microscopists. The core of each ommatidium comprises a group of **crystalline cone cells** and the crystalline cone that they produce, sometimes a crystalline cone stalk, and a basal retinula. There are typically four (rarely three or five) crystalline cone cells; an ommatidium with a four-part crystalline cone is highly diagnostic of crustacean-hexapod eyes and is

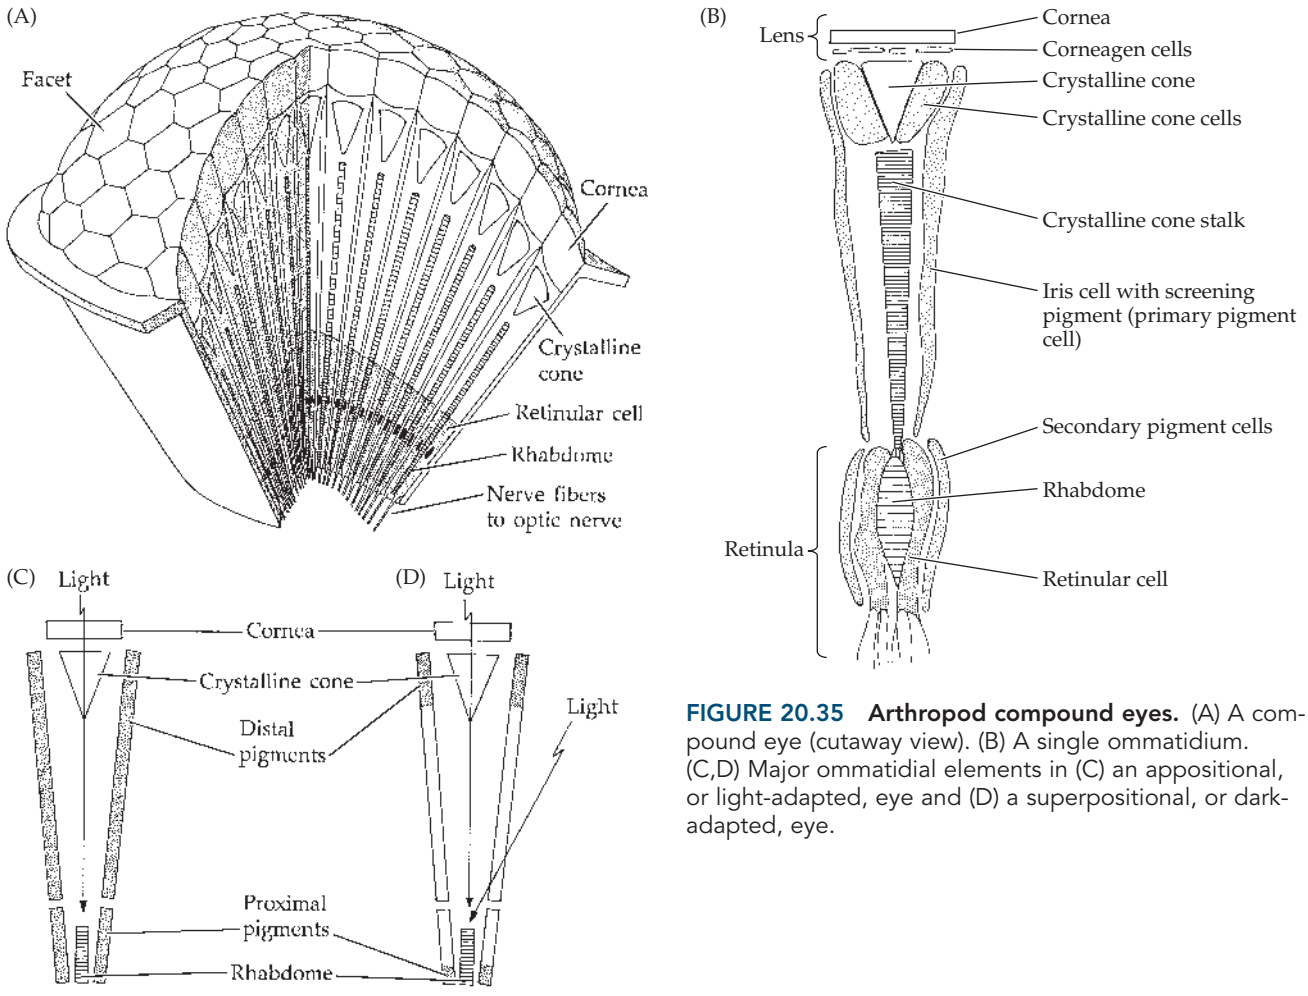

FIGURE 20.35 Arthropod compound eyes. (A) A compound eye (cutaway view). (B) A single ommatidium. (C,D) Major ommatidial elements in (C) an appositional, or light-adapted, eye and (D) a superpositional, or dark-adapted, eye.

termed a **tetrapartite ommatidium**.[7] The crystalline cone is a hard, clear structure bordered laterally by the primary pigment cells. The retinula is a complex structure formed from several retinular cells, which are the actual photosensitive units that give rise to the sensory nerve tracts. These retinular cells, usually numbering 8 but ranging from 5 to 13 in various derived conditions, are arranged in a cylinder along the long axis of the ommatidium. The retinular cells are surrounded by secondary pigment cells, which isolate each ommatidium from its neighbors. The core of the cylinder is the **rhabdome**, which is made up of rhodopsin-containing microtubular folds (microvilli) of the cell membranes of the retinular cells. Each retinular cell's contribution to the rhabdome is called a **rhabdomere**. The microvilli of the rhabdomeres extend toward the central axis of the ommatidium at right angles to the long axis of the retinular cell.

The initiation of an impulse depends upon light striking the rhabdome portion of the retinular element. Light that enters through the facet of a particular ommatidium is directed to its rhabdome by the lens-like qualities of the cornea and the crystalline cone. The lens has a fixed focal length, so accommodation to objects at different distances is not possible. Light is shared among all the rhabdomeres of a given rhabdome, although not necessarily equally.[8]

In contrast to those of insects and crustaceans, the lateral eyes of most myriapods are probably not true compound eyes, but clusters of simple ocelli. However, there is evidence that the eyes of scutigeromorph centipedes (and of some fossil myriapods) may be true compound eyes. The only chelicerates with typical compound eyes, the xiphosurans, have ommatidia that differ in most details from the insect-crustacean design. There is some evidence that the lateral eye groups of terrestrial chelicerates may be derived from reduced and fused compound eye ommatidia. The pigment cells are arranged in a cuplike manner, and the bottom of the "cup" is occupied by a sheet of cells secreting a protuberance of the cuticle, which is a functional but not a morphological equivalent of a crystalline cone. In fact, crystalline cones are generally regarded as an apomorphy unique to the Mandibulata (they do not occur in chelicerates). A special "eccentric cell"—a large specialized photoreceptor—found in chelicerate ommatidia has no equivalent in the insect or crustacean retina.

Compound eyes evolved early in arthropod history and were present in trilobites and many stem-group arthropods, including anomalocaridids. Compound eyes remarkably similar to modern ones have been described from 521-million-year-old trilobite fossils, although those had calcite lenses beneath the cuticle. The versatility of compound eyes is to a large degree a result of the distal and proximal screening pigments located in cells that wholly or partially surround the core of the ommatidium (Figure 20.35B–D). Distal screening pigments are located in the primary pigment cells (iris cells), and proximal pigments are often located in the retinular cells and secondary pigment cells. In many cases, these screening pigments are capable of migrating in response to varying light conditions and thus changing their positions somewhat along the length of the ommatidium. In bright light, the screening pigments may disperse so that nearly all of the light that strikes a particular rhabdomere must have entered through the facet of its ommatidium. In other words, the screening pigment prevents light that strikes the facets at an angle from passing through one ommatidium and into another. Many crustacean eyes are fixed in this condition. Such **appositional eyes** (= light-adapted eyes) are thought to maximize resolution, in that the image from the visual field of each ommatidium is maintained as a discrete unit. It is thought that even trilobite compound eyes were of the appositional type, and the overall similarity of trilobite eyes to those of the Mandibulata is evidence that Trilobita may hold a position along the stem lineage of mandibulates. Conversely, under conditions of dim light, screening pigments may concentrate, usually distally, thereby allowing light to pass through more than one ommatidium before striking rhabdomeres. The result is that the image formed by each ommatidium is superimposed on the images formed by neighboring ommatidia. This design has the advantage of producing enhanced irradiances on the retinula, but at the cost of reduced resolution. Many crustacean eyes are fixed in this condition also. Such **superpositional eyes** (= dark-adapted eyes) function as efficient light-gathering structures while sacrificing some visual acuity and image formation capabilities.

Some arthropod groups possess compound eyes that are always either appositional or superpositional; thus they lack the ability to switch back and forth with varying light conditions. For example, most "maxillopodans" and branchiopods apparently all possess appositional eyes. However, within the two principal malacostracan clades, Eucarida and Peracarida, both types of eyes occur (e.g., isopods and amphipods have appositional eyes, but mysidans have superpositional eyes). Furthermore, crustacean larvae that possess compound eyes almost always have the appositional type, which metamorphose into superpositional eyes in those groups that possess them in adulthood.

Among the arthropods, compound eyes elevated on stalks occur mostly in certain crustaceans (and perhaps a few Paleozoic trilobites and anomalocaridids). Stalked eyes also occur in at least one genus of insects, *Scopiastes* (Hemiptera), the stalk-eyed bugs. And a species of *Drosophila* in Hawaii also has stalked eyes. Biologists

[7] The crystalline cone cells are often called Semper cells (especially by entomologists).

[8] The compound eyes of multiple groups of crustaceans, formerly grouped as the maxillopodans, differ considerably from those of other crustaceans; see Chapter 21.

have long argued over the derivation of such stalked eyes, and the matter is still far from settled—are they the primitive condition in arthropods or in crustaceans, or have they been derived multiple times from unstalked, sessile-eyed ancestors (the latter seems far more likely). The eyestalk is much more than a device to support and move the eye. Eyestalk movements are produced by up to a dozen or more muscles with complex motor innervation. In most malacostracans the eyestalks contain several optic ganglia separated by chiasmata, as well as important endocrine organs, usually including the sinus gland and X-organ. Thus, neither loss of eyestalks nor convergent recreation of these structures would have been a simple evolutionary feat. The loss of functional eyes is a common evolutionary pathway among the Crustacea (and other arthropods), especially in species that inhabit subterranean, deep-sea, or interstitial habitats. But among those clades with stalked eyes, the eyestalk remains even when the eye itself degenerates—testimony to the importance of this complex bit of anatomy.

Reproduction and Development

The great diversity of adult form and habit among arthropods is also reflected in their reproductive and developmental strategies. The extreme evolutionary and ontogenetic plasticity of arthropods has led to a great deal of convergence and parallelism as different groups have developed similar structures under similar selective conditions or pressures.

Nearly all arthropods are gonochoristic, and most engage in some sort of formal mating. Fertilization is usually, although not always, internal and is often followed by brooding or some other form of parental care, at least during early development. Development is frequently mixed, with brooding and encapsulation followed by larval stages, although direct development occurs in many groups.

Arthropod eggs are centrolecithal (Figure 20.36), but the amount of yolk varies greatly and results in different patterns of early cleavage. Cleavage is holoblastic in the relatively weakly yolked eggs of xiphosurans, some scorpions, and various crustaceans (e.g., copepods and barnacles) and is meroblastic in the strongly yolked eggs of most insects and many other crustaceans. A number of arthropods exhibit a unique form of meroblastic cleavage that begins with nuclear divisions within the yolky mass. These intralecithal nuclear divisions are followed by a migration of the daughter nuclei to the periphery of the cell and subsequent partitioning of the nuclei by cell membranes. These processes typically result in a periblastula that consists of a single layer of cells around an inner yolky mass. Holoblastic cleavage is usually more or less radial in appearance.

One of the most striking features of arthropods is their segmentation and the complex way in which it is embryologically derived. This developmental process is very similar to that seen in annelids (and in onychophorans), and until the advent of molecular phylogenetic techniques, it was taken as evidence of a close annelid-arthropod shared ancestry. The process is called **teloblastic segmental growth** (or simply teloblasty) (Greek *telos*, "end"; *blasto*, "bud"). It is characterized by a progressive, anterior-to-posterior addition of segments from a distinct posterior growth zone situated near the anus (i.e., in front of the terminal, or anal, segment—often called the **telson** or **pygidium**). So programmed is the development of the segments that the growth zone is often composed of a fixed number of uniquely identifiable stem cells (**teloblasts**) whose progeny undergo a predictable and stereotyped sequence of segmentally iterated cell divisions. Teloblasty is further characterized by the formation of secondary body cavities (coelomic cavities) at the growth zone as segments are elaborated. In arthropods, the adult body cavity is derived from the fusion of the blood vascular system with these transitory

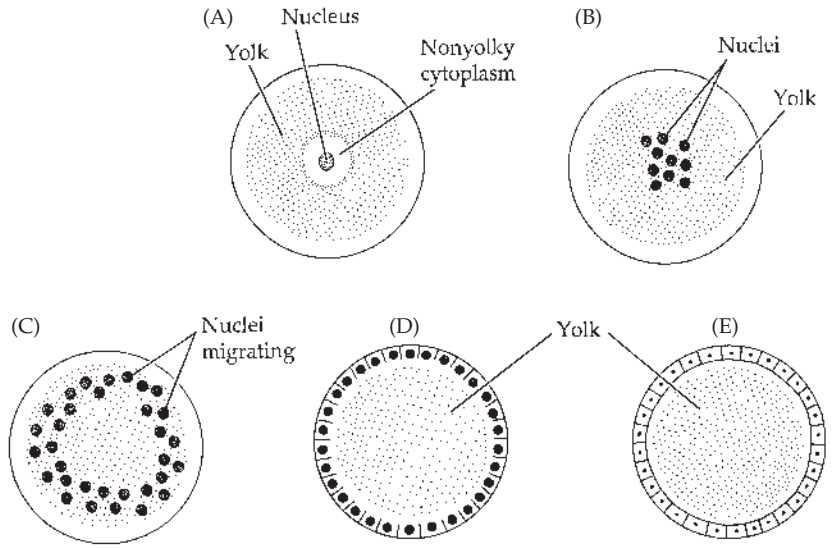

FIGURE 20.36 Superficial cleavage of a centrolecithal egg and the formation of a periblastula in arthropods. (A) Centrolecithal egg. (B) Intralecithal nuclear divisions following fertilization. (C) Migration of nuclei to the periphery of the cell. (D,E) The periblastula is produced by a partitioning of nuclei as cell membranes form.

embryonic coelomic cavities. Although the coelomic cavities are secondarily lost during arthropod embryogenesis, they form by way of schizocoely, originating from a pair of caudally situated mesodermal cell bands. These bands have long been thought to originate from a 4d (mesentoblast) cell, as in annelids, but in fact there is little evidence for this. Adding further nuance to all this is the fact that in some arthropods the appearance of new segments is not completed by the end of embryogenesis, but continues after hatching, in some cases up to the last postembryonic molt. This protracted addition of body segments is called **anamorphosis (**the opposite, hatching with the complete number of segments, is called epimorphosis). In addition, the widespread, α-proteobacterium symbiont *Wolbachia* infects species in all living subphyla of arthropods, and estimates suggest about two-thirds of all arthropod species can be infected with *Wolbachia*. The bacterium is normally transmitted vertically, from mother to offspring, and it manipulates the host's reproduction through a broad variety of mechanisms.

Not only do the segments form in a similar fashion in annelids and arthropods, but the two groups also appear to use a similar genetic mechanism (especially the products of the *engrailed* gene) to define segmental boundaries and polarity. The *engrailed* (*en*) gene belongs to a class of genes known as segment polarity genes. It plays a key role in determining and maintaining the posterior cell fates of segmental structures in all arthropods (and in annelids and onychophorans). Because this gene occurs in iterated transverse stripes in the posterior portion of each developing segment in the germ band of all annelids and arthropods, it can be used to clarify ambiguities in segment position and number. Embryonic *Hedgehog* signaling pathways also play similar roles in annelids and arthropods, in both cases playing a crucial role in the axial patterning of developing segments.

In arthropods, the transitory embryonic coelomic cavities are lined with simple epithelium, but this gradually disappears as the embryo develops, and the large adult body cavity comes to be lined by an extracellular matrix. Hence, the body cavity of adult arthropods is derived by the fusion of a primary body cavity (the blood vascular system) and a secondary body cavity (the coelom) and is therefore termed a hemocoel (or mixocoel). Segmentally arranged pairs of transitory coelomic cavities, and their embryonic fusion, have been reported in the early developmental stages of virtually every onychophoran and arthropod that has been studied.

The Evolution of Arthropods

The Origin of Arthropods

In 1997, a groundbreaking analysis of animal phylogeny based on 18S rRNA sequence data led Maria Aguinaldo and her colleagues to propose a new hypothesis of arthropod relationships—that they belong to a clade of animals that we now know also includes nematodes, nematomorphans, kinorhynchs, priapulans, and loriciferans (as well as tardigrades and onychophorans), but *not* annelids. The newly recognized clade was called **Ecdysozoa**. The idea of this clade of molting animals was perhaps first suggested by R. S. K. Barnes and his colleagues in their 1988 text on invertebrates. Today, scores of molecular phylogenetic studies support this view of animal relationships, and it is broadly accepted that the protostomes comprise two main clades: Ecdysozoa and Spiralia. One of the most revolutionary outcomes is compelling evidence that Annelida and Panarthropoda are not sister groups (a long-held hypothesis based on morphological and developmental studies). This modern view of animal relationships stimulated new morphological and developmental investigations, and significant differences between the annelids and arthropods have emerged, the most obvious being fundamental differences in the adult body cavity and cleavage patterns during embryogenesis. However, the relationships among the three main clades within Ecdysozoa are still uncertain, and we depict the clade Panarthropoda as an unresolved trichotomy with the other two ecdysozoan clades—Nematoida and Scalidophora—on our phylogenetic tree of Metazoa (Chapter 28).

Evolution within the Arthropoda

Molecular clock estimates place the origin of Arthropoda at around 600 million years ago, give or take. They were among the earliest animals to leave a good fossil record, and even the Ediacaran fauna of the Neoproterozoic Era included animals regarded by many as stem arthropods, some of which had stalked eyes as in modern Crustacea. Today, with nearly 1.2 million described species, arthropods are arguably the most successful animal phylum on Earth. They encompass an unparalleled range of structural disparity and taxonomic diversity, have a rich fossil record, and have become favored study animals of evolutionary developmental biology. Some arthropod "model systems" (e.g., *Drosophila melanogaster*) have been studied intensively for many decades and are among the best-known animals genetically and developmentally. For all these reasons, we know a lot about arthropods.

Speculating on arthropod evolution has been a favorite pastime of zoologists for centuries. Every imaginable pattern of relationship has been proposed among the crustaceans, hexapods, chelicerates, and myriapods at one time or another. However, since the 1980s a virtual explosion of new information on this phylum has appeared, much of it concerning phylogeny, paleontology, gene expression, and developmental biology. If we examine the evolution of arthropods in light of these discoveries, especially recent genomic analyses, the phylogeny of the Arthropoda shown in Figure 20.39 is apparent. Extant arthropods comprise two clades, Chelicerata and Mandibulata, the latter including the myriapods and pancrustaceans. Mandibulates are named for their

for more ebook/ testbank/ solution manuals Request to email me at 9601267340@qq.com

homologous biting appendages, whereas in chelicerates the homologous pair of appendages are walking legs. The split between these two large arthropod clades probably dates to the Ediacaran. The Mandibulata, in turn, comprise the sister groups Myriapoda and Pancrustacea, the latter composed of the Crustacea and Hexapoda. The Hexapoda arose from within crustaceans, making Crustacea a paraphyletic group (hence the more inclusive, monophyletic group name "Pancrustacea"). The sister group of Hexapoda appears to be the remipede crustaceans. The Remipedia, with homonomous segmentation in the trunk, were once thought to have arisen near the base of the crustacean tree, but recent phylogenetic work suggests they arose higher in the pancrustacean tree. The hexapod-remipede clade is named Labiocarida (both groups having a functional labium), and branchiopods are a likely sister group to labiocarids.

Some of the most important ancient arthropod fossils are those in which even the soft parts of the animal were preserved—the so-called ancient *Lagerstätten*, such as the faunas of the late Cambrian Orsten deposits of Sweden, the middle Cambrian Burgess Shale of Canada (and elsewhere), and the early Cambrian Chengjiang deposits of China. Recent discoveries from these well-preserved deposits have shown that the fossil record of Crustacea and Pycnogonida date to at least the early Cambrian and possibly to the late Precambrian. In 2015, Ma and colleagues described the brains of an early Cambrian (517 Ma) shrimplike crustacean, *Fuxianhuia protensa*, that were basically identical to those of modern crustaceans. And in 2017, the oldest known arthropod with supposed mandibles was described and named (*Tokummia katalepsis*) from 508-million-year-old fossils in British Columbia (Canada). If this arthropod was truly a mandibulate (a fact that has been debated in the recent literature), these extraordinary faunas are now informing us that crustaceans possibly predate the appearance of trilobites in the fossil record.

The Chengjiang fauna includes around 100 species of animals, many without hard skeletons, including the first known members of many modern groups. However, it is the arthropods that dominate this fauna, including trilobites and bradoriid crustaceans (and also lobopodians with possible affinities to tardigrades and onychophorans). The largest of the Chengjiang animals are the anomalocaridids, stem arthropods that were common during the mid-Cambrian and are also known from a single described species (*Schinderhannes bartelsi*) from the Early Devonian Hunsrück Slate of Germany. Some anomalocaridids reached 2 m in length; most were predators, but some were probably suspension feeders. The Chengjiang fauna is very similar to that of the slightly older Burgess Shale, and it demonstrates that the arthropods were already far advanced by this early date. In fact, arthropods may have been the dominant animals in terms of species diversity since the Cambrian, and they constitute over one-third of all species described from lower Cambrian strata.

The spectacular research by Klaus Müller and Dieter Waloszek since the 1980s on microscopic arthropods from the Cambrian Orsten deposits of Sweden (Cambrian Epoch 3) has brought to light a rich fauna of crustaceans, many of which are onychophoran-like lobopodians, possibly stem tardigrades and pentastomids, or closely resemble modern cephalocarids, mystacocarids, and branchiopods. Orsten-type preservation is a secondary phosphatization of the upper cuticle, apparently occurring soon after death of the animal, as no further destruction takes place. Such preservation can produce exquisite three-dimensional fossils with all the details of eyes, limbs, setae, cuticular pores, and other structures less than a micrometer in size. It generally occurs with a postmortem embedding of the animals in limestone (that later formed into nodules). Since the fossils themselves are phosphatized, they can be etched from their surrounding limestone rock with weak acids. Orsten-type fossils are now known from several continents from the early Cambrian (around 520 Ma) to the mid-Cretaceous (100 Ma). The recovery of these three-dimensionally preserved animals and the developmental series that have been found (with successive larval, juvenile, and adult stages) have provided us with information on the detailed anatomy of the body segments and appendages of many ancient stem arthropods and crustaceans. The Orsten fauna shows that Cambrian Crustacea had all the attributes of modern crustaceans, such as compound eyes, a head shield, naupliar larvae (with locomotory first antennae), and biramous appendages on the second and third head somites (i.e., the second antennae and mandibles).

A modern view of arthropod phylogeny thus places a panorama of crustacean-like early Cambrian lineages at its base—a diverse array of early arthropods that had typical crustacean, or crustaceamorphan, bodies, eyes, development, and naupliar larvae, though perhaps with a smaller number of fused head somites than seen in modern Crustacea. Early in the Cambrian, the trilobites may have emerged from this crustaceamorph stem line, radiating rapidly to become the most abundant arthropods of Paleozoic seas, but then abruptly disappearing in the Permian-Triassic extinction. Next to appear were probably the chelicerates, in the form of giant marine water scorpions nearly 3 m long (eurypterids) and their kin, which had appeared at least by the Ordovician; by the Silurian, eurypterids had probably become keystone predators in the marine realm. Also by the Silurian, the chelicerates had invaded land and begun to leave a fossil record of terrestrial arachnids. By the Late Ordovician or early Silurian the first myriapods had evolved, perhaps marine creatures, and about 15 million years later terrestrial millipedes appear in the fossil record. The last major arthropod group to appear was the hexapods, making their appearance in the Devonian, or perhaps the Silurian, and radiating rapidly to dominate the terrestrial world, ultimately qualifying the Cenozoic to be called "the age of insects."

The relationship of trilobites to living arthropods is still being debated (Figures 20.37 and 20.38). The two main opposing views see them as close to either the Chelicerata or the Mandibulata. Our view, in contrast, positions them as one of many extinct lineages stemming from a crustaceamorph stem-line ancestry (Figure 20.39).

Arthropods are the first land animals for which we have a paleontological record. The first land arthropods appeared in the Late Ordovician or Early Silurian (arachnids, millipedes, centipedes), and these fossils represent the first terrestrial invertebrates for which we have direct evidence. Indeed, animal life on land might not have been possible before the Late Ordovician, when terrestrial plants first made their appearance. The first insects in the fossil record are 390-million-year-old Devonian springtails (Collembola) and bristletails (Archaeognatha). By the mid-Paleozoic all four living arthropod subphyla were in existence and had already undergone substantial radiation. By the Middle Devonian, centipedes, millipedes, mites, amblypygids, opilionids, scorpions, pseudoscorpions, and hexapods were all well established. Hence, terrestrial arthropods seem to have undergone major radiations in the Silurian. The presence of a wide variety of predatory terrestrial arthropods during the early Paleozoic suggests that complex terrestrial ecosystems were in place at least as early as the late Silurian. However, interestingly, molecular dating studies suggest the origin of terrestrial arthropods much earlier, as early as 510 million years ago, in the mid-Cambrian.

Work by the great comparative biologist Robert Snodgrass in the 1930s established a benchmark in arthropod biodiversity research. The Snodgrass classification embraced three important hypotheses: (1) arthropods constitute a monophyletic taxon; (2) myriapods and hexapods are sister groups, together forming a taxon called Atelocerata (= Tracheata, or Uniramia of some authors); and (3) Crustacea and Atelocerata are sister groups, together forming a taxon called the Mandibulata. Snodgrass united the Atelocerata on the basis of several attributes: a tracheal respiratory system, uniramous legs, Malpighian tubules for excretion, and loss of the second antennae (as the name Atelocerata implies). The Mandibulata were united on the basis of the mandibles (which are almost certainly homologous in these taxa) and a similar head and head appendage structure.

It was not until the late 1980s that Snodgrass's long-standing view of arthropod relationships began to be questioned. While the Mandibulata is still supported as a monophyletic group, it now appears almost certain that Hexapoda arose from somewhere within Crustacea, a clade called Pancrustacea, and this then is the sister group to the Myriapoda. It turns out that Snodgrass, and others, were misled by the similarities between myriapods and hexapods, which are now assumed to be convergences (or parallelisms) resulting from adaptations to terrestrial habitats. Recent phylogenomic analyses suggest the sister group of Hexapoda is Remipedia, although remipedes are all restricted to the marine environment today and there is as yet no paleontological evidence that they invaded land in the past. While we treat "Crustacea" as a subphylum in this book, remember

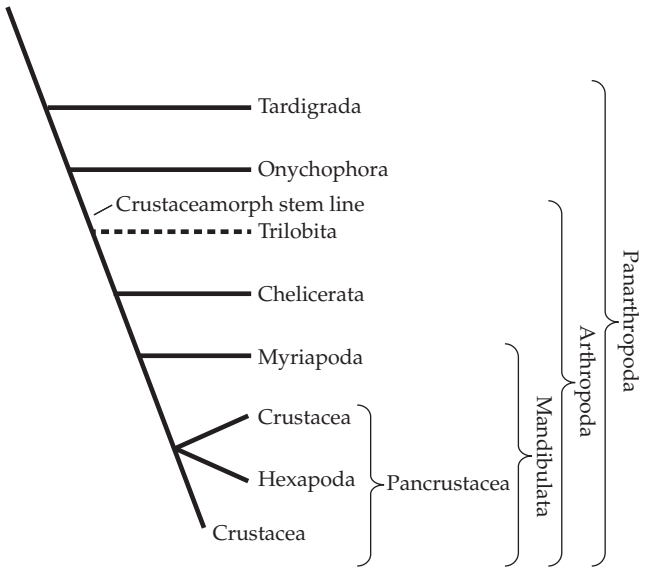

FIGURE 20.39 A phylogeny of the Panarthropoda. Based on a synthesis of paleontological and phylogenetic studies, the arthropods are seen to be rooted in a crustacean-like ancestral line, from which the living subphyla emerged. The subphylum Crustacea is paraphyletic (unless the Hexapoda are included). The position of the Trilobita is uncertain. See text for details.

that the discovery that insects are "flying crustaceans" makes the subphylum Crustacea a paraphyletic group (as long as the Hexapoda are excluded).[9]

Research in the field of developmental biology and gene expression has shown that the Arthropoda are rich with homoplastic characters, and it is now clear that much of the difficulty in reconciling earlier phylogenies based on morphological characters was due to the high levels of parallel evolution seen within the Arthropoda. For example, many characters shared between hexapods and myriapods, which in the past had been assumed to be synapomorphies, are now interpreted as parallelisms (or convergences), including such things as the tracheal gas exchange system, uniramous legs, Malpighian tubules, organs of Tömösvary, loss of the second antennae, and loss of mandibular palps.

The rigid, compartmentalized bodies of arthropods have allowed for body region specialization unavailable to most other metazoan phyla. The fates of segmental units and their appendages are under the ultimate orchestration of Hox and other developmental genes. These genes select the critical developmental pathways followed by groups of cells during morphogenesis. Hox genes determine such basic body architecture as the dorsoventral and anterior–posterior body axes and where body appendages form. Hox genes can either suppress limb development or modify it to create different appendage morphologies. These unique genes have played major roles in the evolution of new body plans among arthropods (and the Metazoa in general). The degree to which such developmental genes have been conserved is remarkable, and most of them probably date back at least to the Cambrian. For example, homologues of the developmental gene *Pax-6* seem to dictate where eyes will develop in all animal phyla. *Pax-6* is so similar in protostomes (e.g., insects) and deuterostomes (e.g., mammals) that their genes can be experimentally interchanged and still function more or less correctly.

It has been known since the late nineteenth century that the compound eyes of hexapods and crustaceans possess many complex homologous features and that they differ markedly from the eyes of myriapods and chelicerates. Recall that in hexapods and crustaceans, each ommatidium consists of a cuticular corneal lens that is, at least partly, secreted by two cells—termed primary pigment cells in Hexapoda and corneagen cells in Crustacea. The crystalline cone, produced by four Semper cells, is fundamentally tetrapartite. A retinula is present, typically composed of eight retinular cells. This common anatomical plan is unique to the Hexapoda + Crustacea and constitutes strong evidence of a close relationship between the two groups. Dohle (2001) even proposed a name on this basis for the clade, the "Tetraconata," although the name "Pancrustacea" has had more popularity.[10]

Recent research on the anatomy and development of the arthropod central nervous system has identified many other neurological features that appear to be unique to the Hexapoda + Crustacea. In fact, Strausfeld (1998) developed a phylogeny of the Arthropoda based solely on the abundant anatomical features of the cerebral ganglia. In particular, numerous anatomical similarities exist in the elements of the optic lobes and "midbrain." Developmental similarities suggest a fundamental distinction between embryonic development in the hexapod + crustacean central nervous system and in that of myriapods and chelicerates. In hexapods and crustaceans, development of the CNS begins with the delamination of enlarged cells, called neuroblasts, from the ectoderm (neuroectoderm) of each segment. The neuroblasts aggregate to form the segmental ganglia. The formation of neuroblasts is highly stereotyped and predictable in both Crustacea and Hexapoda. These large neuroblasts are of a special type, regarded as stem cells, and they divide unequally to generate a specific number of neurons. So far, 29–31 neuroblasts have been identified in each segment of hexapods and 25–30 in crustacean segments, many of which appear to be homologous between the two subphyla. Nothing resembling these stem cell neuroblasts has been seen in myriapods. In both hexapods and crustaceans, longitudinal connectives of the CNS originate in the segmental neurons, whereas in myriapods they derive from neurons in the cerebral ganglia that send their axons posteriorly to set up long parallel connectives. Thus, myriapod segmental ganglia receive contributions from more widely distributed neurons.

Their great size range, especially at the smaller end of the scale, allows arthropods to adapt to a great variety of ecological niches. The Cambrian Orsten deposits inform us that a whole fauna of interstitial/meiofaunal arthropods already existed as early as the mid-Cambrian, and this habitat has continued to be rich in adaptive radiation

[9] Although the idea of a Crustacea-Hexapoda sister-group relationship may seem new to many, the idea was actually proposed at the turn of the twentieth century, when William T. Calman presented detailed arguments from comparative anatomy that argued for an alliance between the Crustacea and the Hexapoda.

[10] Although tetrapartite ommatidia appear to be restricted to the Hexapoda and Crustacea, they may not be a synapomorphy for this clade. We don't yet know when the tetrapartite condition first appeared within the Crustacea or the Arthropoda, but it probably was well before the insects emerged (perhaps in the early Cambrian crustacean stem line). Crustacean fossils from Cambrian Lagerstätten deposits have eyes that strongly resemble modern crustacean eyes, at least superficially. In any case, tetrapartite ommatidia are probably a symplesiomorphy retained in both Hexapoda and crown Crustacea (their transformation in myriapods perhaps being a synapomorphy defining that clade). The compound eyes of xiphosurans are very different from those of other Arthropoda, suggesting they might have evolved apart from the tetrapartite condition seen in Crustacea and Hexapoda (or that they are somehow derived from the crustacean tetrapartite condition).

for more ebook/ testbank/ solution manuals Request to email 9601267340@qq.com

and specialized species ever since. Similar small-body-size niches are filled by arthropods in a great many environments today. We find high diversities of minute arthropods in habitats such as marine sediments, coral reefs, among the fronds of algae, on mosses and other primitive plants, and on the bodies of every kind of animal imaginable. Small insects and mites have exploited virtually every terrestrial microhabitat available. And some of the arthropods (the insects) were presumably the first flying animals, and the ability to fly also led them into niches that other invertebrates simply could not penetrate.

Chapter Summary

Now you are familiar with the wide world of Panarthropoda—the phyla Arthropoda, Tardigrada, and Onychophora. The clade Panarthropoda is characterized by metamerism, reduced coeloms and a hemocoel, ecdysis (molting), muscles isolated in bands (although only weakly so in the tardigrades and onychophorans), and paired ventrolateral segmental appendages with terminal "claws." All Panarthropoda have a ganglionic supraesophageal brain, but the numbers of pairs of ganglia differ among the three phyla: tardigrades have one pair, onychophorans have two pairs (protocerebrum and deutocerebrum), and arthropods have three pairs (protocerebrum, deutocerebrum, tritocerebrum).

Only the phylum Arthropoda has complete "arthropodization," with the body fully segmented (externally and internally) and with segmental sclerites, and the appendages segmented and divided into articles/podomeres separated by arthrodial membranes and with intrinsic musculature. Complete arthropodization also includes tagmosis, in which body segments are regionalized as head + trunk, or head + thorax + abdomen; head (and sometimes thorax) may be covered by a shield or carapace; strong cephalization, with compound eyes; and extreme specialization of appendages.

With an estimated 1,196,816 named living species (995,816 of which are hexapods), the phylum Arthropoda is far and away the largest animal phylum (Mollusca comes in a distant second, with about 73,000 species). Arthropods include four living subphyla: Myriapoda, Chelicerata, Crustacea, and Hexapoda. However, because hexapods (insects and their close relatives) arose from among the crustaceans, Crustacea is a paraphyletic group; the two subclasses together comprise the clade Pancrustacea. Arthropods occur in virtually every environment on Earth, exploiting every imaginable lifestyle. Modern forms range in size from microscopic mites and crustaceans less than 1 mm long, to Japanese spider crabs (*Macrocheira kaempferi*) with leg spans that reach nearly 4 m. Arthropoda is an old group, with Ediacaran fossils likely representing stem arthropods.

Tardigrades are found in aquatic and semiaquatic habitats such as the water film on plants, or in soil and forest litter. Others live in freshwater or marine benthic habitats, often interstitially or among shore algae. Some species live in hot springs. Some marine species are commensals or ectoparasites on other invertebrates. Tardigrades can occur in high densities, up to 300,000 per square meter in soil and more than 2 million per square meter in moss. All are small, usually on the order of 0.1–0.5 mm in length, although some l.3 mm giants have been reported. They are famous for their powers of anabiosis (dormancy) and cryptobiosis (extreme dormancy, in which all external signs of metabolism are absent), as well as the production of a cryptobiotic tun stage. Embryos of one species, *Milnesium tardigradum*, were kept for three months in an outer space hatch and had 100% survival rate after rehydration. Tardigrades have short bodies and four pairs of telescoping lobopodal legs. Free-living species feed on plant or animal cell fluids, bacteria, or algae or decaying plant matter or as predators on small invertebrates. They lack discrete blood vessels, gas exchange structures, or nephridia.

Onychophorans are all terrestrial and are the only animal phylum without aquatic species. They are an old group that has changed very little over the past 310 million years. They have 13–43 pairs of legs and range in length from 5 to 150 mm. Although resembling arthropods in many ways, onychophorans have unjointed, fleshy head appendages and rather unique jaws and lobopodal legs. They are primarily carnivores on small invertebrates, and they have special slime glands that open at the ends of the two oral papillae to discharge powerful jets of fast-drying glue that entangles prey or possible predators. The circulatory system is well developed, and a pair of nephridia lies in each leg-bearing body segment (except the genital segment).

CHAPTER 21

Phylum Arthropoda

Subphylum Crustacea: Crabs, Shrimps, and Their Kin

Crustaceans are one of the most popular invertebrate groups, even among nonbiologists, for they include some of the world's most delectable gourmet fare, such as lobsters, crabs, shrimps,[1] and goose barnacles. There are about 72,000 described living species of Crustacea, and probably five times that number waiting to be discovered and named. They exhibit an incredible diversity of form, habit, and size (Figure 21.1). The smallest known crustaceans are less than 100 μm in length and live on the antennules of copepods. The largest are Japanese spider crabs (*Macrocheira kaempferi*) with leg spans of 4 m, and giant Tasmanian crabs (*Pseudocarcinus gigas*) with carapace widths of nearly a half-meter. The heaviest crustaceans are probably American lobsters (*Homarus americanus*) that, before the present era of overfishing, attained weights in excess of 20 kg. The world's largest land arthropod by weight (and possibly the largest land invertebrate) is the coconut crab (*Birgus latro*), weighing in at up to 4 kg, and the largest freshwater invertebrate is the Tasmanian giant freshwater crayfish (*Astacopsis gouldi*) or *lutaralipina* in Tasmanian Aboriginal language. Crustaceans are found at all depths in every marine, brackish, and freshwater environment, including in pools at 6,000 m elevation (fairy shrimp and cladocerans in northern Chile). A few have become successful on land, the most notable being sowbugs and pillbugs (the terrestrial isopods) and species in several groups of Brachyura (crabs). Beginning

[1] When most people hear the word "shrimp," they think of edible shrimps, two crustacean groups nested within the order Decapoda (in the suborders Dendrobranchiata and Pleocyemata). However, the term "shrimp" is applied to a number of long-tailed crustaceans, many not closely related at all to decapods. So, in this general sense, there are fairy shrimps, tadpole shrimps, mantis shrimps, etc. In much of the English-speaking world, the word "prawn" is used for the edible shrimps, thus eliminating some of the confusion.

Classification of The Animal Kingdom (Metazoa)

early in the twenty-first century, negative effects of ocean acidification on crustaceans began to be recognized, especially on the larval stages and subadults (see Selected References section).

Crustaceans are commonly the dominant organisms in aquatic subterranean ecosystems, and new species of these stygobionts continue to be discovered as new caves are explored. They also dominate ephemeral pool habitats, where many undescribed species are known to occur.[2] And crustaceans are the most widespread, diverse, and abundant animals inhabiting the world's oceans. The biomass of one species of Euphausiacea, the Antarctic krill (*Euphausia superba*), has been estimated at 500 million tons at any given time, probably surpassing the biomass of any other group of marine animals (and rivaling that of the world's ants, summing up all their species!). In fact, krill are the dominant fished species in the Southern Ocean in terms of catch weight. The range of morphological disparity among Crustacea far exceeds that of even the insects. Many species of crustaceans are threatened by environmental degradation; over 3,000 are listed on the IUCN Red List, and about two dozen are protected by the U.S. Environmental Protection Agency. Crustaceans are also among the most common invasive invertebrates, and well over 100 invasive species have established themselves in marine and estuarine waters of North America alone.

Because of their taxonomic diversity and numerical abundance, it is often said that crustaceans are the "insects of the sea." We prefer to think of insects as "crustaceans of the land." And indeed, there is now very strong phylogenetic evidence that insects arose from a branch within the Crustacea and this larger clade is known as **Pancrustacea** (or **Tetraconata**).

[2]One study of ephemeral pools in Northern California discovered 30 probable undescribed/unnamed crustacean species (King et al. 1996).

Despite the enormous morphological disparity seen among crustaceans (Figures 21.1–21.20), they display a suite of fundamental unifying features (Box 21A). In an effort to introduce both the diversity and the unity of this enormous group of arthropods, we first present a classification and synopses of the major taxa. We

BOX 21A Characteristics of the Subphylum Crustacea

1. Body composed of a six-segmented head, or cephalon, and a long postcephalic trunk; trunk divided into two more or less distinct tagmata (e.g., thorax and abdomen) in all but the remipedes and ostracods (Figure 21.2)
2. Cephalon composed of (anterior to posterior) ocular or protocerebral segment (lacking appendages), antennular segment (deutocerebral), antennal segment (tritocerebral), mandibular somite, maxillulary somite, and maxillary somite; one or more anterior thoracomeres fused with the head in some members of some classes (e.g., Remipedia and Malacostraca), their appendages forming maxillipeds
3. Cephalic shield or carapace present (highly reduced in anostracans, amphipods, and isopods)
4. Appendages multiarticulate, uniramous or biramous
5. Mandibles usually multiarticulate limbs that function as biting, piercing, or chewing/grinding jaws
6. Gas exchange by aqueous diffusion across specialized branchial surfaces, either gill-like structures or specialized regions of the body surface
7. Excretion by structures derived from nephridia (e.g., antennal glands, maxillary glands)
8. Both simple ocelli and compound eyes in most taxa (not Remipedia), at least at some stage of the life cycle; compound eyes often elevated on stalks
9. Gut with digestive ceca
10. With nauplius larva (unknown from any other arthropod subphylum); development mixed or direct

then discuss the biology of the group as a whole, drawing examples from its various members. As you read this chapter, we ask that you keep in mind the general account of arthropods presented in Chapter 20.

Classification of the Crustacea

Crustaceans have been known to humans since ancient times and have provided us with sources of both food and legend. It is somewhat comforting to carcinologists (those who study crustaceans) to note that Cancer, one of the two invertebrates represented in the zodiac, is a crab (the other, of course, is Scorpio—another arthropod). Our modern view of Crustacea as a taxon can be traced to Lamarck's scheme in the early nineteenth century. He recognized most crustaceans as such but placed the barnacles and a few others in separate groups. For many years barnacles were classified with molluscs because of their thick, calcareous outer shell. Crustacean classification as we know it today was more or less established during the second half of the nineteenth century, although internal revisions continue. Martin and Davis (2001) presented an overview of crustacean classification, and readers are referred to that publication for a window into the labyrinthine history of this subphylum. Multigene phylogenetics strongly supports the division of Crustacea into two major lineages, Oligostraca and Altocrustacea, which we herein recognize as superclasses. Multigene phylogenetics also supports the division of Altocrustacea into two major clades, which have been named Multicrustacea and Allotriocarida, the latter including Hexapoda (insects and allies). See Crustacean Phylogeny at the end of this chapter for further details.

CLASSIFICATION OF CRUSTACEA

SUPERCLASS OLIGOSTRACA

CLASS OSTRACODA Ostracods

SUBCLASS MYODOCOPA

ORDER MYODOCOPIDA (e.g., *Cypridina*, *Euphilomedes*, *Eusarsiella*, *Gigantocypris*, *Photeros*, *Polycope*, *Skogsbergia*, *Vargula*)

ORDER HALOCYPRIDA (e.g., *Conchoecia*)

SUBCLASS PODOCOPA

ORDER PODOCOPIDA (e.g., *Baffinicythere*, *Cypris*, *Candona*, *Darwinula*, *Limnocythre* , *Loxoconcha*, *Sclerocypris*)

ORDER PLATYCOPIDA (e.g., *Cytherella*)

ORDER PALAEOCOPIDA Almost entirely extinct; living genera are *Manawa* and *Puncia*.

CLASS MYSTACOCARIDA Mystacocarids, with a single family (Derocheilocarididae) and 13 species (e.g., *Ctenocheilocaris, Derocheilocaris*)

CLASS BRANCHIURA Fish lice, or argulids. A single family (Argulidae) (e.g., *Argulus, Chonopeltis, Dipteropeltis, Dolops*)

CLASS PENTASTOMIDA Tongueworms. Two orders, numerous families (e.g., *Cephalobaena, Linguatula, Pentastoma, Waddycephalus*). In some recent classifications combined with the Branchiura in the clade Ichthyostraca.

SUPERCLASS ALTOCRUSTACEA

clade MULTICRUSTACEA

CLASS MALACOSTRACA

SUBCLASS PHYLLOCARIDA

ORDER LEPTOSTRACA Leptostracans or nebaliaceans (e.g., *Dahlella*, *Levinebalia*, *Nebalia*, *Nebaliella*, *Nebaliopsis*, *Paranebalia*)

SUBCLASS HOPLOCARIDA

ORDER STOMATOPODA Mantis shrimps (e.g., *Echinosquilla*, *Gonodactylus*, *Hemisquilla*, *Squilla*)

SUBCLASS EUMALACOSTRACA

SUPERORDER SYNCARIDA Syncarids

ORDER BATHYNELLACEA (e.g., *Bathynella*)

ORDER ANASPIDACEA (e.g., *Allanaspides*, *Anaspides*, *Paranaspides*, *Psammaspides*)

SUPERORDER EUCARIDA

ORDER EUPHAUSIACEA Euphausiaceans, or krill (e.g., *Bentheuphausia*, *Euphausia*, *Meganyctiphanes*, *Nyctiphanes*)

ORDER DECAPODA Crabs, shrimps, lobsters, etc.

SUBORDER DENDROBRANCHIATA Penaeid and sergestid shrimps (e.g., *Lucifer*, *Penaeus*, *Sergestes*, *Sicyonia*)

SUBORDER PLEOCYEMATA All other decapods (shrimp, lobster, crabs, etc.; classified in 10 infraorders: Caridea, Stenopodidea, Brachyura, Anomura, Astacidea, Achelata, Axiidea, Gebiidea, Glypheidea, Polychelida)

SUPERORDER PERACARIDA Ten orders, all of which brood their embryos in a pouch

ORDER MYSIDA Mysidans or opossum shrimps (e.g., *Acanthomysis, Hemimysis, Mysis, Neomysis*)

ORDER STYGIOMYSIDA Stygiomysidans (e.g., *Lepidomysis, Stygiomysis*)

ORDER LOPHOGASTRIDA Lophogastridans (e.g., *Gnathophausia, Lophogaster*)

ORDER CUMACEA Cumaceans (e.g., *Campylaspis, Cumopsis, Diastylis, Diastylopsis*)

ORDER TANAIDACEA Tanaidaceans (e.g., *Apseudes, Heterotanais, Paratanais, Tanais*)

ORDER MICTACEA Mictaceans (e.g., *Mictocaris*, etc.). Some researchers separate out the family Hirsutiidae as a distinct order (Bochusacea, containing *Hirsutia*, *Montucaris*, and *Thetispelecaris*).

ORDER SPELAEOGRIPHACEA Spelaeogriphaceans. Four described living species (*Potiicoara brazilienses, Spelaeogriphus lepidops,* and two species of *Mangkurtu*), and two known fossil species (the Carboniferous *Acadiocaris novascotica* and the Upper Jurassic *Liaoningogriphus quadripartitus*)

ORDER THERMOSBAENACEA Thermosbaenaceans (e.g., *Halosbaena, Limnosbaena, Monodella, Theosbaena, Thermosbaena, Tulumella*)

ORDER ISOPODA Isopods (sea slaters, rock lice, pillbugs, sowbugs, roly-polies)

SUBORDER ASELLOTA (e.g., *Asellus*, *Eurycope*, *Jaera*, *Janira*, *Microcerberus*, *Munna*)

SUBORDER CALABOZOIDEA (*Calabozoa*)

SUBORDER CYMOTHOIDA

SUPERFAMILY ANTHUROIDEA (e.g., *Anthura*, *Colanthura*, *Cyathura*, *Mesanthura*)

SUPERFAMILY CYMOTHOOIDEA (including the families Aegidae, Anuropidae, Barybrotidae, Cirolanidae, Corallanidae, Cymothoidae, Gnathiidae, Protognathiidae, and Tridentellidae)

INFRAORDER EPICARIDEA (e.g., *Bopyrus*, *Dajus*, *Hemiarthrus*, *Ione*, *Pseudione*)

SUBORDER LIMNORIDEA (e.g., *Limnoria*, *Keuphylia*, *Hadromastax*)

SUBORDER MICROCERBERIDEA (e.g, *Atlantasellus*, *Microcerberus*)

SUBORDER ONISCIDEA (e.g., *Armadillidium*, *Ligia*, *Oniscus*, *Porcellio*, *Trichoniscus*, *Tylos*, *Venezillo*)

SUBORDER PHORATOPIDEA (*Phoratopus*)

SUBORDER PHREATOICIDEA (e.g., *Mesamphisopus*, *Phreatoicopis*, *Phreatoicus*)

SUBORDER SPHAEROMATIDEA

SUPERFAMILY SEROLIDEA (*Serolis*)

SUPERFAMILY SPHAEROMATOIDEA (*Ancinus, Paracerceis, Sphaeroma*)

SUBORDER TAINISOPIDEA (*Pygolabis*, *Tainisopus*)

for more ebook/ testbank/ solution manual Requests email 9601267344@qq.com

SUBORDER VALVIFERA (e.g., *Arcturus*, *Idotea*, *Saduria*)

ORDER AMPHIPODA Amphipods (beach hoppers, sand fleas, scuds, skeleton shrimps, whale lice, etc.)

SUBORDER AMPHILOCHIDEA (e.g., *Alicella*, *Ampelisca*, *Byblis*, *Haustorius*, *Ipanema*, *Kroyera*, *Leucothoe*, *Liljeborgia*, *Lysianassa*, *Phoxocephalus*, *Stenothoides*)

SUBORDER COLOMASTIGIDEA (e.g., *Colomastix*)

SUBORDER HYPERIIDEA (e.g., *Cystisoma*, *Hyperia*, *Phronima*, *Primno*, *Themisto*, *Vibilia*)

SUBORDER HYPERIOPSIDEA (e.g., *Hyperiopsis*, *Podosirus*)

SUBORDER PSEUDINGOLFIELLIDEA (e.g., *Pseudingolfiella*)

SUBORDER SENTICAUDATA (e.g., *Ampithoe*, *Caprella*, *Crangonyx*, *Cyamus*, *Elasmopus*, *Gammarus*, *Grandidierella*, *Hadzia*, *Hyale*, *Hyalella*, *Maera*, *Melita*, *Niphargus*, *Pontogeneia*, *Pseudamphithoides*, *Talitrus*)

ORDER INGOLFIELLIDA Ingolfiellidans (e.g. *Ingolfiella*)

CLASS COPEPODA

SUBCLASS PROGYMNOPLEA

ORDER PLATYCOPIOIDA Platycopioids (e.g., *Antrisocopia, Platycopia*)

SUBCLASS NEOCOPEPODA

SUPERORDER GYMNOPLEA

ORDER CALANOIDA Calanoids (e.g., *Bathycalanus*, *Calanus*, *Diaptomus*, *Eucalanus*, *Euchaeta*)

SUPERORDER PODOPLEA

ORDER CYCLOPOIDA Cyclopoids (e.g., *Cyclopina*, *Cyclops*, *Lernaea*, *Notodelphys*)

ORDER GELYELLOIDA Gelyelloids (e.g., *Gelyella*)

ORDER HARPACTICOIDA Harpacticoids (e.g., *Harpacticus*, *Hase*, *Longipedia*, *Peltidium*, *Porcellidium*, *Psammus*, *Sunaristes*, *Tisbe*)

ORDER MISOPHRIOIDA Misophriods (e.g., *Boxshallia*, *Misophria*)

ORDER MONSTRILLOIDA Monstrilloids (e.g., *Monstrilla*, *Stilloma*)

ORDER MORMONILLOIDA Mormonilloids. Monogeneric: *Mormonilla*

ORDER POECILOSTOMATOIDA Poecilostomatoids (e.g., *Chondracanthus*, *Erebonaster*, *Ergasilus*, *Pseudanthessius*)

ORDER SIPHONOSTOMATOIDA Siphonostomatoids (e.g., *Clavella*, *Nemesis*, *Penella*, *Pontoeciella*, *Trebius*)

CLASS THECOSTRACA Barnacles and their kin (about 367 genera and 2120 species)

SUBCLASS FACETOTECTA Monogeneric (*Hansenocaris*): the mysterious "y-larvae," a group of marine nauplii and cyprids for which adults are unknown

SUBCLASS ASCOTHORACIDA Two orders (Laurida, Dendrogastrida) of parasitic thecostracans (e.g., *Ascothorax, Dendrogaster, Laura, Synagoga, Zoanthoecus*)

SUBCLASS CIRRIPEDIA Cirripedes, the barnacles, and their kin

SUPERORDER THORACICA True (stalked and acorn) barnacles, e.g., *Balanus, Chthamalus, Conchoderma*, *Coronula, Lepas*, *Pollicipes, Scalpellum*, *Tetraclita, Verruca*.

SUPERORDER ACROTHORACICA Burrowing barnacles. Two orders, Cryptophialida and Lythoglyptida (e.g., *Cryptophialus, Trypetesa*)

SUPERORDER RHIZOCEPHALA Thirteen families of highly modified parasitic barnacles (e.g., *Heterosaccus, Lernaeodiscus, Mycetomorpha, Peltogaster, Sacculina, Sylon*)

CLASS TANTULOCARIDA Deep water, marine parasites (e.g., *Basipodella, Deoterthron, Microdajus*)

clade ALLOTRIOCARIDA

CLASS CEPHALOCARIDA Cephalocarids (e.g., *Chiltoniella*, *Hampsonellus*, *Hutchinsoniella*, *Lightiella, Sandersiella*)

CLASS BRANCHIOPODA Branchiopods

SUBCLASS ANOSTRACA Fairy shrimps and brine shrimps (e.g., *Artemia*, *Branchinecta*, *Branchipus*, *Linderiella*, *Streptocephalus*)

SUBCLASS PHYLLOPODA

ORDER NOTOSTRACA Tadpole shrimps (*Lepidurus*, *Triops*)

ORDER DIPLOSTRACA The "bivalved" branchiopods

SUBORDER LAEVICAUDATA Flat-tailed clam shrimps (e.g., *Lynceus*)

SUBORDER ONYCHOCAUDATA Clam shrimps, cladocerans (water fleas), and cyclestherians

INFRAORDER SPINICAUDATA Clam shrimps (e.g., *Cyzicus*, *Imnadia*, *Leptestheria*, *Limnadia*, *Metalimnadia*)

INFRAORDER CLADOCEROMORPHA Water fleas and cyclestheriids

PARVORDER CYCLESTHERIDA Monotypic: *Cyclestheria hislopi*

PARVORDER CLADOCERA Water fleas (e.g., *Anchistropus*, *Daphnia*, *Diaphonosoma*, *Leptodora*, *Moina*, *Polyphemus*)

CLASS REMIPEDIA Remipedes. One living order, Nectiopoda (e.g., *Cryptocorynectes*, *Godzillius*, *Lasionectes*, *Pleomothra*, *Speleonectes*, *Xibalbanus*). Sometimes combined with the Hexapoda as the clade Labiocarida.

Synopses of Crustacean Taxa

The following descriptions of major crustacean taxa will give you an idea of the range of diversity within the group and the variety of ways in which these successful animals have exploited the basic crustacean body plan.

Subphylum Crustacea

Body generally composed of a 6-segmented cephalon or head (the ocular segment, plus 5 limb-bearing segments)[3] and multisegmented postcephalic trunk; trunk divided into thorax and abdomen (except in remipedes and ostracods). First segment of cephalon (ocular segment) bears the eyes and protocerebrum; subsequent segments bear first antennae (antennules), second antennae, mandibles, maxillules, and maxillae (see Table 20.2); one or more anterior thoracomeres may fuse with the head (e.g., in Remipedia and Malacostraca), their appendages forming maxillipeds (secondarily modified for feeding); cephalic shield or carapace present (secondarily lost in some groups); with antennal glands or maxillary glands (excretory nephridia); both simple ocelli and compound eyes in most groups, at least at some stage of the life cycle; compound eyes stalked in many groups. With nauplius larval stage (suppressed or bypassed in some groups), and often a series of additional larval stages.[4]

Superclass Oligostraca

Class Ostracoda

Body segmentation reduced, trunk not clearly divided into thorax and abdomen; trunk with 0 to 3 pairs of limbs; abdomen greatly reduced; caudal rami (furca) present; gonopores on lobe anterior to caudal rami; carapace bivalved, hinged dorsally and closed by a central adductor muscle, enclosing body and head; carapace highly variable in shape and ornamentation, smooth or with various pits, ridges, spines, etc.; most with 1 simple median naupliar eye and sometimes weakly stalked compound eyes (e.g., in Myodocopida); adults with maxillary and (in some) antennal glands; males with distinct copulatory limbs (Figure 21.3).

Ostracods include about 13,000 described living species (and nearly 65,000 fossil species) of small bivalved crustaceans, ranging in length from 0.1 to 2.0 mm, although some giants (e.g., *Gigantocypris*) reach 32 mm. They superficially resemble clam shrimps in having the entire body enclosed within the valves of the carapace. However, ostracod valves lack the concentric growth rings of clam shrimps, and there are major differences in the appendages. The carapace is usually penetrated by pores, some bearing setae, and is shed with each molt. A good deal of confusion exists about the nature of ostracod limbs, and homologies with other crustacean taxa (and even within the Ostracoda) are unclear—this confusion is reflected in the variety of names applied by different authors. We have adopted terms here that allow the easiest comparison with other taxa.

Ostracods possess the fewest limbs of any crustacean class. The four or five head appendages are followed by zero to three trunk appendages. Superficially, the (second) maxillae appear to be absent; however, the highly modified fifth limbs are in fact these appendages. The trunk seldom shows external evidence of segmentation, although all 11 postcephalic somites are discernable in

[3]For a very long time the arthropod ocular segment, which has no appendages but houses the protocerebrum and the eyes, was called the "acron," a term borrowed from annelid development when the two phyla were thought to be very closely related (i.e., the Articulata hypothesis). However, the demise of the Articulata hypothesis, and the realization that arthropods are ecdysozoans (and annelids are spiralians) undermined the concept of acron homology between the two phyla. Further, unlike the arthropod ocular segment, the "acron" in annelids (usually called the prostomium) commonly bears both eyes and antennae, as well as a variety of palps, tentacles, and sense organs. Thus, the term "ocular segment" (or "opthalmic segment") best describes the first, eye-bearing segment of Crustacea and other arthropods.

[4]Segments of the thorax are called thoracomeres (regardless of whether or not any of these segments are fused to the head), whereas appendages of the thorax are called thoracopods. The term "pereon" refers to that portion of the thorax not fused to the head (when such fusion occurs), and the terms "pereonites" (= pereomeres) and "pereopods" are used for the segments and appendages, respectively, of the pereon. Hence, on a crustacean with the first thoracic segment (thoracomere 1) fused to the head, thoracomere 2 is typically called pereonite 1, the first pair of pereopods represents the second pair of thoracopods, and so on. Be assured that we are trying to simplify, not confuse, this issue. Also, we caution you that the homology of the thorax and abdomen among the major crustacean lineages is probably more reverie than reality; the segmental homologies of the thorax and abdomen have not yet been unraveled among the crustacean classes. For summaries of naupliar development across the group and larval features in all crustaceans, see Martin et al. (2014). In most crustacean species the number of body segments is fixed, but in at least two groups (notostracans and remipedes) the segment number can vary within a given species.

some taxa. The third pair of trunk limbs bears the gonopores and constitutes the so-called copulatory organ.

Ostracods are one of the most successful groups of crustaceans. They also have the best fossil record of any arthropod group, dating from at least the Ordovician, and an estimated 65,000 fossil species have been described (a bit over 20,000 fossil trilobites have been described). Most are benthic crawlers or burrowers, but many have adopted a suspension-feeding planktonic lifestyle, and a few are terrestrial in moist habitats. One species is known to be parasitic on fish gills—*Sheina orri* (Myodocopida, Cypridinidae). Ostracods are abundant worldwide in all aquatic environments and are known to depths of 7,000 m in the sea. Some are commensal on echinoderms or other crustaceans. A few podocopans have invaded supralittoral sandy regions (members of the family Terrestricytheridae), and members of several families inhabit terrestrial mosses and humus. Two principal taxa (ranked as subclasses here) are recognized within the Ostracoda: Myodocopa and Podocopa.

Myodocopans are all marine. Most are benthic, but the group also includes all of the marine planktonic ostracods. The largest of all ostracods, the planktonic *Gigantocypris*, is a member of this group. Myodocopans include scavengers, detritus feeders, suspension feeders, and some predators. There are two orders: Myodocopida and Halocyprida.

Podocopans include predominantly benthic forms; although some are capable of temporary swimming, none are fully planktonic. Their feeding methods include suspension feeding, herbivory, detritus feeding, and parasitism. The Podocopa are divided into three orders: the exclusively marine Platycopida, the ubiquitous Podocopida, and the Palaeocopida. The Palaeocopida were diverse and widespread in the Paleozoic but are represented today only by the extremely rare Punciidae (known from a few living specimens and from dead valves dredged in the South Pacific).

One of the most remarkable examples of bioluminescence in the animal kingdom occurs among ostracods in the family Cypridinidae. Worldwide, over half of the known 300 species in this family are luminescent, probably all to deter predators, but one clade (that occurs only in the Caribbean) also uses their luminescence for complex courtship displays much the same way fireflies do, only by ejecting pulses of light into the sea in near darkness. The luminescent reaction involves cypridinid luciferin and luciferase that, together with mucus, are ejected separately through specialized nozzles from separate secretory cells in the upper lip, and they mix in the seawater. As a result, light is extracellular, being produced external to the body of the ostracod. Virgin females respond to species-specific male displays by swimming to intercept a signaling male in the water column, but without luminescing themselves. These mating arenas are equivalent to underwater leks. Mated females immediately move to the seafloor and begin brooding embryos. And in a remarkable twist of nature, a number of bioluminescent fishes have been shown to obtain their luciferase from their ostracod prey—a process called kleptoprotein bioluminescence. Fertilization in these luminescent ostracods is internal, with sperm being transferred by a spermatophore. The male eighth limb functions as a copulatory organ, which is enlarged and modified for grasping. In females the eighth limb is reduced and includes a pair of knobs, probably grasped by the males. The spermatophore appears to act as a mating plug to block other male copulations. All offspring in one brood are thus fertilized by the same male, and females can store sperm and produce multiple broods from one insemination.

Class Mystacocarida

Body divided into cephalon and 10-segmented trunk; telson with clawlike caudal rami; cephalon characteristically cleft; antennae and mandibles biramous; antennules, maxillules, and maxillae uniramous; first trunk segment bears maxillipeds but is not fused with cephalon; no carapace; gonopores on fourth trunk segment; trunk segments 2–5 with short, single-segment appendages (Figure 21.4A).

There are only 13 described species of mystacocarids, 8 in the genus *Derocheilocaris* and 5 in *Ctenocheilocaris*. Most are less than 0.5 mm long, although *D. ingens* reaches 1 mm. The head is marked by a transverse "cephalic constriction" between the origins of the first and second antennae, perhaps a remnant of primitive head segmentation. In addition, the lack of fusion of the cephalon and maxillipedal trunk segment, the simplicity of the mouth appendages, and other features have led some workers to propose that the mystacocarids are among the most primitive living crustaceans. These attributes may, however, be related to a neotenic origin and specialization for interstitial habitats. Mystacocarids are marine, interstitial crustaceans that live in littoral and sublittoral sands throughout the world's temperate and subtropical seas. Their rather vermiform body and small size are clearly adaptations to life among sand grains. Mystacocarids are thought to feed by scraping organic material from the surfaces of sand grains with their setose mouthparts.

Class Branchiura

Body compact and oval, head and most of trunk covered by broad carapace; antennules and antennae reduced, the latter sometimes absent; mouthparts modified for parasitism; no maxillipeds; thorax reduced to 4 segments, with paired biramous appendages; abdomen unsegmented, bilobed, limbless, but with minute caudal rami; female gonopores at bases of fourth thoracic legs, male with single gonopore on midventral surface of last thoracic somite; paired, sessile compound eyes and 1 to 3 median simple eyes (Figure 21.4M).

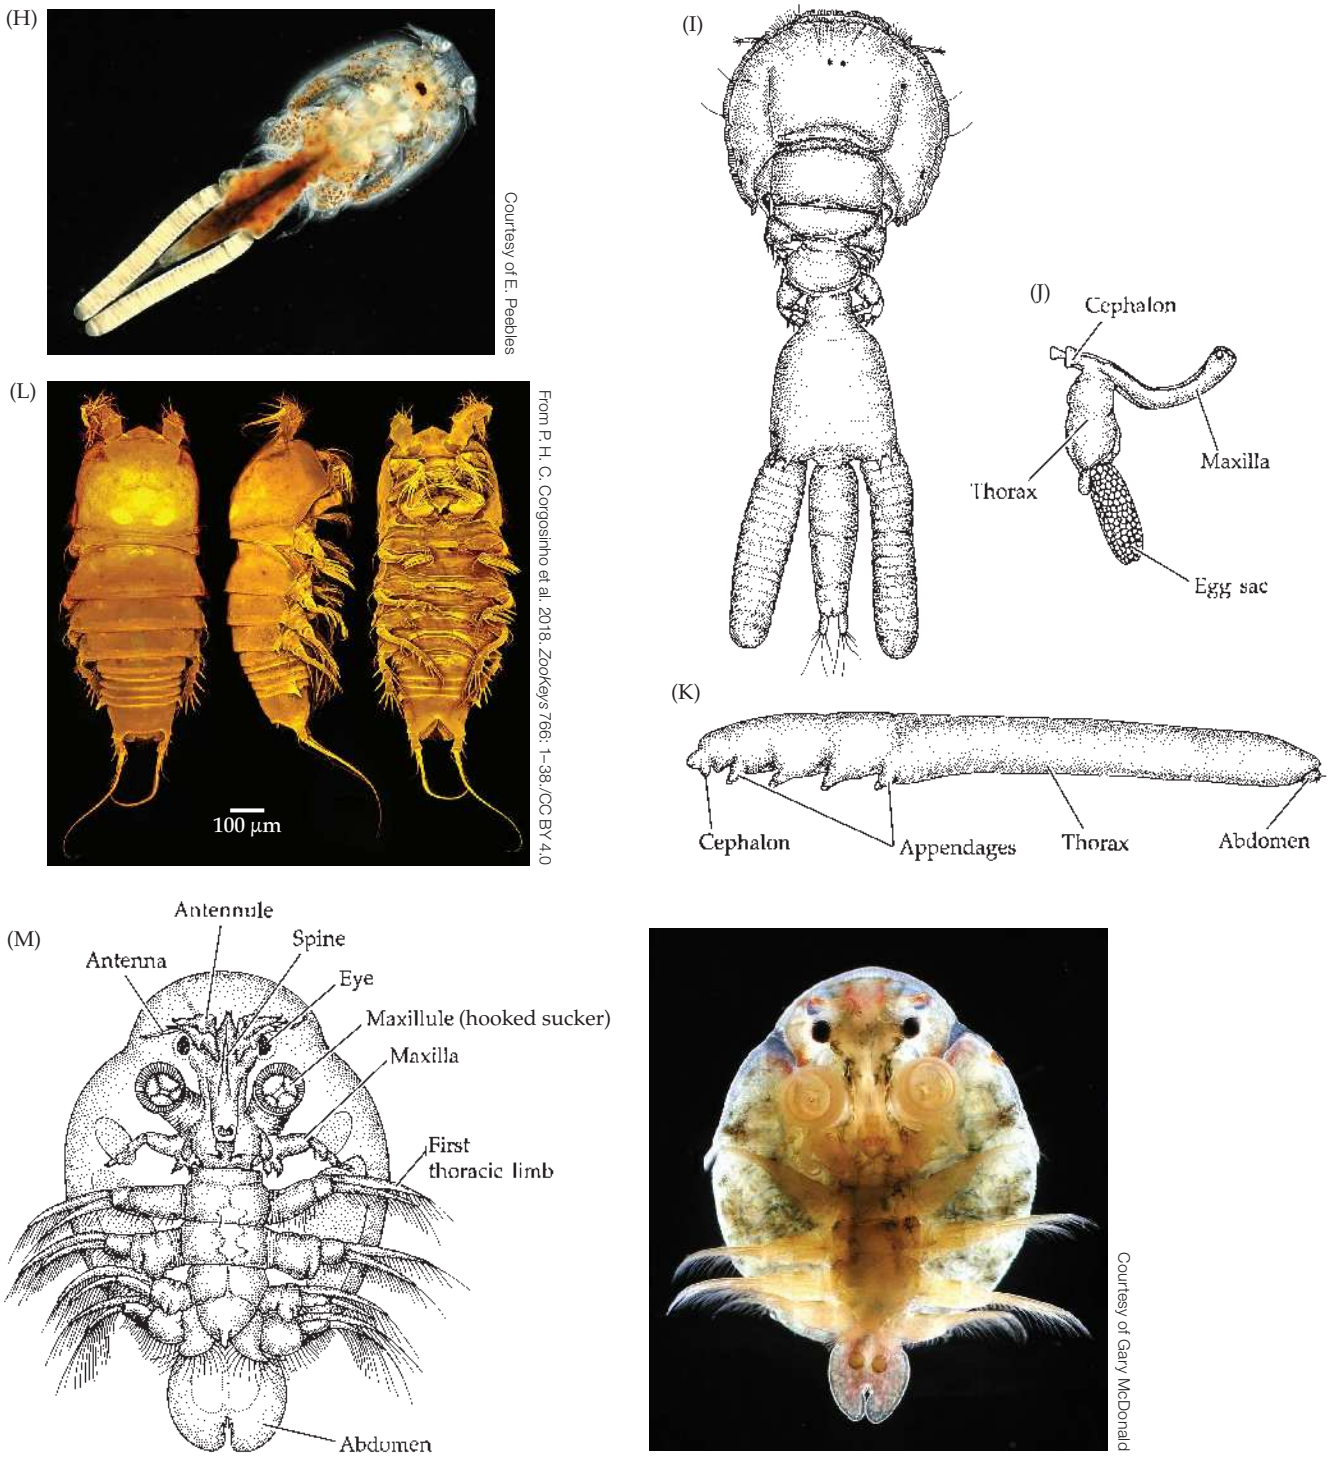

FIGURE 21.4 Anatomy of the classes Mystacocarida, Copepoda, and Branchiura. (A) General anatomy and SEM of the mystacocarid *Derocheilocaris*. (B) General anatomy of a cyclopoid copepod. (C–E) General body forms of (C) a calanoid, (D) a harpacticoid, and (E) a cyclopoid copepod. Note the points of body articulation (dark band) and the position of the genital segment (shaded segment). Roman numerals are thoracic segments; Arabic numerals are abdominal segments; T = telson. (F) An elaborately setose calanoid copepod adapted for flotation. (G) A poecilostomatid copepod, *Ergasilus pitalicus*, ectoparasitic on cichlid fishes. (H) A female siphonostomatid copepod (*Caligus* sp.) with egg sacs. (I) A female siphonostomatid copepod (*Trebius heterodonti*, a parasite of horn sharks in California) with egg sacs. (J) A siphonostomatid copepod, *Clavella adunca*, showing extreme body reduction; this species attaches to the gills of fishes by its elongate maxillae. (K) *Notodelphys*, a wormlike cyclopoid copepod adapted for endoparasitism in tunicates. (L) The harpacticoid copepod *Hase talpamorphicus* (confocal laser scans). (M) Branchiura: *Argulus foliaceus* (drawing and photograph), a branchiuran that parasitizes fishes. Note the powerful hooked suckers (modified maxillules) on the ventral surface. (G after V. E. Thatcher. 1984. *J Crust Biol* 4: 495–501.)

The Branchiura comprise about 230 species of ectoparasites on marine and freshwater fishes. The antennules generally bear hooks or spines for attachment to their host fish. The mandibles are reduced in size and complexity, bear cutting edges, and are housed within a styliform "proboscis" apparatus. The maxillules are clawed in *Dolops*, but they are modified as stalked suckers in the other genera (*Argulus, Chonopeltis, Dipteropeltis*). The uniramous maxillae usually bear attachment hooks. The thoracopods are biramous and used for swimming when the animal is not attached to a host. Branchiurans feed by piercing the skin of their hosts and sucking blood or tissue fluids. Once they locate a host, they crawl toward the fish's head and anchor in a spot where water flow turbulence is low (e.g., behind a fin or gill operculum). Members of the genus *Argulus* occur worldwide, and can pose a serious problem to aquaculture, but members of the other genera have restricted distributions. *Chonopeltis* is found only in Africa, *Dipteropeltis* in South America, and *Dolops* in South America, Africa, and Tasmania.

Class Pentastomida

Obligatory parasites of various amphibians, reptiles, birds, and mammals. Adults inhabit respiratory tract (lungs, nasal passages, etc.) of their host. Body highly modified, wormlike, 2–13 cm in length. Adult appendages reduced to 2 pairs of head appendages, lobelike and with chitinous claws used to cling to host. Body cuticle nonchitinous and highly porous. Body muscles somewhat sheetlike, but clearly segmental and cross-striated. Mouth lacks jaws; often on end of snoutlike projection; connected to a muscular pumping pharynx used to suck blood from host. The combination of the snout and the 2 pairs of legs gives the appearance of there being 5 mouths, hence the name (Greek *penta*, "five"; *stomida*, "mouths"). In many species the appendages are reduced to no more than the terminal claws. No specific gas exchange, circulatory, or excretory organs. Gonochoristic; females larger than males. About 130 described species, including 2 cosmopolitan species that can occasionally infest humans (Figure 21.4K, 21.5).

For years it was believed that pentastomids were allied with the fossil lobopodians, onychophorans, and tardigrades as some kind of segmented, vermiform, proto-arthropod creature. However, molecular phylogenetics informs us that pentastomids are highly modified crustaceans, perhaps derived from the Branchiura. Corroboration has come from studies of sperm and larval morphology, nervous system anatomy, and cuticular fine structure.

Work on the Swedish Orsten fauna indicates that pentastomid-like animals had appeared as early as the late Cambrian (500 Ma), long before the land vertebrates had evolved. What might the original hosts of these parasites have been? Conodont fossils are common in all the Cambrian localities that have yielded pentastomids, raising the possibility that conodonts (also long a mystery, but now widely regarded as parts of early fishlike vertebrates) may have been at least one of the original hosts of these early Pentastomida.

Superclass Altocrustacea: Clade Multicrustacea

Class Malacostraca

Body of 19–20 segments, including 6-segmented cephalon/head, 8-segmented thorax (anterior-most somites often fused with head), and 6-segmented pleon (7-segmented in leptostracans), plus telson; with or without caudal rami; carapace covering part or all of thorax, or reduced, or absent; 0–3 pairs of maxillipeds; thoracopods primitively biramous, uniramous in some groups, phyllopodous only in members of the subclass Phyllocarida; antennules and antennae usually biramous; abdomen (pleon) usually with 5 pairs of biramous pleopods and 1 pair of biramous uropods; eyes usually present, compound, stalked or sessile. Mainly gonochoristic; female gonopores on sixth, and male pores on eighth thoracomeres. When uropods are present, they are often broad and flat, lying alongside the broad telson to form a tail fan.

Most classification schemes divide the more than 40,200 species of malacostracans into three subclasses, Phyllocarida (leptostracans), Hoplocarida (stomatopods), and the megadiverse Eumalacostraca. The phyllocarids are typically viewed as representing the primitive malacostracan condition (6-8-7 body segments plus telson; Figure 21.6). The basic eumalacostracan body plan, characterized by the 6-8-6 (plus telson) arrangement of body segments, was recognized in the early 1900s by W. T. Calman, who termed the defining features of the Eumalacostraca "caridoid facies" (Figure 21.7). Much work has been done since Calman's day, but the basic elements of his caridoid facies are still present in all members of the subclass Eumalacostraca.

Subclass Phyllocarida

Order Leptostraca With typical malacostracan characteristics, except notable for presence of 7 free pleomeres (plus telson), generally taken to represent the primitive condition for the class. Also, with phyllopodous thoracopods (all similar to one another); no maxillipeds; large

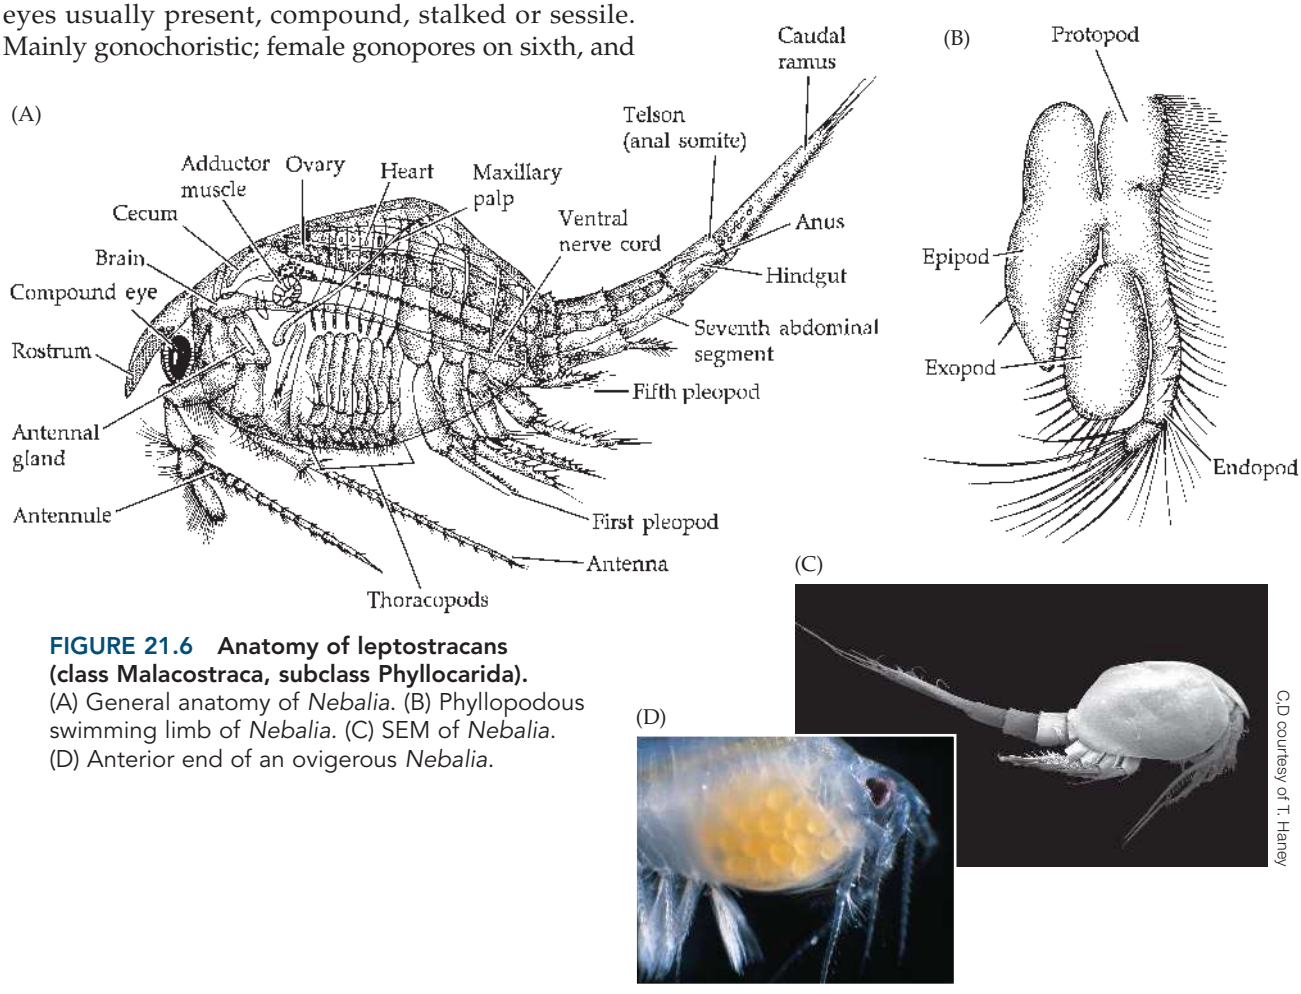

FIGURE 21.6 Anatomy of leptostracans (class Malacostraca, subclass Phyllocarida). (A) General anatomy of *Nebalia*. (B) Phyllopodous swimming limb of *Nebalia*. (C) SEM of *Nebalia*. (D) Anterior end of an ovigerous *Nebalia*.

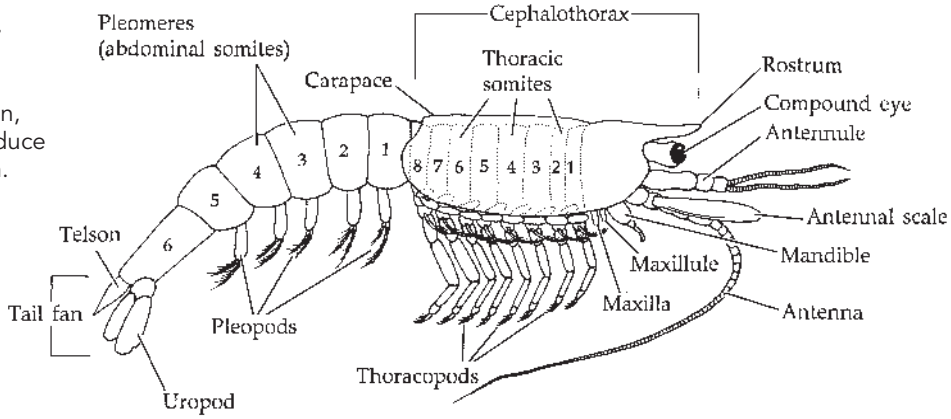

FIGURE 21.7 The basic eumalacostracan body plan and the "caridoid facies." Note the thick (muscled) abdomen and the tail fan, which work in combination to produce a powerful tail flip escape reaction.

carapace covering thorax and compressed laterally so as to form an unhinged bivalved "shell," with an adductor muscle; cephalon with a movable, articulated rostrum; pleopods 1–4 similar and biramous, 5–6 uniramous; no uropods; paired stalked compound eyes; antennules biramous; antennae uniramous; adults with both antennal and maxillary glands (Figures 21.6 and 21.21C).

The subclass Phyllocarida includes about 40 species in 10 genera. Most are 5–15 mm long, but *Nebaliopsis typica* is a giant at nearly 5 cm in length. The leptostracan body form is distinctive, with its loose bivalved carapace covering the thorax, a protruding rostrum, and an elongate abdomen. All leptostracans are marine, and most are epibenthic from the intertidal zone to a depth of 400 m; *Nebaliopsis typica* is bathypelagic. Most species seem to occur in low-oxygen environments. One species, *Dahlella caldariensis*, is associated with the hydrothermal vents of the Galapagos and the East Pacific Rise. *Speonebalia cannoni* is known only from marine caves.

Most leptostracans suspension feed by stirring up bottom sediments. They are also capable of grasping relatively large bits of food directly with the mandibles. Some are carnivorous scavengers, and some are known to aggregate in areas on the seafloor where large amounts of detritus accumulate. In many species the antennae or antennules of males are modified to hold females during copulation.

Subclass Hoplocarida

Order Stomatopoda Carapace covering portion of head and fused with thoracomeres 1–4; head with movable, articulated rostrum; thoracopods 1–5 uniramous and subchelate, second pair massive and raptorial (all 5 are sometimes called "maxillipeds" or gnathopods because they are involved in feeding); thoracopods 6–8 biramous, ambulatory; pleopods biramous, with dendrobranchiate-like gills on exopods; antennules triramous; antennae biramous, with large, paired, stalked compound eyes that are unique in the animal kingdom (Figures 21.8A–C, 21.27D, and 21.33K). Stomatopods are one of only two groups of malacostracans that possess pleopodal gills. Only the isopods share this trait, but the pleopods are quite different in the two groups. The tubular, thin, highly branched gills of stomatopods provide a large surface area for gas exchange in these active animals.

All 500 or so living hoplocarids are placed in the order Stomatopoda, known as mantis shrimps. They are relatively large crustaceans, ranging in length from 2 to 30 cm. Compared with that of most malacostracans, the muscle-filled abdomen is notably robust. Most stomatopods are found in shallow tropical or subtropical marine environments. Nearly all of them live in burrows excavated in soft sediments or in cracks and crevices, among rubble, or in other protected places. All species are raptorial carnivores, preying on fishes, molluscs, cnidarians, and other crustaceans. The large, distinctive subchelae of the second thoracopods act either as crushers or as spears (Figure 21.8C).

Stomatopods crawl about using the posterior thoracopods and the flaplike pleopods. They also can swim by metachronal beating of the pleopods (the "swimmerets"). For these relatively large animals, living in narrow burrows requires a high degree of maneuverability. The short carapace and the flexible, muscular abdomen allow these animals to twist double and turn around within their tunnels or in other cramped quarters. This ability facilitates an escape reaction whereby a mantis shrimp darts into its burrow rapidly head first, then turns around to face the entrance.

Subclass Eumalacostraca

Head, thorax, and abdomen of 6-8-6 somites respectively (plus telson); with 0, 1, 2, or 3 thoracomeres fused with head, their respective appendages usually modified as maxillipeds; antennules and antennae primitively biramous (but often reduced to uniramous); most with well-developed carapace, secondarily reduced in syncarids and some peracarids; gills primitively as thoracic epipods; tail fan composed of telson plus paired uropods; abdomen long and muscular. Three superorders: Syncarida, Peracarida, Eucarida, although the monophyly of the last has been contested in morphological and molecular analyses.

for more ebook/ testbank/ solution manual Requests email 9601267344@qq.com

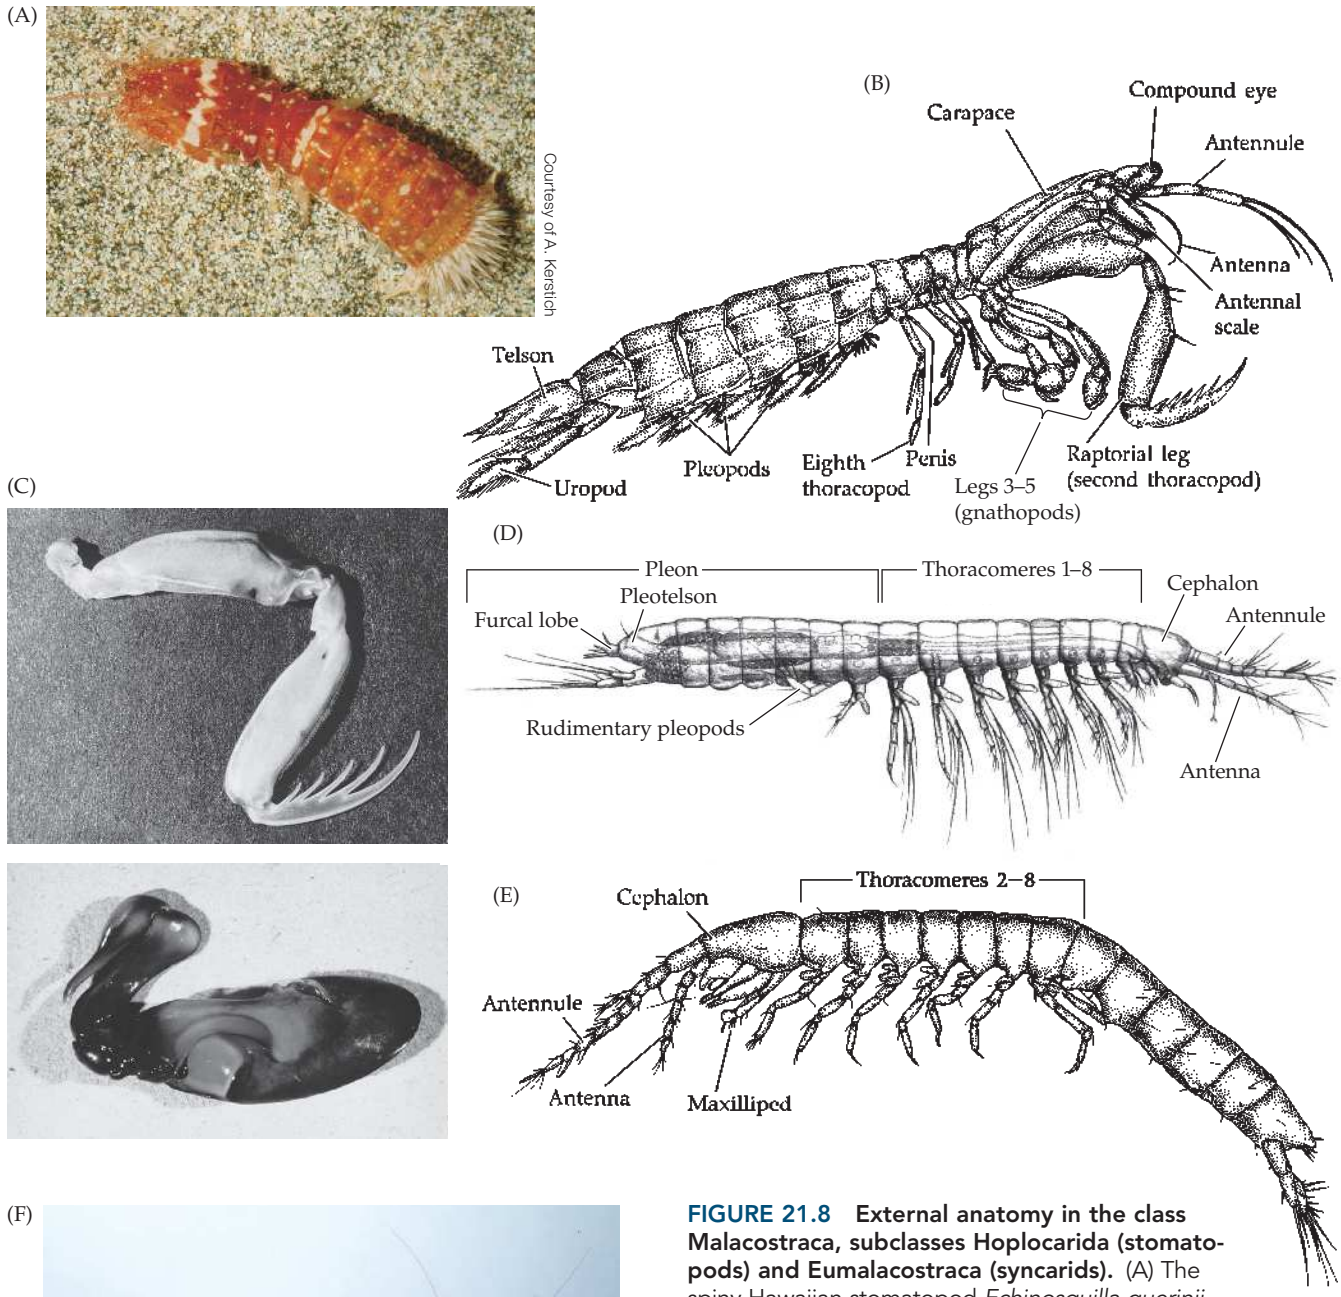

FIGURE 21.8 External anatomy in the class Malacostraca, subclasses Hoplocarida (stomatopods) and Eumalacostraca (syncarids). (A) The spiny Hawaiian stomatopod *Echinosquilla guerinii*. (B) External anatomy of the stomatopod *Squilla*. (C) "Spearing" claw and "clubbing" claw (second thoracopod) of stomatopods. (D) A bathynellacean, *Bathynella*. (E) An anaspidacean, *Stygocarella*. (F) An anaspidacean, *Paranaspides lacustris*.

Superorder Syncarida Without maxillipeds (Bathynellacea) or with 1 pair of maxillipeds (Anaspidacea, including Stygocarididae); no carapace; pleon bears telson with or without furcal lobes; at least some thoracopods biramous; pleopods variable; compound eyes present (stalked or sessile) or absent (Figure 21.8D–F). There are about 285 described species of syncarids in 2 orders, Anaspidacea and Bathynellacea. Syncarids might be an ancient relictual taxon now restricted to refugial habitats. Through studies of the fossil record and extant members of the order Anaspidacea (e.g., *Anaspides*), it has been suggested that syncarids may

encompass the most primitive living eumalacostracan body plan. Bathynellaceans occur worldwide in interstitial or groundwater habitats, whereas the anaspidaceans are strictly Gondwanan in distribution. Many Anaspidacea are endemic to Tasmania, where they inhabit freshwater environments, such as open lake surfaces, streams, ponds, and crayfish burrows. No syncarids are marine. These reclusive eumalacostracans show various degrees of characteristics of what some have regarded as paedomorphism, including small size (Anaspidacea includes members to 5 cm, whereas most others are less than 1 cm long), eyelessness, and reduction or loss of pleopods and some posterior pereopods. Bathynellaceans are small (1–3 mm long), possess 6 or 7 pairs of long, thin swimming legs, and have a pleotelson formed by the fusion of the telson to the last pleonite.

Syncarids either crawl or swim. Little is known about the biology of most species, although some are considered omnivorous. Unlike most other crustaceans, which carry the eggs and developing early embryos, syncarids lay their eggs or shed them into the water following copulation.

Superorder Eucarida Telson without caudal rami; 0, 1, or 3 pairs of maxillipeds; carapace present, covering and fused dorsally with head and entire thorax; usually with stalked compound eyes; gills thoracic. Although members of this group are highly diverse, they are united by the presence of a complete carapace that is fused with all thoracic segments, forming a characteristic cephalothorax. Most species (several thousand) belong to the order Decapoda. The other order is Euphausiacea (krill). The formerly monotypic order Amphionidacea (*Amphionides reynaudii*) has been shown to be a larval caridean decapod.

Order Euphausiacea Euphausiaceans (**krill**) are distinguished among the eucarids by their shrimplike appearance, absence of maxillipeds, exposure of the thoracic gills external to the carapace, and possession of biramous pereopods (the last 1 or 2 pairs sometimes being reduced). Adults have antennal glands. Most of them have photophores on the eyestalks, the bases of the second and seventh thoracopods, and between the first 4 pairs of abdominal limbs.

The 86 known species of euphausiaceans are all pelagic, range in length from 4 to 15 cm, and are known from all oceanic environments to depths of 5,000 m. Most species are distinctly gregarious, and species that occur in huge schools provide a major source of food for larger nektonic animals (baleen whales, squids, fishes) and even some marine birds. Northern krill has been a significant fishery in Japan and Canada, but the largest commercial stock is from the Southern Ocean, where the annual catch can exceed a half-million tons. Krill densities, particularly for *Euphausia superba*, often exceed 1,000 animals/m^3 (614 g wet weight/m^3).[5] The high concentrations of omega-3 fatty acids in krill make them popular for use in dietary supplements. Generally, euphausiaceans are suspension feeders, although predation and detritivory also occur (Figures 21.9A,B and 21.21E).

Order Decapoda With over 15,000 named species, the decapods are among the most familiar eumalacostracans. They possess a well-developed carapace enclosing a branchial chamber, but they differ from other eucarid orders in always possessing 3 pairs of maxillipeds, leaving 5 pairs of functional uniramous or weakly biramous pereopods (hence the name Decapoda); 1 or more pairs of anterior pereopods are usually clawed (chelate). Adults have antennal glands. In vernacular terms, nearly every decapod may be recognized as some sort of shrimp, crab, lobster, or crayfish.

We do not want to belabor the issue of decapod gill nomenclature. However, the gills play a prominent role in the taxonomy of this group; thus, we provide brief descriptions of the basic types. All decapod gills arise as thoracic coxal exites (epipods), but their final placement varies. Those that remain attached to the coxae are **podobranchs** (= "foot gills"), but others eventually become associated with the articular membrane between the coxae and body and are thus called **arthrobranchs** (= "joint gills"). Some actually end up on the lateral body wall, or side-surface of the thorax, as **pleurobranchs** (= "side gills"). The sequence by which some of these gills arise ontogenetically varies. For example, in the Dendrobranchiata and the Stenopodidea, arthrobranchs appear before pleurobranchs, whereas in members of the Caridea the reverse is true. In most of the other decapods the arthrobranchs and pleurobranchs tend to appear simultaneously. These developmental differences may be minor heterochronic dissimilarities and of less phylogenetic importance than actual gill anatomy.

Among the decapods, the gills can also be one of three basic structural types, described as dendrobranchiate, trichobranchiate, and phyllobranchiate (Figure 21.28B–D). All three of these gill types include a main axis carrying afferent and efferent blood vessels, but they differ markedly in the nature of the side filaments

[5]Where krill densities exceed about 100 g/m^3, they are often fished commercially. Krill schools can extend for tens of miles, contain millions of tons of krill, and stain the ocean red with their surface swarms in coastal waters. Large baleen whales can eat a ton of krill in one mouthful. Seals, fish, squid, and humans also eat krill. Krill fishing has been banned in most of North America, but it continues in Japan, where tens of thousands of tons are landed annually and used mainly as feed for farmed fish. The largest krill fishery is in the ocean surrounding Antarctica, where they have been harvested commercially since the 1970s. In the 1980s, large fleets from the Soviet Union caught up to 400,000 tons of Antarctic krill annually, but by 2015 the annual catch was down to 120,000 tons (taken by Argentina, Chile, Japan, Korea, Norway, Poland, the Ukraine, and the United States).

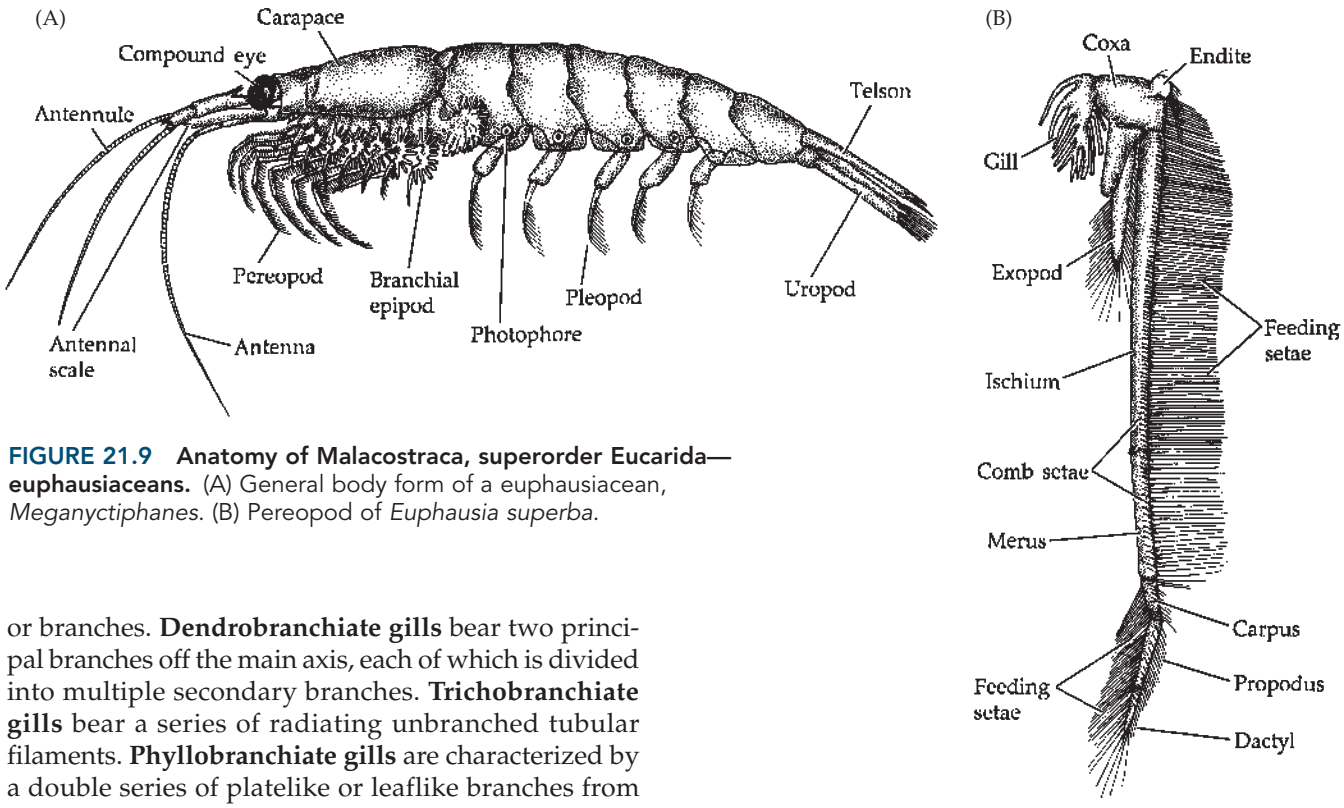

FIGURE 21.9 Anatomy of Malacostraca, superorder Eucarida—euphausiaceans. (A) General body form of a euphausiacean, *Meganyctiphanes*. (B) Pereopod of *Euphausia superba*.

or branches. **Dendrobranchiate gills** bear two principal branches off the main axis, each of which is divided into multiple secondary branches. **Trichobranchiate gills** bear a series of radiating unbranched tubular filaments. **Phyllobranchiate gills** are characterized by a double series of platelike or leaflike branches from the axis. Within each gill type, there may be considerable variation. The occurrences of these three major gill types among various taxa are presented below.

Close inspection of the proximal parts of the pereopods usually reveals another decapod feature: in most forms, the basis and ischium are fused (as a basi-ischium), with the point of fusion often indicated by a suture line (see Figure 21.21E-I). Tegumental glands are also a ubiquitous feature among the Decapoda. These glands originate below the epidermal cells and produce a fluid that opens on the surface of the cuticle. They have been reported from gills, legs, pleopods, and uropods. The roles of tegmental glands are not well known, and they have been suspected to be involved in cuticular tanning, the production of mucus by the mouthparts, the production of cement substance involved with egg attachment, and possibly also grooming.

Decapods occur in all aquatic environments at all depths, and a few spend most of their lives on land. Many are pelagic, but others have adopted benthic sedentary, errant, or burrowing lifestyles. Decorating of the exoskeleton is frequently seen among the decapods, especially in spider crabs (Brachyura: Majoidea), which use Velcro-like hooked setae to attach dead or living seaweeds and animals; decorating has been shown to reduce predation through camouflage and/or chemical deterrence. Decapod feeding strategies include suspension feeding, predation, herbivory, scavenging, and more. Two suborders are recognized: Dendrobranchiata and Pleocyemata. Recent phylogenetic research supports the monophyly of the suborders and infraorders.

Suborder Dendrobranchiata This group includes over 500 species of decapods, most of which are penaeid (Penaeoidea) and sergestid (Sergestoidea) shrimps. As the name indicates, these decapods possess dendrobranchiate gills (see Figure 21.28B), a unique synapomorphy of the taxon. One genus, *Lucifer*, has secondarily lost the gills completely. The dendrobranchiate shrimps are further characterized by chelae on the first 3 pereopods, copulatory organs modified from the first pair of pleopods in males, and ventral expansions of the abdominal tergites (called pleural lobes). Generally, none of the chelipeds is greatly enlarged. In addition, females of this group do not brood their eggs. Fertilization is external, and the embryos hatch as nauplius larvae. Many of these animals are quite large, over 30 cm long. The sergestids are pelagic and all marine, whereas the penaeids are pelagic or benthic, and some occur in brackish water. Some dendrobranchiates (e.g., *Penaeus, Sergestes, Acetes, Sicyonia*) are of major commercial importance in the world's shrimp fisheries, most of which are now being exploited beyond sustainable levels and often with fishing techniques that are highly habitat destructive (Figures 21.10A and 21.33G).

Suborder Pleocyemata All of the remaining decapods belong to the suborder Pleocyemata, divided among 10 infraorders (see below). Members of this taxon never possess dendrobranchiate gills. The embryos are brooded on the female's pleopods and hatch at some stage later than the nauplius larva.

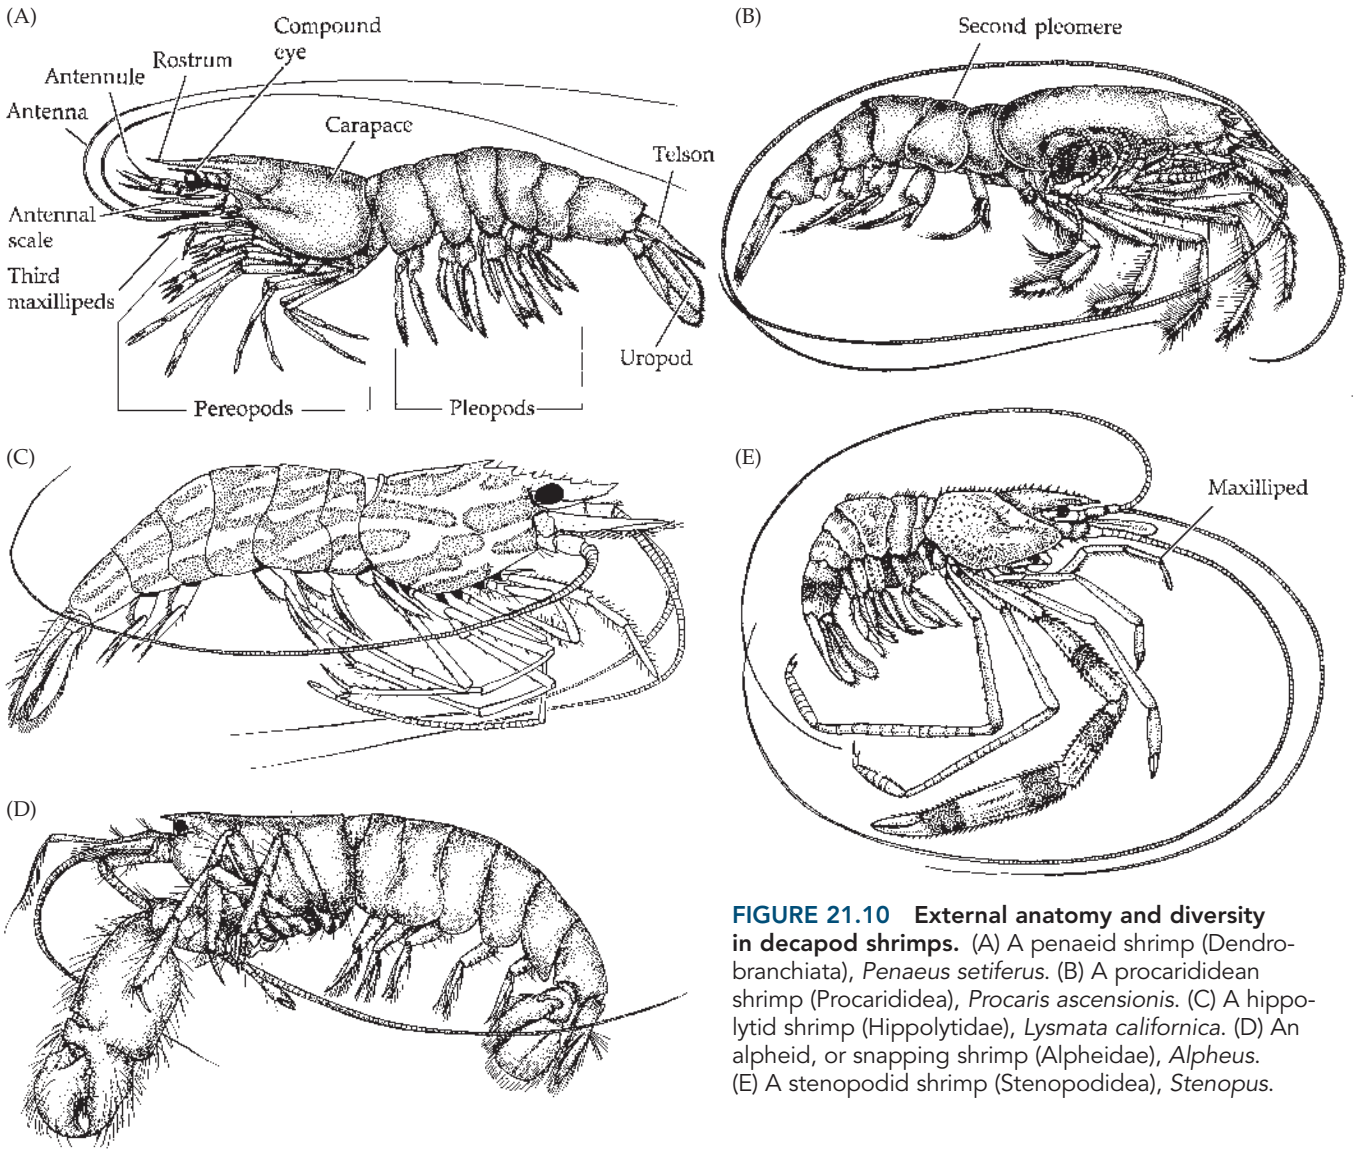

FIGURE 21.10 External anatomy and diversity in decapod shrimps. (A) A penaeid shrimp (Dendrobranchiata), *Penaeus setiferus*. (B) A procaridid shrimp (Procaridida), *Procaris ascensionis*. (C) A hippolytid shrimp (Hippolytidae), *Lysmata californica*. (D) An alpheid, or snapping shrimp (Alpheidae), *Alpheus*. (E) A stenopodid shrimp (Stenopodidea), *Stenopus*.

Included in this suborder are several kinds of shrimps, the crabs, crayfish, lobsters, and a host of less familiar forms. De Grave et al. (2009) divide the Pleocyemata into 10 infraorders (below). One older approach divided decapods into 2 large groups, called the Natantia and Reptantia—the swimming and walking decapods, respectively. Although these terms have largely been abandoned as formal taxa, recent molecular phylogenetic work finds support for a monophyletic Reptantia (pleocyemates with dorsoventrally flattened pleons). In any case, the terms still serve a useful descriptive purpose, and one continues to see references to natant decapods and reptant decapods.

Infraorder Caridea Caridean and procaridid shrimps; about 3,270 species (e.g., *Alpheus*, *Ambidexter*, *Atya*, *Betaeus*, *Crangon*, *Hippolyte*, *Hymenocera*, *Hymenodora*, *Leander*, *Lysmata*, *Macrobrachium*, *Ogyrides*, *Palaemon*, *Pandalus*, *Pasiphaea*, *Periclimenes*, *Procaris*, *Processa*, *Syncaris*, *Thor*, *Typton*, *Typhlocaris*, *Vetericaris*). Swimming decapods with phyllobranchiate gills. The first 1 or 2 pairs of pereopods may be chelate and variably enlarged. The second abdominal pleurae (side walls) are distinctly enlarged to overlap both the first and third pleurae (Figures 21.1K, 21.10C,D, 21.24E, and 21.31D). *Procaris* and *Vetericaris* are known from anchialine habitats—inland pools with brackish water on top and seawater below, with connections to the ocean (Figure 21.10B).

Infraorder Stenopodidea Stenopodidean shrimps; about 70 species (e.g., *Odontozona*, *Spongicola*, *Stenopus*). The first 3 pairs of pereopods are chelate, and the third pair is significantly larger than the others. The gills are trichobranchiate. The second abdominal pleurae are not expanded as they are in carideans (Figures 21.10E and 21.31B).

These colorful shrimps are usually only a few centimeters long (2–7 cm). Most species are tropical and

for more ebook/ testbank/ solution manuals Requests email 960126734@qq.com

associated with shallow benthic environments, especially with coral reefs; some are known from the deep sea. Many are commensal, and the group includes the cleaner shrimps (e.g., *Stenopus*) of tropical reefs, which are known to remove parasites from fishes. Stenopodids often occur as male-female couples. Perhaps the most noted example of this bonding is associated with the glass sponge (*Euplectella*) shrimp, *Spongicola venusta*: a young male and female shrimp enter the atrium of a host sponge, eventually growing too large to escape and thus spending the rest of their days together.

Infraorder Brachyura The so-called "true crabs" (about 7,000 species). Abdomen symmetrical but highly reduced and flexed beneath the thorax. Body hidden beneath well-developed carapace and distinctly flattened dorsoventrally. Gills typically phyllobranchiate, but exceptions occur. First pereopods chelate, usually enlarged and larger in males (usually used in contesting mating rights with other males). Pereopods 2 to 5 typically simple stenopodous walking legs. Eyes positioned lateral to the antennae. Males lack pleopods 3 to 5. Always gonochoristic. The distinctive larval stage is called a zoea; its carapace is spherical and bears a ventrally directed rostral spine (or no spine). Common brachyuran genera include *Calappa*, *Callinectes*, *Cancer*, *Cardisoma*, *Dromia*, *Ebalia*, *Epialtus*, *Eriphia*, *Fabia*, *Gecarcinus*, *Geryon*, *Goneplax*, *Grapsus*, *Hepatus*, *Herbstia*, *Libinia*, *Loxorhynchus*, *Maja*, *Menippe*, *Microphrys*, *Ocypode*, *Ozius*, *Panopeus*, *Percnon*, *Pinnixa*, *Portunus*, *Pugettia*, *Thoe*, *Trapezia*, *Uca*, and *Xanthias* (Figures 21.1E, 21.11, 21.27H, 21.28F,G, 21.29C, 21.32, and 21.33H,I).

Brachyuran crabs are mostly marine, but freshwater, semiterrestrial, and terrestrial species occur in the

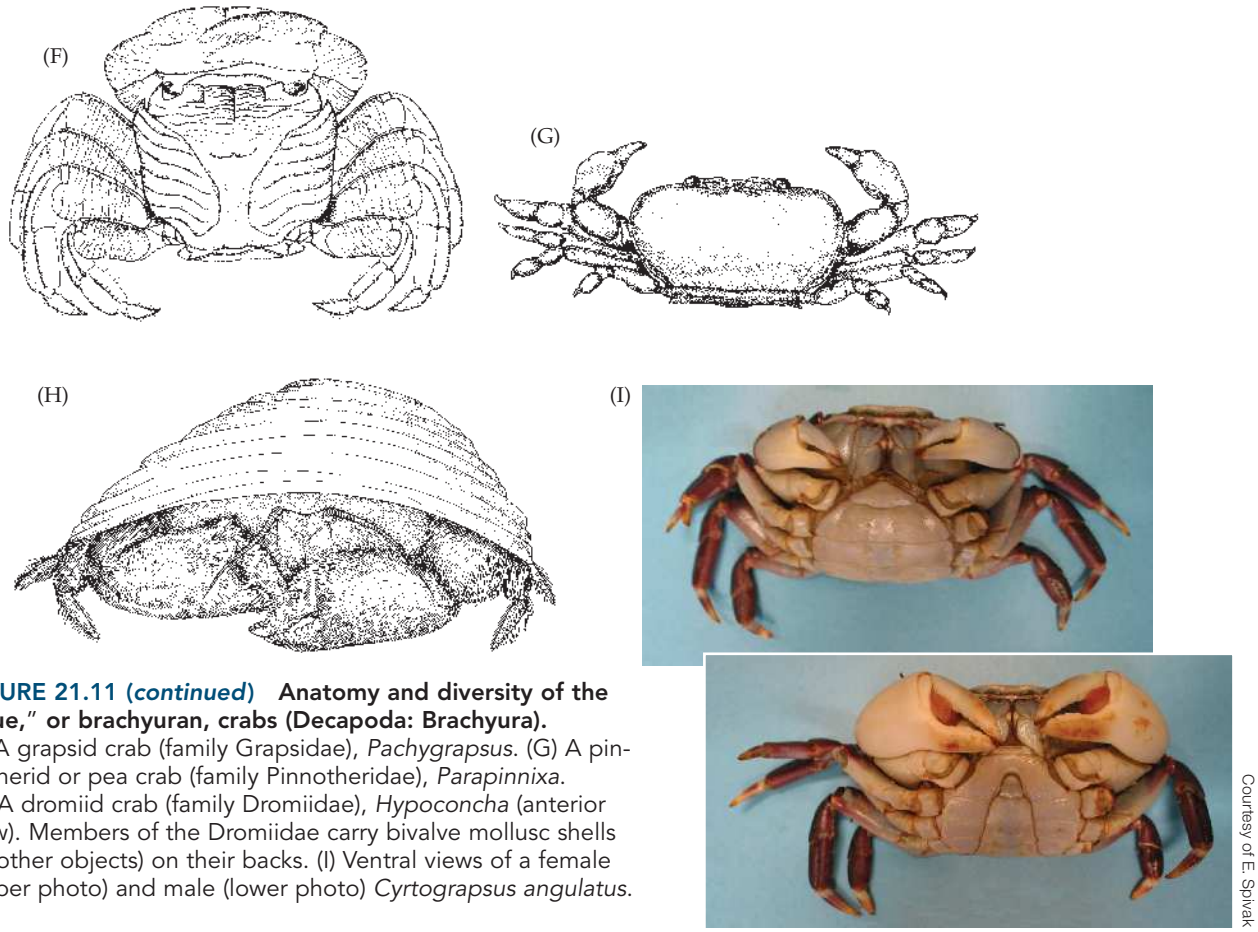

FIGURE 21.11 (*continued*) Anatomy and diversity of the "true," or brachyuran, crabs (Decapoda: Brachyura). (F) A grapsid crab (family Grapsidae), *Pachygrapsus*. (G) A pinnotherid or pea crab (family Pinnotheridae), *Parapinnixa*. (H) A dromiid crab (family Dromiidae), *Hypoconcha* (anterior view). Members of the Dromiidae carry bivalve mollusc shells (or other objects) on their backs. (I) Ventral views of a female (upper photo) and male (lower photo) *Cyrtograpsus angulatus*.

tropics. The land crabs (certain species in the families Gecarcinidae, Ocypodidae, Grapsidae, etc.) are still dependent on the ocean for breeding and larval development. The surprisingly large number of freshwater crabs (about 3,000 species, classified into about a dozen families) all have direct development, incubate their embryos, and are independent of seawater. Some freshwater crabs are intermediate hosts of *Paragonimus*, a cosmotropical parasitic human lung fluke, and others are obligate phoretic hosts of larval black flies (*Simulium*), the vector for *Onchocerca volvulus* (the causative agent of river blindness). A number of crab species carry other invertebrates on their carapace (e.g., sponges, tunicates) or on their claws (e.g., anemones); these associations are generally thought to be mutualistic, providing camouflage or predator deterrence for the crab while their partner is moved about in the environment and may feed off debris from their host's feeding activities. In the northeast Pacific, megalopae and juveniles of the crab *Metacarcinus gracilis* ride (and feed) on the bell of certain jellyfish; individuals of *Phacellophora camtschatica* (Scyphozoa) have been found with hundreds of *M. gracilis* megalopae. Evidence suggests Brachyura and Anomura are sister groups (a clade known as Meiura).

Infraorder Anomura This group includes about 2,500 species of hermit crabs, galatheid crabs, king crabs, porcelain crabs, mole crabs, and sand crabs. The abdomen may be soft and asymmetrically twisted (as in hermit crabs) or symmetrical, short, and flexed beneath the thorax (as in porcelain crabs and others). Those with twisted abdomens typically inhabit gastropod shells or other empty "houses" not of their own making. Carapace shape and gill structure vary among the Anomura. The first pereopods are chelate; the third pereopods are never chelate. The second, fourth, and fifth pairs are usually simple, but occasionally they are chelate or subchelate. The fifth pereopods (and sometimes the fourth) are generally much reduced and do not function as walking limbs; the fifth pereopods function as gill cleaners and often are not visible externally. The pleopods are reduced or absent. The eyes are positioned medial to the antennae. The zoea larva is similar to that of the true crabs but is typically longer than broad, with the rostral spine directed anteriorly. Most anomurans are marine, but a few freshwater and semiterrestrial species are known. The so-called "yeti crab" (*Kiwa hirsuta*) was discovered in 2005 at a depth of 2,200 m in hydrothermal vents south of Easter Island. It is remarkable for its "garden" of filamentous bacteria that grow on the long setae of the exoskeleton; the bacteria are heterotrophic, utilizing sulfides in the deep environment (the precise role of the bacteria, of several species, in the life history of the yeti crab is not yet well understood).

for more ebook/ testbank/ solution manual Requests email 9601267734@qq.com

Several additional *Kiwa* species have been described since 2011. Common anomuran genera include *Aegla*, *Birgus*, *Blepharipoda*, *Calcinus*, *Clibanarius*, *Coenobita*, *Dardanus*, *Diogenes*, *Emerita*, *Hapalogaster*, *Hippa*, *Kiwa*, *Lepidopa*, *Lithodes*, *Lomis*, *Pagurus*, *Petrocheles*, *Petrochirus*, and *Pleuroncodes* (Figures 21.1F–J, 21.12C–G, 21.24A–C, 21.31A, and 21.33I).

Infraorder Astacidea Freshwater crayfish and clawed lobsters; 685 species (e.g., *Astacus*, *Cambarus*, *Cherax*, *Faxonella*, *Homarus*, *Nephrops*, *Pacifastacus*). As in most other decapods, the dorsoventrally flattened abdomen terminates in a strong tail fan (Figure 21.2). The gills are trichobranchiate. The first 3 pairs of pereopods are always chelate, and the first pair is greatly enlarged. *Homarus americanus*, the American or Maine lobster, is strictly marine and is the largest living crustacean by weight (the record weight being over 20 kg). Most crayfish live in fresh water, but a few species live in damp soil, where they may excavate extensive and complex burrow systems. The 670+ species of freshwater crayfish (in 5 families) comprise a monophyletic group that is sister group to clawed lobsters, the crayfish originating around 330 million years ago. Over 425 species of

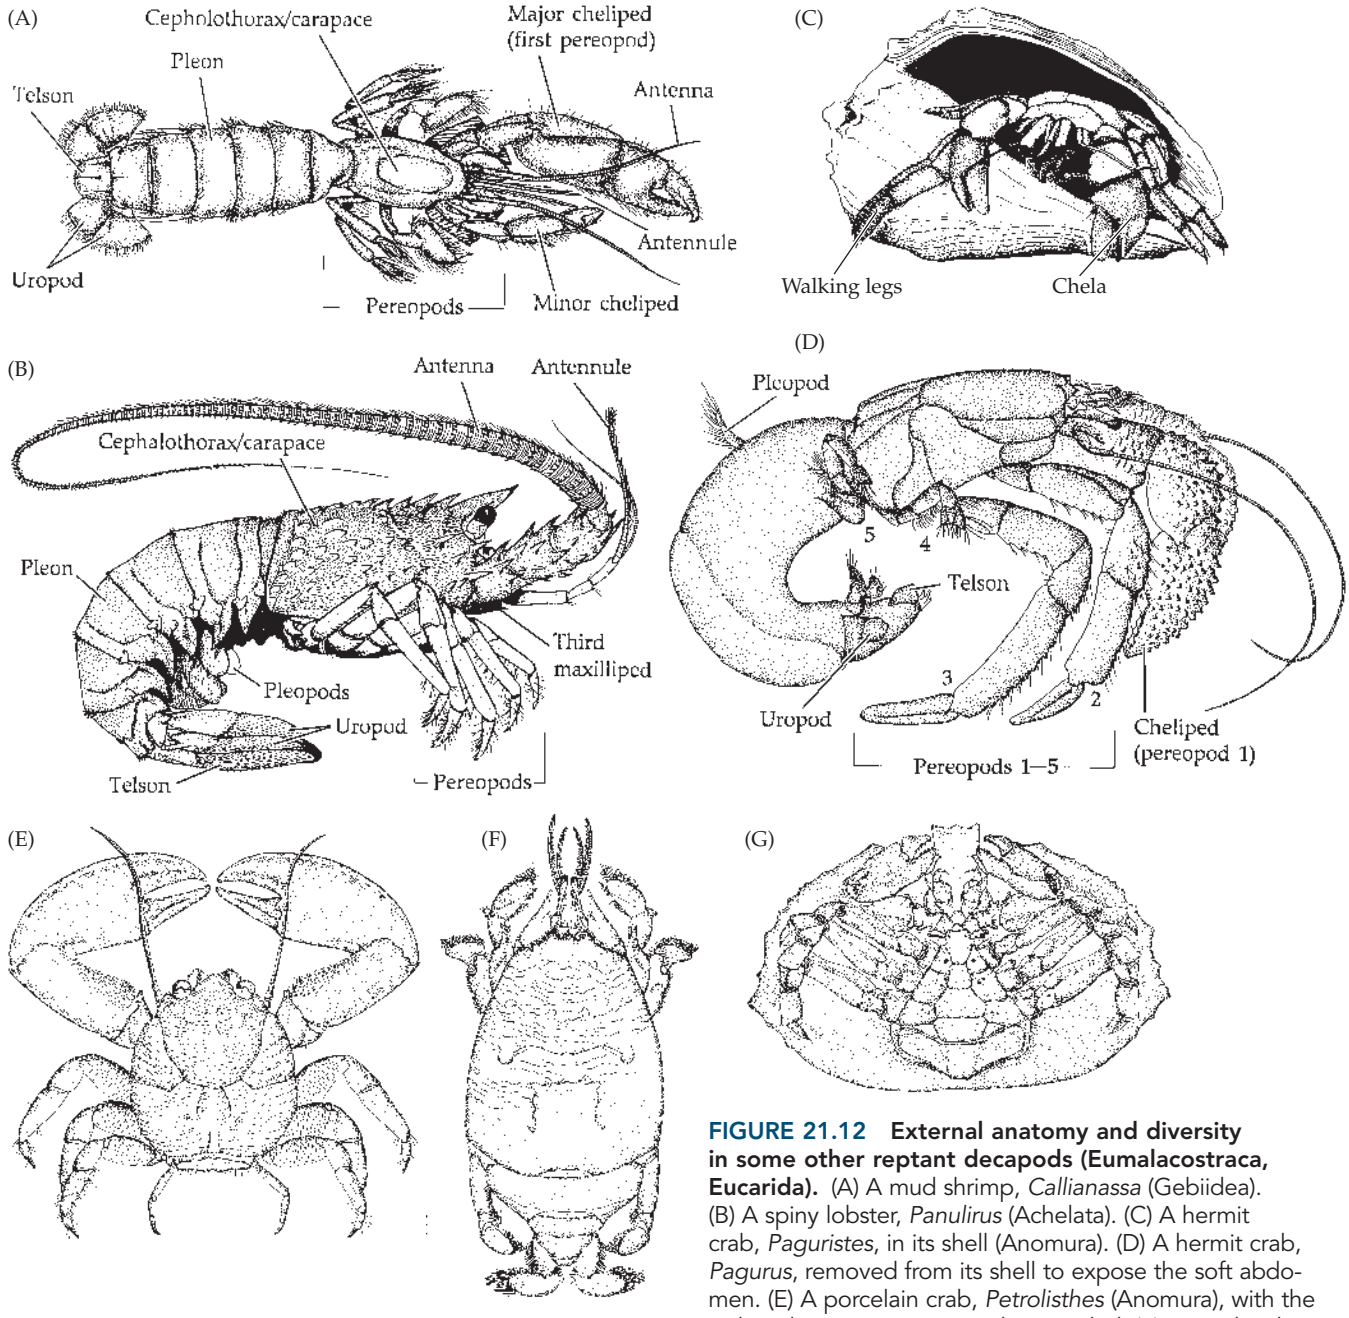

FIGURE 21.12 External anatomy and diversity in some other reptant decapods (Eumalacostraca, Eucarida). (A) A mud shrimp, *Callianassa* (Gebiidea). (B) A spiny lobster, *Panulirus* (Achelata). (C) A hermit crab, *Paguristes*, in its shell (Anomura). (D) A hermit crab, *Pagurus*, removed from its shell to expose the soft abdomen. (E) A porcelain crab, *Petrolisthes* (Anomura), with the reduced posterior pereopods extended. (F) A sand crab, *Emerita* (Anomura). (G) The umbrella crab *Cryptolithodes* (Anomura), in ventral view.

crayfish occur in North America alone, where they show high levels of endemicity to particular regions or river drainages (Figures 21.27E,G and 21.29B). Many of these are among the most invasive freshwater crustaceans.

Infraorder Achelata This group includes 140 species of spiny and slipper lobsters, many of economic importance (e.g., *Arctides*, *Evibacus*, *Ibacus*, *Panulirus*). The name Achelata comes from the fact that they lack chelae on all pereopods as adults (except for a small grooming claw on pereopod 5 in some females). The flattened abdomen bears a tail fan; the carapace may be cylindrical or flattened dorsoventrally; the gills are trichobranchiate. The large, flattened larvae, called phyllosomas because of their leaflike appearance, are unique and distinctive. All species are marine, and they are found in a variety of habitats throughout the tropics. Many species produce sounds by rubbing a process (the plectrum) at the base of the antennae against a "file" on the head (Figures 21.1M, 21.12B, 21.30A,C, and 21.33L).

Infraorders Axiidea and Gebiidea The lobster shrimps (Axiidea, 423 species, e.g., *Axius*, *Callianassa*, *Neotrypaea*, *Upogebia*) and mud/ghost shrimps (Gebiidea, 192 species, e.g., *Axianassa*, *Naushonia*). These 2 infraorders, formerly combined as Thalassinidea, have recently been recognized as distinct (the vernacular term "thalassinid" is still sometimes used to refer to them together) though they are very similar in appearance. The phylogenetic relationships of these shrimps remain unsettled. The symmetrical abdomen is flattened dorsoventrally and extends posteriorly as a well-developed tail fan. The carapace is somewhat compressed laterally, and the gills are trichobranchiate. The first 2 pairs of pereopods are chelate, and the first pair is generally much enlarged. Most of these animals are marine burrowers or live in coral rubble. They generally have a rather thin, lightly sclerotized cuticle, but some (e.g., members of the family Axiidae) have thicker skeletons and are more lobsterlike in appearance. Gebiideans often occur in huge colonies on tidal flats, where their burrow holes form characteristic patterns on the sediment surface (Figures 21.1L and 21.12A).

Infraorders Glypheidea and Polychelida The glypheids are something of a relict group, represented by 2 living genera (*Neoglyphea* and *Laurentaeglyphea*), each with a single species, of a formerly diverse group known from the fossil record. Polychelids are a group of about 38 blind deep-sea lobsters (e.g., *Polycheles*), notable for having chelae on all of their pereopods and unusual, large, globate larvae (called eryoneicus larvae) unique among the decapods.

Superorder Peracarida Telson without caudal rami; 1 pair (rarely 2–3) of maxillipeds; maxilliped basis typically produced as a bladelike endite; mandibles with articulated accessory process in adults, between molar and incisor process, called the **lacinia mobilis**; carapace, when present, not fused with posterior pereonites and usually reduced in size; gills thoracic or abdominal; with unique, thinly flattened thoracic coxal endites, called oostegites, that form a ventral brood pouch or marsupium in females of all species except members of the order Thermosbaenacea (the latter using the carapace to brood embryos); young hatch as **mancas**, a prejuvenile stage lacking the last pair of thoracopods (no free-living larvae occur among the Peracarida) (Figures 21.13–21.16).

The roughly 25,000 species of peracarids are divided among ten orders. The peracarids are an extremely successful group of malacostracan crustaceans known from many habitats. Although most are marine, many also occur on land and in fresh water, and several species live in hot springs at temperatures of 30°C–50°C. Aquatic forms include planktonic as well as benthic species at all depths. The group includes the most successful terrestrial crustaceans—the pillbugs and sowbugs of the order Isopoda—and a few amphipods that have invaded land and live in damp forest leaf litter or gardens. Peracarids range in size from tiny interstitial forms only a few millimeters long to planktonic amphipods over 12 cm long (*Cystisoma*), deep-sea necrophagous amphipods exceeding 34 cm (*Alicella gigantea*), and benthic isopods growing to 50 cm in length (*Bathynomus giganteus*; Cirolanidae). These animals exhibit all sorts of feeding strategies; a number of them, especially isopods and amphipods, are commensals or parasites.

Order Mysida Carapace well developed, covering most of thorax, but never fused with more than 4 anterior thoracic segments; maxillipeds (1–2 pairs) not associated with cephalic appendages; thoracomere 1 separated from head by internal skeletal bar; abdomen with well-developed tail fan; pereopods biramous, except last pair, which are sometimes reduced; pleopods reduced or, in males, modified; compound eyes stalked, sometimes reduced; gills absent; usually with a statocyst in each uropodal endopod; adults with antennal glands (Figures 21.13A,B, 21.30B, and 21.33C).

There are more than 1,050 species of mysidans, ranging in length from about 2 mm to 8 cm, in two families: Mysidae and Petalophthalmidae. Most swim by action of the thoracic exopods. These are shrimplike crustaceans that are often confused with the superficially similar euphausiaceans (which lack oostegites and uropodal statocysts). Mysidans are pelagic or demersal and are known from all ocean depths; a few species occur in fresh water. Some species are intertidal and burrow into the sand during low tides. Most are omnivorous suspension feeders, eating algae, zooplankton, and suspended detritus. In the past, mysidans were combined with lophogastridans, stygiomysidans, and the extinct Pygocephalomorpha as the "Mysidacea." Phylogenetic studies show these groups to be very closely related to one another.

Order Stygiomysida Similar to mysidans. With biramous male and female pleopods, reduced to 1-segmented endopods and 3-segmented exopods; elongated uropod protopodites; uropods lacking statocysts; lack of podobranchs; thoracopods 2–4 modified as gnathopods; marsupium formed of 4 pairs of oostegites arising from thoracopods 3–6. Found primarily in subterranean waters with a marine influence, including anchialine caves, land crab burrows, and shrimp culture fields. Endemic species are known from anchialine caves in Caribbean Sea and Italy. Two families, fewer than 20 described species.

Order Lophogastrida Similar to mysidans, except for the following: maxillipeds (1 pair) associated with the cephalic appendages; thoracomere 1 not separated from head by internal skeletal bar; pleopods well developed; gills present; adults with both antennal and maxillary glands; without uropodal statocysts; all 7 pairs of pereopods well developed and similar (except among members of the family Eucopiidae, in which their structure varies) (Figures 21.13C,D and 21.21G).

There are three families and about 55 known species of lophogastridans, most of which are 1–8 cm long, although the giant *Neognathophausia ingens* reaches 35 cm. All are pelagic swimmers, and the group has a cosmopolitan oceanic distribution. Lophogastridans are primarily predators on zooplankton.

Order Cumacea Carapace present, covering and fused to first 3 thoracic segments, whose appendages are modified as maxillipeds, the first with modified branchial apparatus associated with branchial cavity formed by carapace; pereopods 1–5 ambulatory and simple, 1–4 may be biramous; pleopods usually absent

in females and present in males; telson sometimes fused with sixth pleonite, forming pleotelson; uropods styliform; compound eyes absent, or sessile and usually fused (Figures 21.1P and 21.13E,F).

Cumaceans are small, odd-looking crustaceans with a large, bulbous anterior end and a long, slender posterior—resembling a horizontal comma! The great carcinologist Waldo Schmitt referred to them as "little wonders and queer blunders." They occur worldwide and include about 1,500 species, most of which are between 0.1 and 2 cm long, though some species in cold waters reach 3 cm in length. Most are marine, although a few brackish-water species are known. They live in association with bottom sediments but are capable of swimming and probably leave the bottom to breed. Most are deposit feeders or predators on the meiofauna; others eat the organic film on sand grains. The oldest known fossil cumacean, *Eobodotria muisca*, is from an exquisite, mid-Cretaceous (90–95 Ma), sedimentary deposit in tropical Colombia, and it has modern familial affinities.

Order Tanaidacea Carapace present and fused with first 2 thoracic segments, forming a cephalothorax; thoracopods 1–2 are maxillipeds, the second being chelate; thoracopods 3–8 are simple, ambulatory pereopods; pleopods present or absent; uropods biramous or uniramous; telson and last 1 or 2 pleonites fused as pleotelson; adults with maxillary and (vestigial) antennal glands; compound eyes absent, or present and on cephalic lobes. Members of this order are known worldwide from benthic marine habitats; a few live in brackish or nearly fresh water. Most of the 1,500 or so species are small, ranging from 0.5 to 2 cm in length. They often live in burrows or tubes and are known from all ocean depths. Many are suspension feeders, others are detritivores, and still others are predators (Figure 21.13G,H).

Order Mictacea Without a carapace, but with a well-developed head shield fused with first thoracomere and produced laterally over bases of mouthparts; 1 pair of maxillipeds; pereopods simple, 1–5 or 2–6 biramous, exopods natatory; gills absent; pleopods reduced, uniramous or biramous; uropods biramous, with 2–5 segmented rami; telson not fused with pleonites; stalked eyes present (*Mictocaris*) but lacking any evidence of visual elements, or absent (*Hirsutia*) (Figure 21.14D–E).

The order was erected to accommodate two species of unusual crustaceans: *Mictocaris halope* (from marine caves in Bermuda) and *Hirsutia bathyalis* (from a benthic sample 1,000 m deep in the Guyana Basin off northeastern South America). A third species of Mictacea was described in 1988 from Australia, and a fourth from the Bahamas in 1992; there are now six species known. Mictaceans are small, 2–3.5 mm in length. *Mictocaris halope* is the best known of these species because many specimens have been recovered and some have been studied alive. It is pelagic in cave waters and swims by using its pereopodal exopods. Some workers recognize the family Hirsutiidae (containing *Hirsutia*, *Montucaris,* and *Thetispelecaris*) as a separate order, the Bochusacea (male pleopods biramous).

Order Spelaeogriphacea Carapace short, fused with first thoracomere; 1 pair of maxillipeds; pereopods 1–7 simple, biramous, with shortened exopods; exopods on legs 1–3 modified for producing currents, on legs 4–7 as gills; pleopods 1–4 biramous, natatory; pleopod 5 reduced; tail fan well developed; compound eyes nonfunctional or absent, but eyestalks persist (Figures 21.14A and 21.21H). The order Spelaeogriphacea is currently known from only four living species. These rare, small (less than 1 cm) peracarids were long known only from a single species living in a freshwater stream in Bat Cave on Table Mountain, South Africa (*Spelaeogriphus lepidops*; Figure 21.14A). A second species is known from a freshwater cave in Brazil, and a third and fourth species were described from an aquifer in Australia. Little is known about the biology of these animals, but they are suspected to be detritus feeders. Like thermosbaenaceans, spelaeogriphaceans are thought to be relicts of a more widespread shallow-water marine Tethyan fauna stranded in interstitial and ground-water environments during periods of marine regression.

Order Thermosbaenacea Carapace present, fused with first thoracomere and extending back over 2–3 additional segments; 1 pair of maxillipeds; pereopods biramous, simple, lacking epipods and oostegites; carapace forms dorsal brood pouch (unlike all other peracarids, which form the brood pouch from ventral oostegites); 2 pairs of uniramous pleopods; uropods biramous; telson free or forming pleotelson with last pleonite; eyes absent (Figure 21.14B,C). About 35 species of thermosbaenaceans are recognized in 7 genera. *Thermosbaena mirabilis* is known from freshwater hot springs in North Africa, where it lives at temperatures in excess of 40°C. Several species in other genera occur in much cooler fresh waters, typically in groundwater or in caves. Other species are marine or inhabit underground anchialine pools. Limited data suggest that thermosbaenaceans feed on plant detritus.

Order Isopoda Carapace absent; first thoracomere fused with head; 1 pair of maxillipeds; 7 pairs of uniramous pereopods, the first of which is sometimes subchelate, others usually simple (gnathiids have only 5 pairs of pereopods, as thoracopod 2 is a maxillipedal "pylopod" and thoracopod 8 is missing); pereopods variable, modified as ambulatory, prehensile, or swimming; in the more derived suborders pereopodal coxae are expanded as lateral side plates

for more ebook/ testbank/ solution manuals requests email 9601267734@qq.com

(coxal plates); pleopods biramous and well developed, natatory and for gas exchange (functioning as gills in aquatic taxa, and with air sacs called pseudotrachea in most terrestrial Oniscidea); adults with maxillary and (vestigial) antennal glands; telson fused with 1 to 6 pleonites, forming pleotelson; eyes usually sessile and compound, absent from some, pedunculate in most Gnathiidea; with biphasic molting (posterior region molts before anterior region) (Figures 21.1Q, 21.15, 21.21I, 21.28H,I, and 21.33M).

The isopods comprise about 10,000 marine, freshwater, and terrestrial species, ranging in length from 0.5 to 500 mm, the largest being species of the benthic genus *Bathynomus* (Cirolanidae). They are common inhabitants of nearly all environments, and some groups are exclusively (e.g., Bopyridae, Cymothoidae) or partly (e.g., Gnathiidae) parasitic.

The suborder Oniscidea includes about 3,600 species that have invaded land (pillbugs and sowbugs); they are the most successful terrestrial crustaceans. Their direct development, osmoregulatory capabilities, thickened cuticle, and aerial gas exchange organs (pseudotrachea) allow most oniscideans to live completely divorced from aquatic environments. However, recent molecular phylogenies suggest Oniscidea is not a monophyletic group, invasion of land from the sea happened more than once, and the first land isopods appeared about 290 million years ago (coincident with the formation of Pangaea and the diversification of vascular plants on land). Males of several species of Oniscidea are reported to have tegumental glands; the glands comprise secretory cells and ducts to the cuticle surface, and they are suspected to produce peptides or glycoproteins involved in mating.

Isopod feeding habits are extremely diverse. Many are herbivorous or omnivorous scavengers, but direct plant feeders, detritivores, and predators are also common. The wood-boring marine gribbles, *Limnoria* (Oniscidea), comprise one of the few animal groups able to survive on a diet of cellulose without relying on resident gut microbiota. Some isopods are parasites (e.g., on fishes or on other crustaceans) that feed on the tissue fluids of their hosts. Overall, grinding mandibles and herbivory seem to represent the primitive state, with slicing or piercing mandibles and predation appearing later in the evolution of several isopod clades.

Order Amphipoda Carapace absent; first thoracomere fused to head; 1 pair of maxillipeds; 7 pairs of uniramous pereopods, with first, second, and sometimes others frequently modified as chelae or subchelae; pereopodal coxae expanded as lateral side plates (coxal plates); gills thoracic (medial pereopodal epipods); adults with antennal glands; abdomen "divided" into 2 regions of 3 segments each, an anterior "pleon" and posterior urosome, with anterior appendages as typical pleopods and urosomal appendages modified as uropods; telson free or fused with last urosomite; other urosomites sometimes fused; compound eyes sessile, absent in some, huge in many (but not all) members of the suborder Hyperiidea (Figures 21.1N,O, 21.16, 21.23, 21.27F, and 21.29D). Our classification follows Lowry and Myers (2013, 2017) who recognize 6 suborders.

The roughly 10,000 species of amphipods range in length from tiny 1 mm forms to giant deep-sea benthic species reaching 30 cm, and some planktonic forms exceed 10 cm. They have invaded most marine and freshwater habitats and often constitute a large portion of the biomass in many areas. Some are common in subterranean groundwater ecosystems, the majority being stygobionts (e.g., *Niphargus*, *Stygobromus*)—obligatory groundwater species characterized by reduction or loss of eyes, pigmentation, and occasionally appendages. There are many intertidal species, and a great many of these live in association with other invertebrates and with algae. Domicolous gammaridean amphipods in at least three families spin silk from their legs that is used for consolidating the walls of their tube or shelter. The largely terrestrial superfamily Talitroidea alone comprises 117 genera, some of which are common in moist gardens and greenhouses (e.g., *Arcitalitrus sylvaticus*). The largest known amphipod is *Alicella gigantea*, a cosmopolitan marine species living at depths of up to 7,000 m.

The suborder Hyperiidea includes exclusively pelagic amphipods that have escaped the confines of benthic life by becoming associated with other plankters, particularly gelatinous zooplankton such as medusae, ctenophores, and salps. The hyperiideans are usually characterized by transparent bodies and huge eyes (and a few other inconsistent features), but several groups bear eyes no larger than those of most other amphipods. The Hyperiidea are almost certainly a polyphyletic group, and it is thought that several lineages are derived independently from various ancestors, although a modern phylogenetic analysis has yet to be attempted. The precise nature of the relationships between hyperiideans and their zooplankton hosts remains controversial. Some appear to eat host tissue, others may kill the host to fashion a floating "home," and still others may utilize the host merely for transport or as a nursery for newly hatched young. Specimens of the scyphozoan *Phacellophora camtschatica* have been found with nearly 500 *Hyperia medusarum* riding (and feeding) on them. Species of *Phronima* are famous for their habit of hollowing out the bodies of salps (pelagic tunicates) to reside inside, propelling themselves around like miniature submersible vehicles. Their extraordinarily large eyes are said to have inspired the look of the creature in the legendary science fiction film *Alien*.

The 300 or so species of caprelloidean amphipods, or "skeleton shrimp" (a clade within the suborder Senticaudata), are highly modified for clinging to other

organisms, including filamentous algae and hydroids. In most species the body and appendages are very narrow and elongated. In one family of Caprelloidea, the Cyamidae (with 28 species), individuals are obligate symbionts on cetaceans (whales, dolphins, and porpoises) and have flattened bodies and prehensile legs.

In addition to parasitism, amphipods exhibit a vast array of feeding strategies, including scavenging, herbivory, carnivory, and suspension feeding.

Order Ingolfiellida Head with vestigial pedunculate eyes; gnathopods 1–2 eucarpochelate; pleosome with 6 relatively undifferentiated segments, without epimera, with reduced pleopods and uropods. Formerly placed within Amphipoda; 45 species in 2 families distributed worldwide, from deep waters to underground fresh waters in all sorts of habitats.

Class Copepoda

Without a carapace, but with a well-developed cephalic shield; single, median, simple maxillopodan eye (sometimes lacking); 1 or more thoracomeres fused to head; thorax of 6 segments, the first always fused to the head and with maxillipeds; abdomen of 5 segments, including anal somite (= telson); well-developed caudal rami; abdomen without appendages, except an occasional reduced pair on the first segment, associated with the gonopores; point of main body flexure varies among major groups; antennules uniramous, antennae uniramous or biramous; 4–5 pairs of natatory thoracopods, most locked together for swimming; posterior thoracopods always biramous; many species with myelin-like sheaths on some nerves (Figures 21.1U, 21.4B–L, 21.27A, 21.30D, and 21.33D).

There are more than 14,500 described species of copepods. They can be incredibly abundant in the world's seas, and also in some lakes, and they compete with euphausiaceans and ants for the title of most numerous of all animals on Earth. Some estimates suggest that copepods account for 80% of all mesozooplankton biomass in the ocean. Most are small, 0.5–10 mm long, but some free-living forms exceed 1.5 cm in length, and certain highly modified parasites may reach 25 cm. The bodies of most copepods are distinctly divided into three tagmata, the names of which vary among authors. The first region includes the fused head segments and one or two additional fused thoracic somites; it is called a cephalosome (= cephalothorax) and bears the usual head appendages and maxillipeds. All of the other limbs arise on the remaining thoracic segments, which together constitute the metasome. The abdomen, or urosome, bears no limbs. The appendage-bearing regions of the body (cephalosome and metasome) are frequently collectively called the prosome. The majority of the free-living copepods, and those most frequently encountered, belong to the orders Calanoida, Harpacticoida, and Cyclopoida, although even some of these are parasitic. We focus here on these three groups and then briefly discuss some of the other, smaller orders and their modifications for parasitism.

The calanoids are characterized by a point of major body flexure between the metasome and the urosome, marked by a distinct narrowing of the body. They possess greatly elongate antennules. Most of the calanoids are planktonic, and as a group they are extremely important as primary consumers in freshwater and marine food webs. The point of body flexure in the orders Harpacticoida and Cyclopoida is between the last two (fifth and sixth) metasomal segments. (Note: Some authors define the urosome in harpacticoids and cyclopoids as that region of the body posterior to this point of flexure.) Harpacticoids are generally rather vermiform, with the posterior segments not much narrower than the anterior; cyclopoids generally narrow abruptly at the major body flexure. Both the antennules and the antennae are quite short in harpacticoids, but the latter are moderately long in cyclopoids (although never as long as the antennules of calanoids). Most harpacticoids are benthic, and those that have adapted to a planktonic lifestyle show modified body shapes. Harpacticoids occur in all aquatic environments; encystment is known to occur in at least a few freshwater and marine species. Cyclopoids are known from fresh and salt water, and most are planktonic.

The nonparasitic copepods move by crawling or swimming, using some or all of the thoracic limbs. Many of the planktonic forms have very setose appendages, offering a high resistance to sinking. Calanoids are predominantly planktonic feeders. Benthic harpacticoids are often reported as detritus feeders, but many feed predominantly on microorganisms living on the surface of detritus or sediment particles (e.g., diatoms, bacteria, and protists).

Of the seven remaining orders, the Mormonilloida are planktonic; the Misophrioida are known from deep-sea epibenthic habitats as well as anchialine caves in both the Pacific and Atlantic; and the Monstrilloida are planktonic as adults, but the larval stages are endoparasites of certain gastropods, polychaetes, and occasionally echinoderms. Members of the orders Ergasilida and Siphonostomatoida are exclusively parasitic and often have modified bodies; some form galls on their hosts (e.g., lamippids on sea pens). Siphonostomatoids are endo- or ectoparasites of various invertebrates as well as marine and freshwater fishes; they are often very tiny and show a reduction or loss of body segmentation. Ergasilidans parasitize invertebrates and marine fishes and may also show a reduced number of body segments. The Platycopioida are benthic forms known primarily from marine caves; the Gelyelloida are known only from European groundwaters. Huys and Boxshall (1991) estimated that nearly half of all known copepod species are parasites.

Class Thecostraca

This group includes the barnacles, parasitic ascothoracidans, and the mysterious Facetotecta (so far, known only from their larvae). The thecostracan clade is defined by several rather subtle synapomorphies of cuticular fine structure, including cephalic chemosensory structures known as lattice organs. The group is also supported by molecular phylogenetic analyses. All taxa have pelagic larvae, the terminal instar of which is a unique larva, the **cypris larva (or cyprid)**, with prehensile antennules specialized for locating and attaching to the substratum of the sessile adult state.

Subclass Facetotecta Monogeneric (*Hansenocaris*): The "y-larvae," a half dozen small (250–620 mm) marine nauplii and cyprids (Figure 21.17I). Although known since Hansen's original description in 1899, the adult stage of these animals has still not been identified. However, a stage subsequent to the cypris larva, the sluglike ypsigon stage, has been induced by treating y-larvae with molting hormones. The prehensile antennules and hooked labrum of the y-cyprids and the degenerative nature of the ypsigon suggest that the adults are parasitic in yet-to-be-identified hosts.

Subclass Ascothoracida About 125 described species of parasites of cnidarians and echinoderms. Although greatly modified, they retain a bivalved carapace and the full complement of thoracic (11 segments) and abdominal (5 segments) somites. Ascothoracidans generally have mouthparts modified for piercing and sucking body fluids, but some live inside other animals and absorb the host's tissue fluids. In at least one species, *Synagoga mira*, males retain the ability to swim throughout their lives, attaching only temporarily while feeding on corals (Figure 21.17F).

Subclass Cirripedia Primitively with tagmata as in the class, but in most groups the adult body is modified for sessile or parasitic life. Thorax of 6 segments with paired biramous appendages; abdomen strongly reduced or absent; telson absent in most, although caudal rami persist on abdomen in some; unique nauplius larva with frontolateral horns (which house nerves and large unicellular glands). All begin life with a series of free-swimming naupliar instars (planktotrophic or lecithotrophic) terminating in a unique, "bivalved," nonfeeding cypris larva (modified for settlement and subsequent metamorphosis into an adult); cyprid with articulating telson bearing 2 caudal (furcal) rami. Adult carapace "bivalved" (folded) or forming fleshy mantle; first thoracomere often fused with cephalon and bearing maxilliped-like oral appendages; female gonopores near bases of first thoracic limbs, male gonopore on median penis on last thoracic or first abdominal segment; compound eyes lost in adults (Figures 21.1S,T, 21.17A–E, 21.25, 21.26, 21.27B,C, 21.32E, and 21.33F).

The 1,300 or so described cirripede species are mostly free-living barnacles, but this group also includes some strange parasitic "barnacles" rarely seen except by specialists. The common acorn and goose barnacles belong to the superorder Thoracica. Some acorn barnacles are known to transform from their oval-shaped aperture to a narrow or bent aperture when exposed to predatory snails, making them better able to withstand predator assaults. The superorder Acrothoracica consists of minute animals that burrow into calcareous substrata, including corals and mollusc shells (Figure 21.17G). The superorder Rhizocephala are exceptionally modified parasites of other crustaceans, especially decapods (Figure 21.17H).

In cyprids the carapace is always present and "bivalved," the two sides being held by a transverse cypris adductor muscle; in adults the carapace may be lost (Rhizocephala) or modified as a membranous, saclike mantle (thoracicans and acrothoracicans). In the barnacles (Thoracica), it is this mantle that produces the familiar, hard, calcareous plates that enclose the body. Cyprids and adult acrothoracicans share a unique tripartite crystalline cone structure in the compound eye, a feature not known from any other crustacean group. Most species of barnacles are hermaphrodites, although separate sexes are the rule in acrothoracicans and rhizocephalans, and some androgonochoristic species (males + hermaphrodites; e.g., *Scalpellum*) have also been reported.

Locomotion in barnacles is generally confined to the larval stages, although adults of a few species are specifically adapted to live attached to floating objects (e.g., seaweeds, pumice, logs) or nektonic marine animals (e.g., whales, sea turtles). Cyprids can both swim and walk (on the antennules) to locate a suitable site for settlement, whereupon they cement themselves to the substratum; the paired cement glands constitute a synapomorphy for cirripedes (ascothoracidan cyprids attach by mechanical means). Others are often found on the shells and exoskeletons of various errant invertebrates (e.g., crabs and gastropods), which inadvertently provide a means of transportation from one place to another. Thoracican and acrothoracican barnacles use their feathery thoracopods (called **cirri**) to suspension feed. Barnacles in the family Coronulidae are suspension feeders that attach to whales and turtles (e.g., *Chelonibia, Platylepas, Stomatolepas, Coronula, Xenobalanus*). The 300 or so known species of rhizocephalans are all endoparasitic in other Crustacea, and they are the most highly modified of all cirripedes. They mainly inhabit decapod crustaceans, but a few are known from isopods, cumaceans, stomatopods, and even thoracican barnacles. Some even parasitize freshwater and terrestrial crabs. The body consists of a reproductive part (the **externa**) positioned outside the host's body, and an internal, ramifying, nutrient-absorbing part (the **interna**). Most of the externa is female and contains the ovary as well as the male "organs" in the form of one or several dwarf males that are implanted into the virginal female.

(I) A cypris y-larva, in lateral and dorsal views. (E after P. A. Meglitsch. 1972. *Invertebrate Zoology*. Oxford University Press, Oxford.)

All stages, including the nauplii and cyprids, lack any trace of an alimentary canal, and the parasitic stages lack any segmentation or appendages.[6]

Class Tantulocarida

A small group of about 3 dozen bizarre parasites of mostly deep-water crustaceans, although some are known from the intertidal zone and from anchialine pools and hydrothermal vents (Figures 21.1V and 21.18). Tantulocarids are the smallest living crustaceans, at least in the juvenile or "larval" stage (the **tantulus**), which ranges from just 70 to 150 μm (comparable in size to some protists). The unique tantulus stage is adapted to both free swimming (through sediments) and an attached parasitic mode of life. In the free-swimming phase there is a cephalon, 6-segmented thorax, and abdomen with up to 7 segments. The cephalon lacks appendages (except for unsegmented antennules in sexual females; absent in larvae) but has an internal median stylet. Natatory thoracopods 1–5 are biramous, 6 is uniramous; the abdomen lacks appendages but bears caudal rami. Paired bundles of longitudinal muscles run along the midline in the thoracic somites and partly into the abdomen. There is emerging molecular and morphological evidence that tantulocarids are closely related to thecostracans, and they might one day be moved into that class.

Tantulocarids have a most remarkable life cycle. Atypically, the tantulus is able to switch its lifestyle from one of mobility to that of a sessile parasite without further molting. Thus, this one stage represents adaptations for both motile and attached/sessile lifestyles, and the transformation from one to the other involves dramatic changes in the animal's physiology and anatomy. When the free-swimming tantulus finds a proper host, a unique cuticular organ, the proboscis (sometimes called the "funnel-shaped organ"), is everted from an oral disc to establish an attachment, likely using a type of glue. The proboscis is then retracted back into the tantulus,

[6]Rhizocephalans of the family Sacculinidae infest only decapod crustaceans and have been suggested as biological control agents for invasive exotics such as the green crab (*Carcinus maenas*), which are upsetting coastal ecosystems worldwide. Sacculinds have the ability to take control over such major host functions as molting and reproduction, and also to compromise the host's immune system.

and a permanent attachment is made by the oral disc. To access the host's nutrients, the tantulus pierces the victim's cuticle with a stylet (which has protractor and retractor muscles), which is subsequently withdrawn back into the larval head. The tip of the stylet is solid, and the organ apparently does not inject anything into the host. The tiny hole left from this puncture serves as an entrance for a unique rootlet system that grows into the host to absorb nutrients. Once attached to a host, the tantulus loses its attachment organs, including the cement glands, and all of the musculature degenerates and is resorbed. It then either sheds the whole trunk and forms a cuticular sac containing a developing parthenogenetic tantulus or female, or retains the trunk somites but expands to form a cuticular sac in which a male develops. Thus, the tantulus either enters a parthenogenetic phase (becoming a so-called parthenogenetic female, which produces more tantuli) or develops into a sexually reproducing adult. In both cases, the next stage develops inside the cuticular sac of the tantulus itself. Progeny are released into the environment.

Superclass Altocrustacea: Clade Allotriocarida

Class Cephalocarida

Head followed by 8-segmented thorax with each segment bearing limbs, an 11-segmented limbless abdomen, and a telson with caudal rami; common gonopore on protopods of sixth thoracopods; carapace absent but head covered by cephalic shield; thoracopods 1–7 biramous and phyllopodous, with large flattened exopods and epipods (exites) and stenopodous endopods; thoracopods 8 reduced or absent; maxillae resemble thoracopods; no maxillipeds; eyes absent; nauplii with antennal glands, adults with maxillary glands and (vestigial) antennal glands; with long and gradual (anamorphic) larval development (Figures 21.1B 21.19A–C, and 21.21A).

Cephalocarids are tiny, elongate crustaceans ranging in length from 2 to 4 mm. There are 12 species in five genera. All are benthic marine detritus feeders, although many seem to have commensal relationships with sedentary polychaetes. Most are associated with sediments covered by a layer of flocculent organic detritus, although some have been found in clean sands. They occur from the intertidal zone to depths of over 1,500 m, from the North and South Pacific to the North and South Atlantic and in the Mediterranean. Hatching is at a slightly advanced naupliar stage (called a metanauplius).

Class Branchiopoda

Numbers of segments and appendages on thorax and abdomen vary, the latter usually lacking appendages; carapace present or absent; telson usually with caudal rami; body appendages generally phyllopodous; maxillules and maxillae reduced or absent; no maxillipeds (Figures 21.1C,D, 21.20, 21.21B, 21.31C, and 21.35B).

The branchiopods are difficult to describe in a general way. The majority are small freshwater forms with leaflike legs and minimal body tagmosis. Most are short-lived, and those inhabiting ephemeral waters complete their life cycle in just a few weeks. Because of their short life cycle and predilection for temporary pools (e.g., vernal pools), many groups produce drought-resistant eggs or zygotes, called cysts, which can survive years or decades until the next adequate rains appear. As diverse as the branchiopods might appear, both morphological and molecular analyses indicate that they comprise a monophyletic group. Development is remarkably uniform across the group, with naupliar larvae distinguishable by several unique features. A few groups have conquered the world oceans secondarily (e.g., marine cladocerans). Most species are filter feeders, but predators are known both within Anostraca and Cladocera. About 1,130 extant species have been described (around half of which are cladocerans), and at least one fossil branchiopod (*Rehbachiella*) is known from the middle Cambrian, confirming that they are an ancient group. Although branchiopod taxonomy is still in a bit of flux, the group is generally divided into two subclasses, Anostraca (the carapaceless fairy shrimps) and Phyllopoda (the carapaced branchiopods).

Subclass Anostraca

Postcephalic trunk divisible into appendage-bearing thorax of 11 segments (or, rarely, 10, 17, or 19) and abdomen of 8 segments plus telson with caudal rami; gonopores on genital region of abdomen; trunk limbs biramous and phyllopodous; small cephalic shield present, though fully developed carapace lacking; paired, large, stalked compound eyes and a single median simple (naupliar) eye.

Anostracans are primitive-looking crustaceans commonly called fairy shrimps and brine shrimps that differ from all other branchiopods in lacking a carapace. There are just over 300 living species, worldwide, most of which are less than 1 cm in length, although a few giants attain lengths of 10 cm. Anostracans inhabit ephemeral ponds (including snowmelt ponds and desert pools), hypersaline lakes, and marine lagoons. In many areas they are an important food resource for water birds. Anostracans are sometimes united with the extinct Lipostraca as the "Sarsostraca." Their fossil record dates back to the Devonian.

Anostracans swim ventral side up by metachronal beating of the trunk appendages. Many use these limb movements for suspension feeding. Some other species scrape organic material from submerged surfaces, and at least two species (*Branchinecta gigas, B. raptor*) are specialized as predators on other fairy shrimps. Although most anostracans live in isolated ponds, their eggs are transported on the feathers of birds and feet of mammals

(F) The anterior end of a remipede (ventral view). In both the cephalocarids and the remipedes, the trunk is a long, homonomous series of somites with biramous swimming appendages. In cephalocarids the first trunk appendages are like all the others, which bear large swimming epipods (exites). In remipedes the first trunk somite is fused to the head, and its appendages are maxillipeds. See chapter opener photo of *Xibalbanus tulumensis*.

and might also be transported during passage through the gut of predatory diving beetles (Dytiscidae).

Subclass Phyllopoda

The tadpole shrimps (Notostraca) and "bivalved" branchiopods (Diplostraca).

Order Notostraca Thorax of 11 segments, each with 1 pair of phyllopodous appendages; abdomen of "rings," each formed of more than 1 true segment; each anterior ring with several pairs of appendages; posterior rings lack appendages; telson with long caudal rami; gonopores on last thoracomere; broad, shield-like carapace fused only with head, but extending to

Champeau. 1988. *J Crust Biol* 8: 70–78.)

loosely cover thorax and part of abdomen; paired, sessile compound eyes and a single simple eye near anterior midline on carapace.

There are only about a dozen living species of tadpole shrimps, in two genera (*Triops* and *Lepidurus*) placed in a single family, Triopsidae. Most species are 2–10 cm long. The common name derives from the general body shape: the broad carapace and narrow "trunk" give the animals a superficial tadpolelike appearance.

Notostracans inhabit inland waters of all salinities, but none occur in the ocean. Of the two known genera, *Triops* (Figure 21.20D,E) lives only in temporary waters, and its eggs are capable of surviving extended dry periods. Most species of *Lepidurus* live in temporary ponds, but at least one species (*L. arcticus*) inhabits permanent ponds and lakes. However, all species are short-lived, and most complete their life cycle in just 30 to 40 days. *Triops* is of some economic importance in that large populations often occur in rice paddies and destroy the crop by burrowing into the mud and dislodging young plants. Tadpole shrimps mostly crawl, but they are also capable of swimming for short periods by beating the thoracic limbs. They are omnivorous, feeding mostly on organic material stirred up from the sediments, although many species scavenge or prey on other animals, including molluscs, other crustaceans, frog eggs, and even frog tadpoles and small fishes. Some species of notostracans are exclusively gonochoristic, but others may include hermaphroditic populations (often those populations living at high latitudes). Earlier reports of parthenogenetic populations have been questioned.

Order Diplostraca The "bivalved" branchiopods: clam shrimps and cladocerans (water fleas) (Figure 21.20J–L). Large "bivalved" carapace covers all or most of the body; body divided into cephalon and trunk, the latter with 10–32 segments, all with appendages, and with no regionalization into thorax and abdomen; trunk limbs phyllopodous, decreasing in size posteriorly; males with trunk limbs 1, or 1–2, modified for grasping females during mating; trunk typically terminates in spinous anal somite or telson, usually with robust caudal rami (cercopods); gonopores on eleventh trunk segment; bivalved carapace completely encloses body; valves folded (Onychocaudata) or hinged (Laevicaudata) dorsally; usually with a pair of sessile compound eyes and a single, median, simple eye.

Most diplostracans are benthic, but many swim during reproductive periods. Some are direct suspension feeders, whereas others stir up detritus from the substratum and feed on suspended particles, and others scrape pieces of food from the sediment. There are two suborders, Laevicaudata and Onychocaudata.

The suborder Laevicaudata, or flat-tailed clam shrimps, contains the single family Lynceidae with close to 40 freshwater species. They are characterized by a hinged, globular carapace that encloses the entire animal. This carapace gives them a superficial resemblance to cladocerans and ostracods, and lack of obvious growth lines on the carapace quickly distinguishes them from Spinicaudata and Cyclestherida. The suborder Onychocaudata contains the spiny-tailed or "true" clam shrimp (Spinicaudata), the monotypic Cyclestherida (*Cyclestheria hislopi*), and the cladocerans (the water fleas). *Cyclestheria* is also sometimes called a clam shrimp, though it is more closely related to the Cladocera than to Spinicaudata. Despite the confused taxonomy of *Daphnia* (only a quarter of the >360 named species are valid), it has become a model genus for ecological, toxicological, and evolutionary studies.

The common name "clam shrimp" derives from the clamlike appearance of the valves, which usually bear concentric growth lines reminiscent of bivalved molluscs. The approximately 200 species of clam shrimps (including laevicaudatans, spinicaudatans, and *Cyclestheria*) live primarily in ephemeral freshwater habitats worldwide. *Cyclestheria hislopi* inhabits permanent freshwater habitats throughout the world's tropics and is one of the most widespread animals on Earth. *Cyclestheria* is also the only clam shrimp with direct development, the larval and juvenile stages being passed within the brood chamber, one of the features allying it with the cladocerans in the infraorder Cladoceromorpha.

In cladocerans, the carapace is never hinged (only folded dorsally, like a taco) and never covers the entire body, and appendages do not occur on all the trunk somites. The body segmentation is generally reduced. The thorax and abdomen are fused as a "trunk" bearing 4–6 pairs of appendages anteriorly and terminating in a flexed "postabdomen" with clawlike caudal rami. The trunk appendages are usually phyllopodous. The carapace typically encloses the entire trunk, but not the cephalon, serving as a brood chamber (and greatly reduced to this function) in some species; a single median compound eye is always present.

The cladocerans, or water fleas, include about 400 species of predominantly freshwater crustaceans. Several American marine genera and species are known (e.g., *Evadne*, *Podon*). Although there are relatively few species, the group exhibits great morphological and ecological diversity. Most cladocerans are 0.5–3 mm long, but *Leptodora kindtii* reaches 18 mm in length. Except for the cephalon and large natatory antennae, the body is enclosed by a folded carapace, which is fused with at least some of the trunk region. The carapace is greatly reduced in members of the families Polyphemidae and Leptodoridae, in which it forms a brood chamber.

Cladocerans are distributed worldwide in nearly all inland waters. Most are benthic crawlers or burrowers, while others are planktonic and swim by means of their large antennae. One genus (*Scapholeberis*) is typically found in the surface film of ponds, and another (*Anchistropus*) is ectoparasitic on *Hydra*. Most of the benthic forms feed by scraping organic material from sediment particles or other objects; the planktonic

for more ebook/ testbank/ solution manuals requests email 9601267734@qq.com

species are suspension feeders. Some, such as *Leptodora* and *Bythotrephes*, are predators on other cladocerans.

In sexual reproduction, fertilization generally occurs in a brood chamber between the dorsal surface of the trunk and the inside of the carapace. Most species have direct development. In the family Daphniidae the developing embryos are retained by a portion of the shed carapace, which functions as an egg case called an **ephippium** (Figure 21.20H), whereas in the Chydoridae the ephippium remains attached to the entire shed carapace. *Leptodora* exhibits a heterogenous life cycle, alternating between parthenogenesis and sexual reproduction, the latter of which results in free-living larvae (metanauplii hatch from the shed resting eggs).

Cladoceran life histories are often compared with those of animals such as rotifers and aphids. Dwarf males occur in many species in all three groups, and parthenogenesis is common. Members of two cladoceran families that undergo parthenogenesis (Moinidae and Polyphemidae) produce eggs with very little yolk. In these groups the floor of the brood chamber is lined with glandular tissue that secretes a fluid rich in nutrients, which is absorbed by the developing embryos. Periods of overcrowding, adverse temperatures, or food scarcity can induce parthenogenetic females to produce male offspring. Occasional periods of sexual reproduction have been shown to occur in most parthenogenetic species. Many planktonic cladocerans undergo seasonal changes in body form through succeeding generations of parthenogenetically produced individuals (Figure 21.20I), a phenomenon known as cyclomorphism.

Class Remipedia

Body of 2 regions, a short cephalon and an elongate homonomous trunk of up to 32 segments, each with a pair of flattened limbs. Cephalon with a pair of sensory preantennular frontal processes; first antennae (antennules) biramous; trunk limbs laterally directed, biramous, paddlelike, but without large epipods; rami of trunk limbs (exopod and endopod) each of 3 or more articles; without a carapace, but with cephalic shield covering head; midgut with serially arranged digestive ceca; first trunk segment fused with head and bearing 1 pair of prehensile maxillipeds; labrum very large, forming a chamber (atrium oris) in which reside the "internalized" mandibles; maxillules function as hypodermic fangs, injecting venom from associated venom glands; last trunk segment partly fused dorsally with telson; telson with caudal rami; segmental double ventral nerve cord; eyes absent in living species; male gonopore on trunk limb 15, female on 8; up to 45 mm in length. The above diagnosis is for the 27 known living remipedes (order Nectiopoda); the fossil record is currently based on a single poorly preserved specimen (order Enantiopoda) (chapter opener and Figures 21.1A, 21.19D–F, 21.21D, 21.22F, and 21.31E,F).

The discovery of living remipedes in 1981 by Jill Yager, strange vermiform crustaceans first collected from a cavern in the Bahamas, gave the carcinological world a turn. The combination of features distinguishing these creatures is puzzling, for they possess characteristics long thought to be primitive (e.g., long, homonomous trunk; double ventral nerve cord; segmental digestive ceca; cephalic shield) as well as some attributes traditionally recognized as advanced (e.g., maxillipeds; nonphyllopodous [though flattened], biramous limbs). They swim about on their backs as a result of metachronal beating of the trunk appendages, similar to anostracans. The remipedes are thus reminiscent of two other classes, the branchiopods and cephalocarids. However, the laterally directed limbs are unlike those of any other crustacean, and the "internalized" mandibles and the poison-injecting hypodermic maxillules are unique (the complex venom contains neurotoxins, peptidases, and chitinases). The presence of the preantennular processes is also puzzling, although similar structures are known to occur in a few other crustaceans. Some phylogenetic analyses based on morphological data suggest that remipedes may be the most primitive living crustaceans, whereas phylogenomic data place them unambiguously as the sister group of the Hexapoda.

All of the living remipedes discovered thus far are troglobitic, found in caves, cenotes, lava tubes, and sinkholes (usually with connections to the sea) in the Caribbean Basin, Canary Islands, and Western Australia. The water in these systems is often distinctly stratified, with a layer of fresh water overlying the denser salt water in which the remipedes swim. Remipedes hatch as lecithotrophic naupliar larvae, which is also unusual given their habitat (most cave crustaceans have direct development). Postnaupliar development is anamorphic; juveniles have fewer trunk segments than do the adults. Based on the three pairs of raptorial, prehensile cephalic limbs (and direct observations), it was long thought that remipedes were strictly predators. However, studies by Stefan Koenemann and his colleagues have suggested they might also be capable of suspension feeding.

The Crustacean Body Plan

We realize that the above synopses are rather extensive, but the diversity of crustaceans demands emphasis before we attempt to generalize about their biology. The evolutionary success of crustaceans, like that of other arthropods, has been closely tied to modifications of the jointed exoskeleton and appendages, the latter having an extensive range of modifications for a great variety of functions.

The most basic crustacean body plan is a **head (cephalon)** followed by a long body (**trunk**) with many similar appendages, as seen in the class Remipedia (Figures 21.1A and 21.19D,E). In the other crustacean classes, however, various degrees of tagmosis occur, and the cephalon is typically followed by a trunk that is usually divided into two distinct regions, a **thorax** and an **abdomen**. The

first segment of the body (ocular segment) and the last segment of the body (telson) are without appendages. Many crustacean groups have a **cephalic shield** (**head shield**) or a **carapace**. The cephalic shield results from the fusion of the dorsal head tergites to form a solid cuticular plate, often with ventrolateral folds (**pleural folds**) on the sides. Head shields are found in ancient Cambrian fossil crustaceans (e.g., from the Orsten fauna), and they are characteristic of the classes Remipedia and Cephalocarida; they also occur in a few other groups. The carapace is a more expansive structure, composed of the head shield and a large fold of the exoskeleton that probably arises (primitively) from the maxillary somite. The carapace may extend over the body dorsally and laterally as well as posteriorly, and it often fuses to one or more thoracic segments, thereby producing a **cephalothorax** (Figure 21.2A). Occasionally, the carapace may grow forward beyond the head as a narrow rostrum.

Most of the differences among the major groups of crustaceans, and the basis for much of their classification, arise from variations in the number of somites in the thorax and abdomen, the form of their appendages, and the size and shape of the carapace. A brief skimming of the synopses (above) and the corresponding figures will give you some idea of the range of variation in these features.

Uniformity within the subphylum Crustacea is demonstrated particularly by the consistency of elements of the cephalon and the presence of the nauplius larva. Except for a few cases of secondary reduction, the head of all crustaceans has five pairs of appendages. From anterior to posterior, these are the **antennules** (first antennae), **antennae** (second antennae), **mandibles**, **maxillules** (first maxillae), and **maxillae** (second maxillae). The presence of two pairs of antennae is, among arthropods, unique to the Crustacea (as is the nauplius larva, although similar "head larvae" are known from other arthropod groups in the fossil record).[7] Although the eyes of some crustaceans are simple, most possess a pair of well-developed compound eyes, either set directly on the head (sessile eyes) or borne on distinct movable stalks (stalked eyes).

In many crustaceans, from one to three anterior thoracic segments (**thoracomeres**) are fused with the cephalon. The appendages of these fused segments are typically incorporated into the head as additional mouthparts called **maxillipeds**. In some cases, anterior thoracopods may not fuse with the cephalon during

[7]Cambrian crustacean-like larvae in the fossil record termed "head larvae" may be precursors to the distinctive nauplius stage seen in many modern crustaceans. See Martin et al. (2014).

TABLE 21.1 Comparison of Distinguishing Features among the 11 Crustacean Classes (and in the Subclasses of Class Eumalacostraca)

Taxon	Carapace or Cephalic Shield	Body Tagmata and Number of Segments in Each (excluding telson)	Thoracopods
Class Ostracoda	Carapace, bivalved	Subdivisions not clear; 6–8 pairs of limbs	Not phyllopodous, reduced
Class Mystacocarida	Cephalic shield	Cephalon (6), trunk (10)	Not phyllopodous
Class Branchiura	Carapace broad, covering head and trunk	Cephalon (6), thorax (6), abdomen (4?)	Not phyllopodous (but all natatory)
Class Pentastomida	None	Not distinguishable; body vermiform	None
Class Malacostraca, subclass Phyllocarida	Large, folded carapace covers thorax	Cephalon (6), thorax (8), abdomen (7)	Phyllopodous
Class Malacostraca, subclass Hoplocarida	Well-developed carapace covers thorax	Cephalon (6), thorax (8), abdomen (6)	Not phyllopodous
Class Malacostraca, subclass Eumalacostraca	Carapace well developed or secondarily reduced or lost	Cephalon (6), thorax (8), abdomen (6)	Not phyllopodous, uniramous in many
Class Copepoda	Cephalic shield	Cephalon (6), thorax (6), abdomen (5)	Not phyllopodous, natatory, often reduced
Class Thecostraca	Carapace bivalved (at some stage), often modified as a mantle	Cephalon (6), thorax (6), abdomen (4)	Not phyllopodous, often reduced
Class Tantulocarida	Cephalic shield	Cephalon (6), thorax (6), abdomen (up to 7)	Not phyllopodous, greatly reduced
Class Cephalocarida	Cephalic shield	Cephalon (6), thorax (8), abdomen (11)	Phyllopodous
Class Branchiopoda	Cephalic shield or carapace	Cephalon (6), thorax (usually 10–32), abdomen (8 to many)	Phyllopodous
Class Remipedia	Cephalic shield	Cephalon (6), trunk (up to 32)	Not phyllopodous

for more ebook/ testbank/ solution manuals Requests email 960126734@qq.com

development, but still become modified to move food to the mouth; these, too, are usually called maxillipeds. In the class Malacostraca, the remaining free thoracomeres are together termed the **pereon**. Each segment of the pereon is called a **pereonite** (= pereomere), and the appendages on those segments are called **pereopods**. The pereopods may be specialized for walking, swimming, gas exchange, feeding, and/or defense. Crustacean thoracic (and pleonal) appendages might be primitively biramous, although the uniramous condition is seen in a variety of taxa. The general crustacean limb is composed of a basal **protopod** (= sympod), from which may arise medial **endites** (e.g., gnathobases), lateral **exites** (e.g., **epipods**), and two rami, the endopod and exopod. Members of the classes Remipedia, Cephalocarida, and Branchiopoda and some members of the class Ostracoda possess appendages with uniarticulate (single-segment) protopods; the remaining classes usually have appendages with multiarticulate protopods (Table 21.1).[8]

[8]The term "peduncle" is a general name often applied to the basal portion of certain appendages; it is occasionally (but not always) used in a way that is synonymous with "protopod." As noted in Chapter 20, the exopod might be no more than a highly modified exite that evolved from an ancestral uniramous condition

The abdomen, called a **pleon** in malacostracans, is composed of several segments, or **pleonites** (= pleomeres), followed by a "postsegmental" plate or lobe, the **telson** or **anal somite**, bearing the anus (Figure 21.2B). In some crustaceans this anal somite bears a pair of appendage-like or spinelike processes conventionally called **caudal rami**. In the Eumalacostraca, the anal somite lacks caudal rami and is followed by a flattened flap; this flap is often referred to as the telson.

In general, distinctive abdominal appendages (**pleopods**) occur only in the malacostracans. These appendages are almost always biramous, and often they are flaplike and used for swimming (e.g., Figures 21.10–21.16). The posteriorly directed last pairs of abdominal appendages are usually different from the other pleopods and are called **uropods**. Together with the telson, the uropods form a distinct **tail fan** in many malacostracans (Figure 21.2B).

Crustaceans produce a characteristic larval stage called the **nauplius** (Figures 21.25B,C and 21.33D). Even upper Cambrian fossil nauplii (*Bredocaris admirabilis*, *Rehbachiella kinnekullensis*) are nearly indistinguishable from modern-day nauplii. In their simplest form, nauplii are oval or pear-shaped, lack external segmentation, and have three pairs of appendages

Maxillipeds	Antennules	Antennae	Compound Eyes	Abdominal Appendages
None	Uniramous	Biramous	Absent (typically)	None
1 pair	Uniramous	Biramous	Absent	None
None	Uniramous, reduced	Biramous, reduced	Present	None
None	None	None	Absent	None
None	Biramous	Uniramous	Present	Pleopods (posteriorly reduced)
5 pairs of thoracopods referred to as maxillipeds	Triramous	Biramous	Present, well developed	Well developed pleopods with gills, 1 pair of uropods
0–3 pairs	Uniramous or biramous	Uniramous or biramous	Present, well developed	Usually 5 pairs of pleopods, 1 pair of uropods
Usually 1 pair	Uniramous	Uniramous or biramous	Absent	None
None	Uniramous	Biramous	Absent (in adults)	None
None	None (paired in one stage)	None	Absent	None
None	Uniramous	Biramous	Absent	None
None	Uniramous	Uniramous, biramous, or vestigial	Present	None, or present but often posteriorly reduced
1 pair	Biramous	Biramous	Absent	All trunk appendages similar

that will become the adult antennules, antennae, and mandibles. The antennules are uniramous and primarily sensory. The antennae and mandibles are almost always biramous and usually natatory and feeding limbs. There is usually a single, anterior eye, the **nauplius eye** (= **naupliar eye**) that may persist into adulthood in some taxa. The nauplius eye is actually a cluster of three or four median eyes. The body is often covered with a dorsal cephalic (naupliar) shield, sometimes called a head shield, that commonly expands

TABLE 21.2 Summary of Crustacean Reproductive Features in Major Groups

Taxon	Development Type, or Larval Type at Hatching	Hermaphroditic (at Least Some Species)	Gonochoristic	Parthenogenesis (in at Least Some Species)
Class Ostracoda	Direct development, or with bivalved nauplius/metanauplius with anamorphic development	No	Yes	Yes
Class Mystacocarida	Metanauplius (partly anamorphic)	No	Yes	No
Class Branchiura	Metanauplius-like (partly anamorphic), or with direct development	No	Yes	No
Class Malacostraca, subclass Phyllocarida	Direct development	No	Yes	No
Class Malacostraca, subclass Hoplocarida	Zoea larva ("antizoea" or "pseudozoea") (metamorphic)	No	Yes	No
Class Malacostraca, subclass Eumalacostraca, superorder Syncarida	Direct development	No	Yes	No
Class Malacostraca, subclass Eumalacostraca, superorder Peracarida	Direct development	No	Yes	No
Class Malacostraca, subclass Eumalacostraca, superorder Eucarida, order Euphausiacea	Nauplius (metamorphic)	No	Yes	No
Class Malacostraca, subclass Eumalacostraca, superorder Eucarida, order Decapoda	Prezoea or zoea larva, and with a nauplius in Dendrobranchiata (metamorphic), or direct development	Rare	Yes	No
Class Copepoda	Nauplius (metamorphic)	No	Yes	No
Class Thecostraca	?	Yes	Yes	No
Class Tantulocarida	Nauplius? + tantulus (metamorphic)	No	Yes	?
Class Cephalocarida	Metanauplius (anamorphic)	Yes	No	No
Class Branchiopoda	Nauplius or metanauplius (anamorphic), or direct development	Yes/no	Yes	Yes
Class Remipedia	Nauplius (anamorphic)	Yes	No	No

over the thorax of the adult as a carapace. Behind the head segments is a growth zone and the telson.

In many groups (e.g., Peracarida, most Decapoda), the free-living nauplius larva is absent or suppressed. In such cases, development is either fully direct or mixed, with larval hatching taking place at some postnaupliar stage (Table 21.2). Often other larval stages follow the nauplius (or other hatching stage) as the individual passes through a series of molts, during which segments and appendages are gradually added. A recent compilation of all crustacean larval forms (Martin et al. 2014) includes keys to the distinctive naupliar larvae in all groups that hatch as a nauplius as well as synopses of larval development in all crustaceans.

Comments
Embryos usually deposited directly on substratum; many myodocopans and some podocopans brood embryos between valves until hatching as reduced adults; no metamorphosis; up to 8 preadult instars.
Little studied, but apparently the eggs are laid free and up to 7 preadult stages may occur.
Embryos are deposited; only *Argulus* is known to hatch as metanauplii; others have direct development and hatch as juveniles.
Undergo direct development in the female brood pouch, emerging as a postlarval/prejuvenile stage called a "manca."
Eggs brooded or deposited in burrow; hatch late as clawed pseudozoea larvae, or earlier as unclawed antizoea larvae. Both molt into distinct ericthus (and some into alima) larvae before settling on bottom as postlarvae or juveniles.
All free larval stages have been lost; eggs deposited on substratum.
Embryos brooded in marsupium of female, typically formed from ventral coxal plates called oostegites; usually released as mancas (subjuveniles with incompletely developed eighth thoracopods). Brood pouch (marsupium) in Thermosbaenacea formed by dorsal carapace chamber.
Embryos shed or briefly brooded; typically undergo nauplius-metanauplius-calyptopis-furcilia-juvenile developmental series.
Dendrobranchiata shed embryos to hatch in water as nauplii or prezoea larvae; all others brood embryos (on pleopods), which do not hatch until a prezoeal or zoeal stage (or later).
Usually with 6 naupliar stages leading to a second series of 5 "larval" stages called copepodites.
Six naupliar stages followed by a unique larval form called a cypris larva.
A benthic nonfeeding stage, possibly a nauplius, has been reported but not formally described. Development entails complex metamorphosis with infective "tantulus larva."
One or 2 eggs at a time are fertilized and carried on genital processes of the first pleonites.
Anostraca: embryos usually shed from ovisac early in development; resistant (cryptobiotic) fertilized eggs accommodate unfavorable conditions.
Notostraca: eggs briefly brooded, then deposited on substratum; resistant (cryptobiotic) fertilized eggs accommodate unfavorable conditions.
Diplostraca: most cladocerans undergo direct development (*Leptodora* hatches as nauplii or metanauplii). Clam shrimps carry developing embryos on the thoracopods prior to releasing them as nauplii or metanauplii.
Eight naupliar stages (2 orthonauplii and 6 metanauplii), followed by a "prejuvenile" stage, have been reported.

Locomotion

Crustaceans move about primarily by use of their limbs (Figure 21.21), and lateral body undulations are not known. They crawl or swim, or more rarely burrow, "hitchhike," or jump. Many of the ectoparasitic forms (e.g., branchiurans, certain isopods and copepods) are largely sedentary on their hosts, and most cirripedes are fully sessile.

Swimming is usually accomplished by a rowing action of the limbs. Archetypical swimming is exemplified by crustaceans with relatively undifferentiated trunks and high numbers of similar biramous appendages (e.g., remipedes, anostracans, notostracans). In general, these animals swim by posterior to anterior metachronal beating of the trunk limbs (Figure 21.22 and Chapter 20). The appendages of such crustaceans are often broad and flattened, and they usually bear fringes of setae that increase the effectiveness of the power stroke. On the recovery stroke the limbs are flexed, and the setae may collapse, reducing resistance. In members of some groups (e.g., cephalocarids, branchiopods, leptostracans), large exites or epipods arise from the base of the leg, producing broad, "leafy" limbs called **phyllopodia**. These flaplike structures aid in locomotion and may also serve as osmoregulatory (branchiopods) or gas exchange (cephalocarids and leptostracans) surfaces (Figure 21.21A–C). Although such epipods increase the surface area on the power stroke, they also are hinged so that they collapse on the recovery stroke, reducing resistance. Metachronal limb movements are retained in many of the "higher" swimming crustaceans, but they tend to be restricted to selected appendages (e.g., the pleopods of shrimps, stomatopods, amphipods, and isopods; the pereopods of euphausiaceans and mysidans). In swimming euphausiaceans and mysidans the thoracopods beat in a metachronal rowing fashion. The movements and neuromuscular coordination of crustacean limbs are deceivingly complex. In the common lophogastridan *Neognathophausia ingens*, for example, 12 separate muscles power the thoracic exopod alone (3 that are extrinsic to the exopod, 5 in the limb peduncle, and 4 in the exopodal flagellum).

FIGURE 21.21 Generalized thoracic appendages of various crustaceans. (A–C) Biramous, phyllopodous thoracopods. (A) Cephalocarida. (B) Branchiopoda. Dashed lines indicate fold or "hinge" lines. (C) Leptostraca (Phyllocarida). (D) A biramous, flattened, but nonphyllopodous thoracopod (Remipedia). (E–I) Stenopodous thoracopods. (E) Euphausiacea. (F) Caridea (Decapoda). (G) Lophogastrida (Peracarida). (H) Spelaeogriphacea (Peracarida). (I) Isopoda (Peracarida). Because of the presence of large epipods on the legs of the cephalocarids, branchiopods, and phyllocarids, some authors refer to them as "triramous" appendages. However, smaller epipods also occur on many typical "biramous" legs, so this distinction seems unwarranted (and confusing). Note that in four groups of crustaceans (cephalocarids, branchiopods, phyllocarids, and remipedes) the protopod is composed of a single article. And in branchiopods and leptostracans the articles of the endopod are not clearly separated from one another. In other crustaceans (Malacostraca and former "maxillopodans") the protopod comprises two or three separate articles, although in most former maxillopodans these may be reduced and not easily observed. In the lophogastridans (G), the large marsupial oostegite characteristic of most female peracarids is shown arising from the coxa. In two groups (amphipods and isopods) all traces of the exopods have disappeared, and only the endopod remains as a long, powerful, uniramous walking leg.

Recall from our discussions in Chapters 3 and 20 that at the low Reynolds numbers at which small crustaceans (such as copepods or larvae) swim about, the netlike setal appendages act not as a filtering net, but as a paddle, pushing water in front of them and dragging the surrounding water along with them due to the thick boundary layer adhering to the limb. Only in larger organisms, with Reynolds numbers approaching 1, do setose appendages (e.g., the feeding cirri of barnacles) begin to act as filters, or rakes, as the surrounding water acts less viscous and the boundary layer is relatively thinner. Of course, the closer together the setae and setules are placed, the more likely it is that their individual boundary layers will overlap; thus densely setose appendages are more likely to act as paddles.

FIGURE 21.22 Some aspects of locomotion (and feeding) in three crustaceans (also see Chapter 20). (A,B) Generation of swimming and feeding currents in an anostracan. (A) An anostracan swimming on its back by metachronal beating of the trunk limbs. The limbs are hinged to fold on the recovery stroke, thereby reducing resistance. (B) Water is drawn from anterior to posterior along the midline and into the interlimb spaces, and food particles are trapped on the medial sides of the endites; excess water is pressed out laterally, and the trapped food is moved anteriorly to the mouth. (C–E) Locomotion in the postlarva of *Panulirus argus*. (C) Normal swimming posture when moving forward slowly. (D) Sinking posture with appendages flared to reduce sinking rate. (E) A quick retreat by rapid tail flexure (the "caridoid escape reaction"), a method commonly employed by crustaceans with well-developed abdomens and tail fans. (F) A swimming remipede, *Lasionectes*. Note the metachronal waves of appendage movement. (C,E after M. D. Calinski and W. G. Lyons. 1983. *J Crust Biol* 3: 329–335.)

Not all swimming crustaceans move by metachronal waves of limb action. Certain planktonic copepods, for example, move haltingly and depend on their long antennules and dense setation for flotation between movements (Figure 21.4F). Watch living calanoid copepods, and you will notice that they may move slowly, by use of the antennae and other appendages, or in short jerky increments, often sinking slightly between these movements. The latter type of motion results from an extremely rapid and condensed metachronal wave of power strokes along the trunk limbs. Although the long antennae may appear to be acting as paddles, they actually collapse against the body an instant prior to the beating of the limbs, thus reducing resistance to forward motion. Some other planktonic copepods create swimming currents by rapid vibrations of cephalic appendages, by which the body moves smoothly through the water. Some copepods execute rapid escape responses, or jumps, when they encounter "upstream" movement that may indicate an approaching predator. These escape responses accelerate them to 200 body lengths per second within milliseconds and, in part, are due to the presence of myelin-like sheaths on key nerve fibers (notably in the antennules). "Rowing" occurs in the swimming crabs (family Portunidae) and some deep-sea asellote isopods (e.g., family Eurycopidae), both of which use paddle-shaped posterior thoracopods to scull about.

Most eumalacostracans with well-developed abdomens exhibit a form of temporary, or "burst," swimming that serves as an escape reaction (e.g., mysidans, syncarids, euphausiaceans, shrimps, lobsters, and crayfish). By rapidly contracting the ventral abdominal (flexor) muscles, such animals shoot quickly backward, the bent-down, spread tail fan providing a large propulsive surface (Figure 21.22C–E). This behavior is sometimes called a **tail flip**, or "**caridoid escape reaction**."

Surface crawling by crustaceans is accomplished by the same general sorts of leg movements seen in insects and other arthropods: by flexion and extension of the limbs to pull or push the animal forward. Walking limbs are typically composed of relatively stout, more or less cylindrical articles (i.e., stenopodous limbs), as opposed to the broader, often phyllopodous limbs of swimmers (see Figure 21.21 for a comparison of crustacean limb types). Walking limbs are lifted from the substratum and moved forward during their recovery strokes; then they are placed against the substratum, which provides purchase as they move posteriorly through their power strokes, pulling and then pushing the animal forward. Like many other arthropods, crustaceans generally lack lateral flexibility at the body joints, so turning is accomplished by reducing the stride length or movement frequency on one side of the body, toward which the animal turns (like a tractor or tank slowing one tread). Many crustaceans migrate; perhaps the most famous is the Chinese mitten crab (*Eriocheir sinensis*), which spends most of its life in fresh water but returns to the sea to breed. These crabs have been found over 1,000 km upriver from the sea—testimony to their superb locomotory ability. Not unexpectedly, *E. sinensis* is also an important (and destructive) invasive species in North America and Europe. It has been accidentally introduced into the Great Lakes several times but has not yet been able to establish a permanent population. Recent work suggests that stomatopods have the ability to accurately return to their "home" burrow using navigation similar to that seen in the terrestrial environment by social hymenopterans, spiders, rodents, fiddler crabs, etc.—through a process known as "path integration." During path integration an animal navigates back on a path previously taken by monitoring the position of the sun and overhead polarization patterns in combination with an internal "odometer."

Most walking crustaceans can also reverse the direction of leg action and move backward, and most brachyuran crabs can walk sideways. Brachyuran crabs are perhaps the most agile of all crustaceans. The extreme reduction of the abdomen in this group allows for very rapid movement because adjacent limbs can move in directions that avoid interference with one another (and much the same thing has happened, independently, in many anomurans with reduced abdomens). Brachyuran crab legs are hinged in such a way that most of their motion involves lateral extension (abduction) and medial flexion (adduction) rather than rotation frontward and backward. As a crab moves, its limbs move in various sequences, as in normal crawling, but those on the leading side exert their force by flexing and pulling the body toward the limb tips, while the opposite, trailing, legs exert propulsive force as they extend and push the body away from the tips. Still, this motion is simply a mechanical variation on the common arthropodan walking behavior. Many crustaceans move into mollusc shells or other objects, carrying these about as added protection. In most cases, the exoskeleton of the crustacean is reduced, especially the abdomen (e.g., hermit crabs). Of course, crustaceans grow in size as they go through their molts, so these mobile-home-carrying crustaceans must continually find larger shells to inhabit. Many hermit crabs assemble in congregations to exchange shells in a sort of group "passing of the shells" as they move into vacated larger abodes.

In addition to these two basic locomotor methods ("typical" walking and swimming by metachronal beating of limbs), many crustaceans move by other specialized means. Ostracods, cladocerans, and clam shrimps (Diplostraca), most of which are largely enclosed by their carapaces (Figures 21.3 and 21.20F,G,J,L,M), swim by rowing with the antennae. Mystacocarids crawl in interstitial water using various head appendages. Most semiterrestrial amphipods known as "beach hoppers" (e.g., *Orchestia* and *Orchestoidea*) execute dramatic jumps by rapidly extending the urosome and its appendages (uropods), reminiscent of the jumping of springtails described in Chapter 22. Most caprelloidean

for more ebook/ testbank/ solution manual Requests email 9601267347@qq.com

amphipods (Figure 21.16E) move about in inchworm fashion, using their subchelate appendages for clinging. There are also a number of crustacean burrowers, and even some that build their own tubes or "homes" from materials in their surroundings. Many benthic amphipods, for example, spin silk-lined mud burrows in which they reside. At least one species, *Pseudamphithoides incurvaria*, constructs and lives in an unusual "bivalved pod" cut from the thin blades of the same alga on which it feeds (Figure 21.23A). Another amphipod, *Photis conchicola*, actually uses empty gastropod shells in a fashion similar to that of hermit crabs (Figure 21.23B). "Hitchhiking" (phoresis) occurs in various ectosymbiotic crustaceans, including isopods that parasitize fishes or shrimps and hyperiidean amphipods that ride on gelatinous drifting plankters.

In addition to simply getting from one place to another in their usual day-to-day activities, many crustaceans exhibit various migratory behaviors, employing their locomotor skills to avoid stressful situations or to remain where conditions are optimal. A number of planktonic crustaceans undertake daily vertical migrations, typically moving upward at night and to greater depths during the day. Such vertical migrators include various copepods, cladocerans, ostracods, and hyperiid amphipods (the latter may make their migrations by riding on their gelatinous hosts). Such movements place the animals in their near-surface feeding grounds during the dark hours, when there is probably less danger of being detected by visual predators. In the daytime, they move to deeper, perhaps safer, waters. These crustaceans can form enormous shoals that contribute to the deep scattering layer seen on ships' sonar. Many intertidal crustaceans use their locomotor abilities to change their behaviors with the tides. Crab larvae in particular are known to migrate upward or downward according to

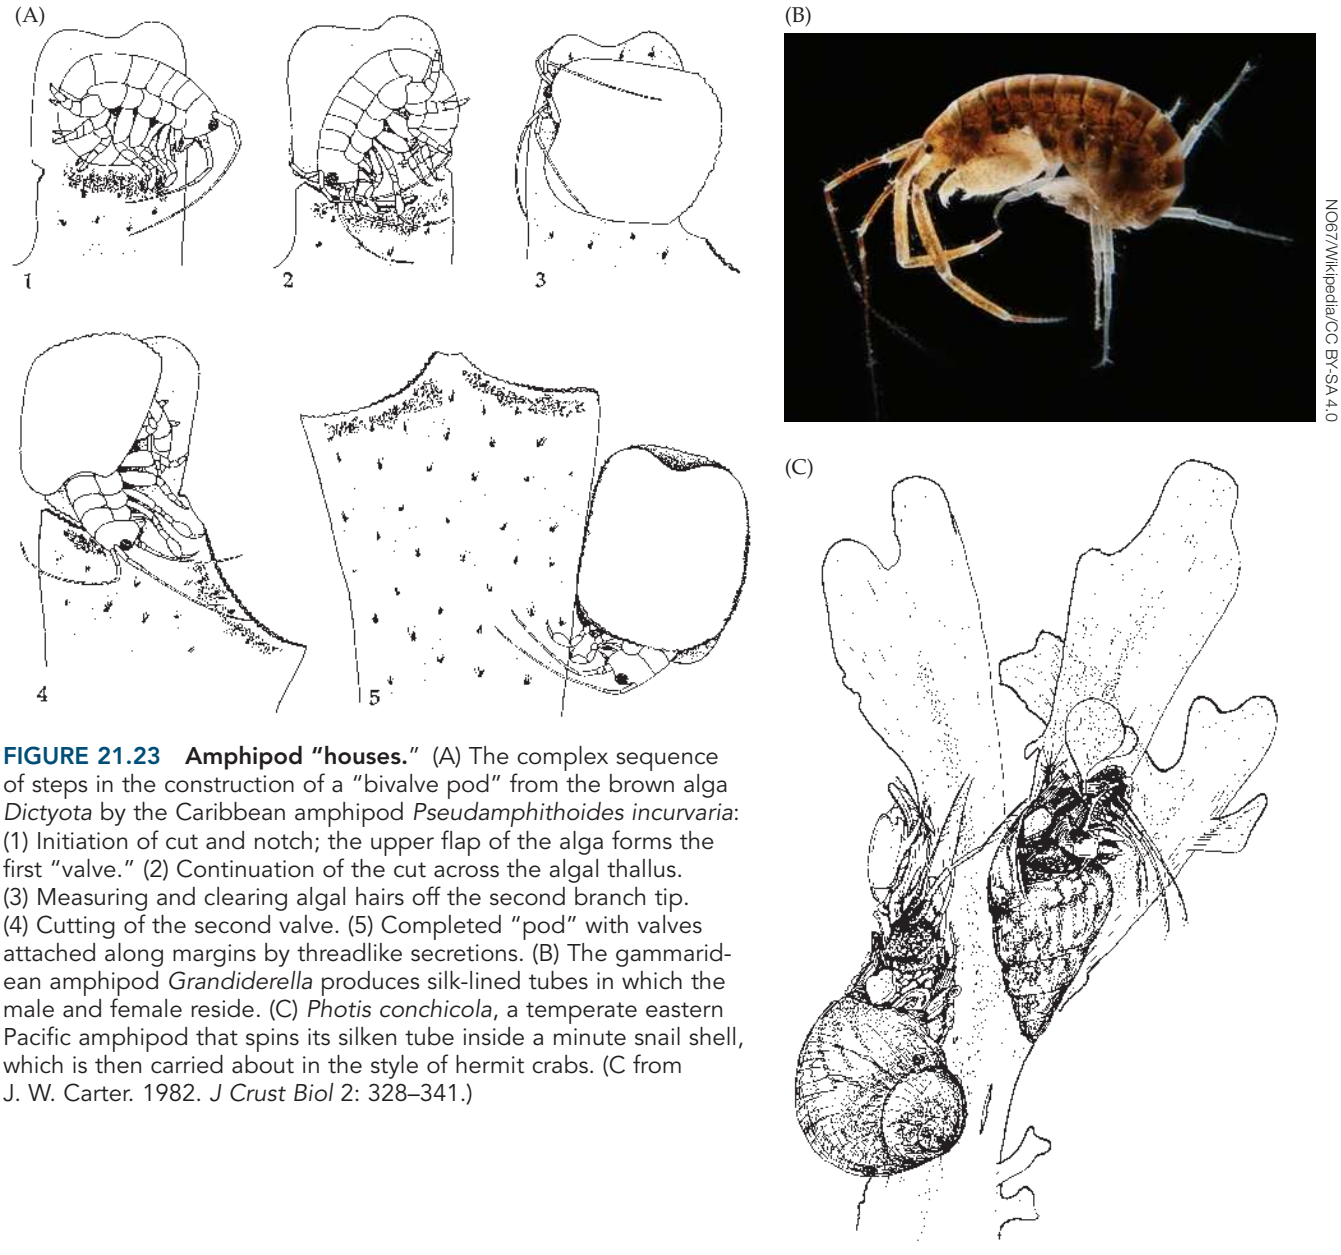

FIGURE 21.23 Amphipod "houses." (A) The complex sequence of steps in the construction of a "bivalve pod" from the brown alga *Dictyota* by the Caribbean amphipod *Pseudamphithoides incurvaria*: (1) Initiation of cut and notch; the upper flap of the alga forms the first "valve." (2) Continuation of the cut across the algal thallus. (3) Measuring and clearing algal hairs off the second branch tip. (4) Cutting of the second valve. (5) Completed "pod" with valves attached along margins by threadlike secretions. (B) The gammaridean amphipod *Grandiderella* produces silk-lined tubes in which the male and female reside. (C) *Photis conchicola*, a temperate eastern Pacific amphipod that spins its silken tube inside a minute snail shell, which is then carried about in the style of hermit crabs. (C from J. W. Carter. 1982. *J Crust Biol* 2: 328–341.)

daily rhythms, taking advantage of incoming or outgoing tides to move in and out of estuaries. Some anomuran and brachyuran crabs simply move in and out with the tide, or seek shelter beneath rocks when the tide is out, thus avoiding the problems of air exposure. One of the most interesting locomotor behaviors among crustaceans is the mass migration of the spiny lobster, *Panulirus argus*, in the Gulf of Mexico and northern Caribbean. Each autumn, lobsters queue up in single file and march in long lines across the seafloor for several days. They move from shallow areas to the edges of deeper oceanic channels. This behavior is apparently triggered by winter storm fronts moving into the area, and it may be a means of avoiding rough water conditions in the shallows. At the beginning of the wet season, the endemic Christmas Island red crabs (*Gecarcoidea natalis*) undertake their annual mass migration from the forest to shore (up to 8 km) to deposit their eggs in the sea.

Feeding

With the exception of ciliary mechanisms, crustaceans have exploited virtually every feeding strategy imaginable (and some "unimaginable"). Even without cilia, many crustaceans generate water currents and engage in various types of suspension feeding. We have selected a few examples to demonstrate the range of feeding mechanisms that occur in this group. In most cases, suspension-feeding Crustacea capture and consume particles in the <100 μm size (unicellular algae, invertebrate eggs and larvae, bacteria, suspended organic detritus).

In some crustaceans the action of the thoracic limbs simultaneously creates the swimming and suspension-feeding currents. As the metachronal wave of appendage motion passes along the body, adjacent limb pairs are alternately moved apart and then pressed together, thus changing the size of each interlimb space (Figure 21.22A,B; see also Chapters 3 and 20). Surrounding water is drawn into an interlimb space as the adjacent appendages move away from one another, and waterborne particles are trapped by setae on the endites as the appendages then press together. From here, the trapped particles are moved to a midventral food groove and then anteriorly, toward the head. This mechanism of forming a boxlike "filter press" with setose phyllopodous limbs is the typical suspension-feeding strategy of cephalocarids, most branchiopods, and many malacostracans.

Planktonic copepods were long thought to "filter" feed by generating lateral feeding gyres or currents by movements of the antennae and mouth appendages. It was believed that these gyres swept in small particles that were directly filtered by the maxillae. This classic idea of maxillary filtration, built on work by H. G. Cannon in the 1920s, has been questioned by recent work, but the model persists and is still commonly presented in general works. As mentioned in Chapter 3, we now know that copepods and other small planktonic crustaceans live in a world of low Reynolds numbers, a world dominated by viscosity rather than by inertia. Thus, the setose mouth appendages behave more like paddles than like sieves, with a water layer near the limb adhering to it and forming part of the "paddle." As the maxillae move apart, parcels of water containing food are drawn into the interlimb space. As the maxillae press together, the "parcel" is moved forward to the endites of the maxillules, which push it into the mouth. Thus, food particles are actually not filtered from the water, but captured in small parcels of water. High-speed cinematography indicates that copepods are capable of capturing individual algal cells, one at a time, by this "hydraulic vacuum" method. In fact, copepods may be fairly selective about what they consume, which includes everything from protistan microplankton (e.g., diatoms) to other small crustaceans.

Sessile thoracican barnacles feed by using their long, feathery, biramous thoracopods, called **cirri**, to filter feed on suspended material from the surrounding water (Figure 21.17A,C,E). Studies indicate that barnacles are capable of trapping food particles ranging from 2 μm to 1 mm, including detritus, bacteria, algae, and various zooplankters. Many barnacles are also capable of preying on larger planktonic animals by coiling a single cirrus around the prey, in tentacle fashion. In slow-moving or very quiet water, most barnacles feed actively by extending the last three pairs of cirri in a fanlike manner and sweeping them rhythmically through the water. The setae on adjacent limbs and limb rami overlap to form an effective filtering net. The first three pairs of cirri serve to remove trapped food from the posterior cirri and pass it to the mouthparts. In areas of high water movement, such as wave-swept rocky shores, barnacles often extend their cirri into the backwash of waves, allowing the moving water to simply run through the "filter," rather than actively moving the cirri through the water. In such areas you will often see clusters of barnacles in which all the individuals are oriented similarly, taking advantage of this labor-saving device.

Most krill (euphausiaceans) feed in a fashion similar to that of barnacles, but while swimming. The thoracopods form a "feeding basket" that expands as the legs move outward, sucking food-laden water in from the front. Once inside the basket, particles are retained on the setae of the legs as the water is squeezed out laterally. Other setae comb the food particles out of the "trap" setae, while yet another set brushes them forward to the mouth region.

Anomuran sand crabs (e.g., *Emerita*, *Lepidopa*, *Blepharipoda*) use their long, setose antennae in a fashion similar to that of barnacle cirri that "passively" strain wave backwash (Figure 21.24; see also Chapter 3). Sand crabs are adapted to living on wave-swept sand beaches. Their compact oval shape and strong appendages facilitate burrowing in the unstable substratum. They burrow posterior end first in the area of wave wash, with the anterior end facing upward. Following

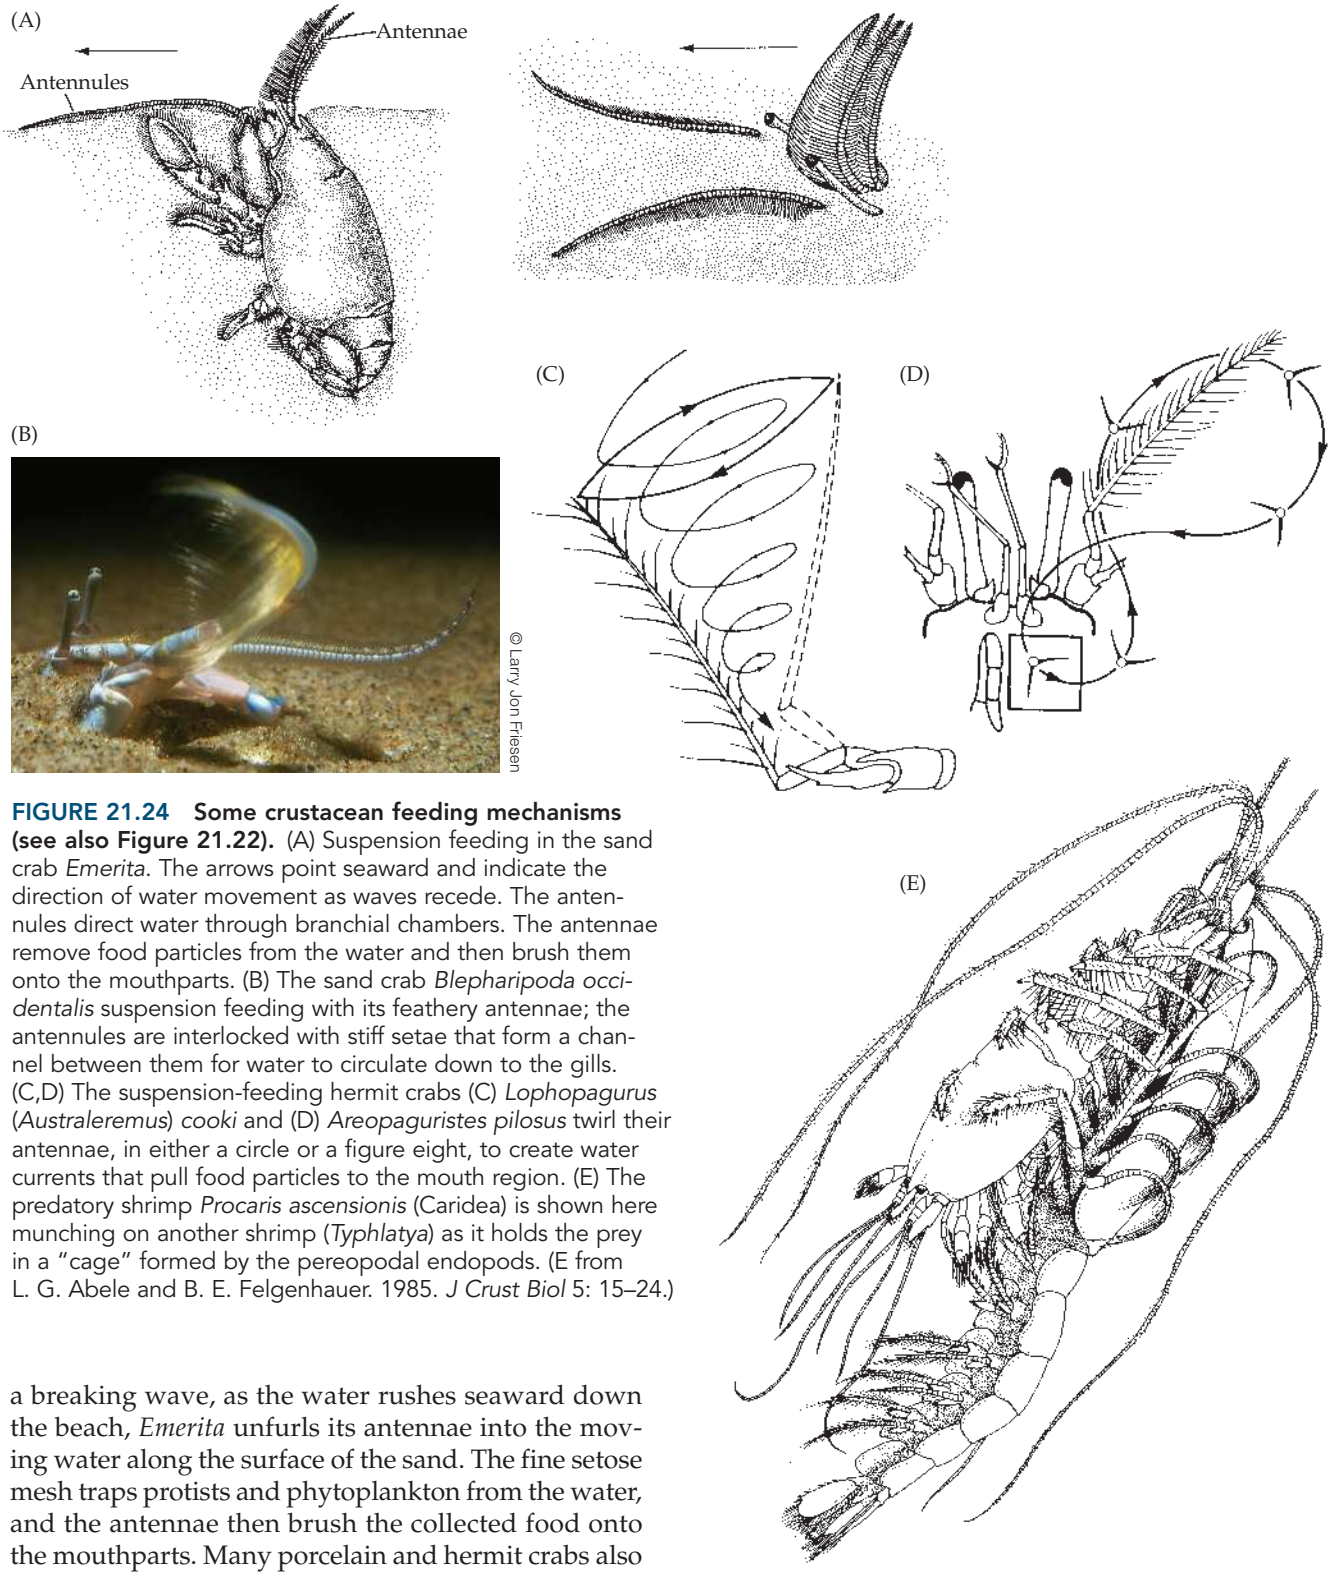

FIGURE 21.24 Some crustacean feeding mechanisms (see also Figure 21.22). (A) Suspension feeding in the sand crab *Emerita*. The arrows point seaward and indicate the direction of water movement as waves recede. The antennules direct water through branchial chambers. The antennae remove food particles from the water and then brush them onto the mouthparts. (B) The sand crab *Blepharipoda occidentalis* suspension feeding with its feathery antennae; the antennules are interlocked with stiff setae that form a channel between them for water to circulate down to the gills. (C,D) The suspension-feeding hermit crabs (C) *Lophopagurus* (*Australeremus*) *cooki* and (D) *Areopaguristes pilosus* twirl their antennae, in either a circle or a figure eight, to create water currents that pull food particles to the mouth region. (E) The predatory shrimp *Procaris ascensionis* (Caridea) is shown here munching on another shrimp (*Typhlatya*) as it holds the prey in a "cage" formed by the pereopodal endopods. (E from L. G. Abele and B. E. Felgenhauer. 1985. *J Crust Biol* 5: 15–24.)

a breaking wave, as the water rushes seaward down the beach, *Emerita* unfurls its antennae into the moving water along the surface of the sand. The fine setose mesh traps protists and phytoplankton from the water, and the antennae then brush the collected food onto the mouthparts. Many porcelain and hermit crabs also engage in suspension feeding. By twirling their antennae in various patterns, these anomurans create spiraling currents that bring food-laden water toward the mouth (Figure 21.24B,C). Food particles then become entangled on setae of the mouth appendages and are brushed into the mouth by the endopods of the third maxillipeds. Many of these animals also feed on detritus by simply picking up particles with their chelipeds.

Some mud, ghost, and lobster shrimps, such as *Callianassa* and *Upogebia* (Axiidea, Gebiidea), suspension feed within their burrows. They drive water through the burrow by beating the pleopods, and the first two pairs of pereopods remove food with medially directed setal brushes. The maxillipeds then comb the captured particles forward to the mouth.

Most other crustacean feeding mechanisms are less complicated than suspension feeding and usually involve direct manipulation of food by the mouthparts and sometimes the pereopods, especially chelate or

subchelate anterior legs. However, even in these cases of direct manipulation, the sheer number of crustacean appendages adapted for feeding makes "simple" feeding a surprisingly complex affair, with the various mouthparts taking on tasks that include tasting (via sensory setae), holding, chewing, scraping, and macerating.

Many small crustaceans may be classified as microphagous selective deposit feeders, employing various methods of removing food from the sediments in which they live. Mystacocarids, many harpacticoid copepods, and some cumaceans and gammaridean amphipods are referred to as "sand grazers" or "sand lickers." By various methods these animals remove detritus, diatoms, and other microorganisms from the surfaces of sediment particles. Interstitial mystacocarids, for example, simply brush sand grains with their setose mouthparts. On the other hand, some cumaceans pick up an individual sand grain with their first pereopods and pass it to the maxillipeds, which in turn rotate and tumble the particle against the margins of the maxillules and mandibles. The maxillules brush and the mandibles scrape, removing organic material. Some sand-dwelling isopods may employ a similar feeding behavior.

Predatory crustaceans include stomatopods, remipedes, and most lophogastridans, as well as many species of anostracans, cladocerans, copepods, ostracods, cirripedes, anaspidaceans, euphausiaceans, decapods, tanaidaceans, isopods, and amphipods. Predation typically involves grasping the prey with chelate or subchelate pereopods (or sometimes directly with the mouth appendages), or even with the antennae in the case of predatory anostracans, followed by tearing, grinding, or shearing with various mouthparts, particularly the mandibles. Perhaps the most highly adapted predatory specialists are the stomatopods (Figure 21.8), which possess greatly enlarged, raptorial subchelate limbs, which they use to stab or to club and smash prey. Some species search out prey, but many sit in ambush at their burrow entrance. The actual attack generally follows visual detection of a potential prey item, which may be another crustacean, a mollusc, or even a small fish. Once captured and stunned or killed by the raptorial claws, the prey is held against the mouthparts and shredded into ingestible pieces.

Although the cave-dwelling and often presumed "primitive" shrimp *Procaris* is omnivorous, its predatory behavior is particularly interesting. Its prey includes other crustaceans, particularly amphipods and shrimps. After *Procaris* locates a potential victim (probably by chemoreception), it moves quickly to the prey and grasps it within a "cage" formed by the pereopodal endopods (Figure 21.24E). Once captured, the prey is eaten while the shrimp swims about. Apparently the third maxillipeds press the prey against the mandibles, which bite off chunks and pass them to the mouth.

The remipedes capture prey with their raptorial mouth appendages (Figures 21.1A, 21.19D–F, and 21.22F) and then immobilize the victim with an injection of venom from the hypodermic maxillules. It is suspected that tissues are then sucked out of the prey by action of a mandibular mill and muscular foregut. Remipedes are probably also facultative suspension feeders and scavengers.

Another fascinating adaptation for predation can be seen in many species of Alpheidae (the snapping shrimps, e.g., *Alpheus, Synalpheus*) (Figure 21.10D). In such species, one of the chelipeds is much larger than the other, and the movable finger is hinged in such a way that it can be held open under muscle tension and then snapped closed quickly; this forceful closing produces a loud popping sound and a pressure or "shock" wave in the surrounding water. Some species appear to use this mechanism in ambushing prey (although most alpheids are probably omnivores and even include algae in their diet). When feeding in a predatory mode, the shrimp sits at its burrow entrance with the antennae extended. When a potential prey approaches (usually a small fish, crustacean, or annelid), the shrimp "pops" its cheliped, and the resulting pressure wave stuns the victim, which is then quickly pulled into the burrow and consumed. These shrimps typically live in male-female pairs within the burrow, and prey captured by one individual is shared with its partner. Two mechanisms have been proposed for the production of the "pop" and associated shock wave. In some species the pop seems to be created by mechanical impact of the dactylus hammering into the propodus. A second mechanism recently proposed is the collapse of cavitation bubbles, which are created by the rapid closure of the claw (in excess of 100 km/sec). Cavitation occurs in liquids when bubbles form and then implode around an object (it is a well-known phenomenon damaging ship propellers). Both mechanisms create shock waves. Cavitation shocks are also used by some stomatopods while feeding. Some boring (endolithic) alpheids even use the claw snap to break off pieces of the rock into which they are digging. In some areas of the world, populations of snapping shrimps are so large that their noise disturbs underwater communication. In the Caribbean, colonies of alpheids have been likened to those of social insects (e.g., *Synalpheus regalis* colonies in Belize inhabit sponges and contain up to 350 sibling males and females, with a single dominant breeding female).

Many crustaceans emerge from the benthos under cover of darkness to feed or mate in the water column. Many predatory isopods emerge at night to feed on invertebrates or fish, particularly weak or diseased fish (or fish caught in fishing nets).

Macrophagous herbivorous and scavenging crustaceans generally feed by simply hanging onto the food source and biting off bits with the mandibles (a feeding technique similar to that of grasshoppers and other insects). Notostracans, some ostracods, and many decapods, isopods, and amphipods are scavengers and herbivores. Isopods in several families bore into wood,

for more ebook/ testbank/ solution manual Requests email 960126734@qq.com

and those in the family Limnoriidae (the gribbles) produce their own cellulase, which they use to digest woody tissues (the presence of blood hemocyanin in the hindgut appears to enhance the digestibility of the cellulose). Some species of Sphaeromatidae bore into the aerial roots of mangrove trees, and their activities often result in root breakage followed by new multiple root initiation, creating the stiltlike appearance characteristic of red mangroves (*Rhizophora*), although at an overall growth-productivity cost to the trees. A number of crustaceans are full-time or part-time detritivores; many scavenge directly on detritus, but others (e.g., cephalocarids) stir up the sediments in order to remove organic particles by suspension feeding.

A great many crustacean species, and entire lineages are symbiotic with other organisms. Many are parasites, but others are commensals or mutualists. Some decapod mutualists are simply cases in which the crustacean defends the host against predators and/or removes detritus and potential pathogens from the host's surface. Among the true crabs (Brachyura), six families consist exclusively of obligate symbionts, and obligate symbionts are also found in at least four additional brachyuran families (and facultative symbionts occur in numerous other families). For example, the gall crabs (Cryptochiridae) comprise over 50 species of obligate symbionts of scleractinian corals. There is a range of "gall" formation, from simple pits or chambers to enclosures formed by the coral as it grows over the crab (presumably induced by the respiratory currents and scratching of the crabs on the coral). Gall crab females always inhabit pits or chambers and rarely leave; males live in separate chambers or free on the coral surface and must move into the females' chambers for copulation. Members of the brachyuran families Domeciidae and Tetraliidae are also all symbionts of zooxanthellate corals, Trapeziidae are obligate symbionts of corals and other colonial cnidarians and sponges, and the subfamily Eumedoninae (Pilumnidae) are obligate symbionts of Indo–West Pacific echinoderms.

Several groups of crustaceans have adopted various degrees of parasitism. These animals range from ectoparasites with mouthparts modified for piercing or tearing and sucking body fluids (e.g., many copepods, branchiurans, tantulocarids, several isopod families, and at least one species of ostracod), to the highly modified and fully parasitic rhizocephalans, whose bodies ramify throughout the host tissue and absorb nutrients directly (Figures 21.25 and 21.26), and pentastomids.

Rhizocephalans, which are cirripeds that have been highly modified to become internal parasites of other crustaceans, are some of the most bizarre organisms in the animal kingdom. The most complex rhizocephalan life cycle is that of the kentrogonid forms, in which a settled female cypris larva undergoes an internal reorganization that rivals that of caterpillar pupae in scope, developing an infective stage, called the **kentrogon**, beneath the cyprid exoskeleton. Once fully developed, the kentrogon forms a hollow cuticular structure, the **stylet**, which injects a motile, multicellular, vermiform stage called the **vermigon** into the host. The vermigon is the active infection stage. It has a thin cuticle and epidermis, several types of cells, and the anlage of an ovary. It invades the host's hemocoel by sending out long, branching, hollow rootlets that penetrate most of the host's body and draw nutrients directly from the hemocoel. So profound is the intrusion by the rootlets that the parasite takes over nearly complete control of the host's body, altering its morphology, physiology, and behavior. Once the parasite invades the host's gonads, parasitic castration may result (i.e., the gonads of parasitized crabs never produce mature gametes). Thus the host is transformed into a slave that serves the needs of its master. The internal root system, or **interna**, eventually develops an external reproductive body (the **externa**), where egg production occurs. A male cyprid settles on the externa, transforms into a minute sexually mature instar called a **trichogon**, and moves into the ovary-filled externa to take up residence, where its sole function is to produce sperm. It takes only one or two trichogons to stimulate the female ovaries to mature and begin releasing eggs into the chamber of the externa. An externa that fails to obtain male trichogons eventually dies. The males are thus parasitic on the female (which is itself parasitic on the crustacean host), and kentrogonids are gonochoristic. A mature externa, usually arising from the host's abdomen, will produce a succession of larval broods, molting after each larval release (it is the only part of the rhizocephalan body that molts). The larvae are lecithotrophic and develop through several nauplius stages to the cyprid (Figures 21.25 and 21.26).

The akentrogonid rhizocephalans lack a kentrogon stage in their life cycle. Instead of injecting a vermigon, the female cyprid has long, slender antennules that it uses to attach to the abdomen of the host, one of which actually penetrates the host's cuticle, becomes hollow, and serves for the passage of embryonic cells from cypris larva to host. Male cyprids somehow find infected hosts and penetrate them in the same fashion as the females, releasing their sperm in such a way that they actually enter the body of the female parasite.

The akentrogonid life cycle is similar to that of kentrogonid species, although in some cases more than one individual parasite might infect a single host, leading to multiple externas. And in at least one genus (*Thompsonia*), multiple externas can develop from a single infection. The anatomy of the externa is more variable than in kentrogonids, and the embryos develop directly into cypris larvae—there are no free-swimming nauplius stages. The extreme sexual size dimorphism of kentrogonids does not occur in akentrogonid species, and no migrating trichogon stage has been observed. These two life cycle types used to be the basis for dividing the Rhizocephala into two orders, Kentrogonida and Akentrogonida, but an elegant phylogenetic analysis by Høeg et al. (2020) showed these two groups to be

◀ **FIGURE 21.25 The life cycle of the rhizocephalan cirripede *Peltogaster paguri*, a kentrogonid parasite of hermit crabs.** (A) The mature reproductive portion of the parasite (externa) produces numerous broods of male and female larvae, which are released as nauplii (B,C) and eventually metamorphose into cypris larvae (D). Female cyprids settle on the thorax and limbs of host crabs (E) and undergo a major internal metamorphosis into the kentrogon form (F), which is provided with a pair of antennules and an injection stylet. The kentrogon's viscera metamorphoses into an infective stage, the vermigon, which is transferred to the host through the hollow stylet. Inside the host, the vermigon grows rootlets that ramify throughout much of the host's body; it is now called the interna (G). Eventually the female parasite emerges on the abdomen of the host as a virginal externa (H). When the externa acquires a mantle pore, or aperture, it becomes attractive to male cyprids (I). Male cyprids settle within the aperture, transform into a trichogon form, and implant part of their body contents in the female's receptacles (J). The deposit proceeds to differentiate into spermatozoa, which fertilize the eggs of the female. (K) The dissected externa, with its rootlets, of *Peltogaster*, removed from its host. Note the mantle aperture.

nonmonophyletic. The kentrogonid mode of host invasion is likely the original, whereas the akentrogonid mode has been derived at least twice.

Isopods of the family Cymothoidae use modified mouthparts to suck the body fluids of their fish hosts. They attach to their host's skin or gills or, in some genera, to the tongue. One species, *Cymothoa exigua*, sucks so much blood out of its host's tongue (the spotted rose snapper, in the Gulf of California) that the tongue completely degenerates. But, remarkably, the fish doesn't die; the isopod remains attached with its clawed legs to the basal muscles of the missing tongue, and the fish uses the crustacean as a "replacement tongue" to continue to feed. This is one of the few known cases of a parasite functionally replacing a host organ it destroys.

Digestive System

The digestive system of crustaceans includes the usual arthropod foregut, midgut, and hindgut. The foregut and hindgut are made from ectodermally derived tissue and are thus lined with a cuticle that is continuous with the exoskeleton and molted with it. The stomodeal foregut is modified in different groups but usually includes a relatively short pharynx-esophagus region followed by a stomach. The stomach often has chambers or specialized regions for storage, grinding, and sorting; these structures are best developed in the malacostracans (Figure 21.27G). The midgut forms a short or long intestine—the length depending mainly on overall body shape and size—and bears variably placed **digestive ceca**. The ceca are serially arranged only in the remipedes. In some malacostracans, such as crabs, the ceca fuse to form a solid glandular mass, best called a **digestive gland** but sometimes called a midgut gland or hepatopancreas, within which are many branched, blind tubules. The digestive gland in some crustaceans has been shown to store lipids. The hindgut is usually short, and the anus is generally borne on the anal somite or telson, or on the last segment of the abdomen (when the anal somite is reduced or lost).

Examples of some crustacean digestive tracts are shown in Figure 21.27. Generally, expansion of the esophagus and foregut creates a suction that draws food into the mouth and esophagus. Foregut contractions push the food into the midgut, where most breakdown and absorption occur. The foregut is typically elaborate with folds and ridges and can even be armed with calcareous ossicles (e.g., many decapods).

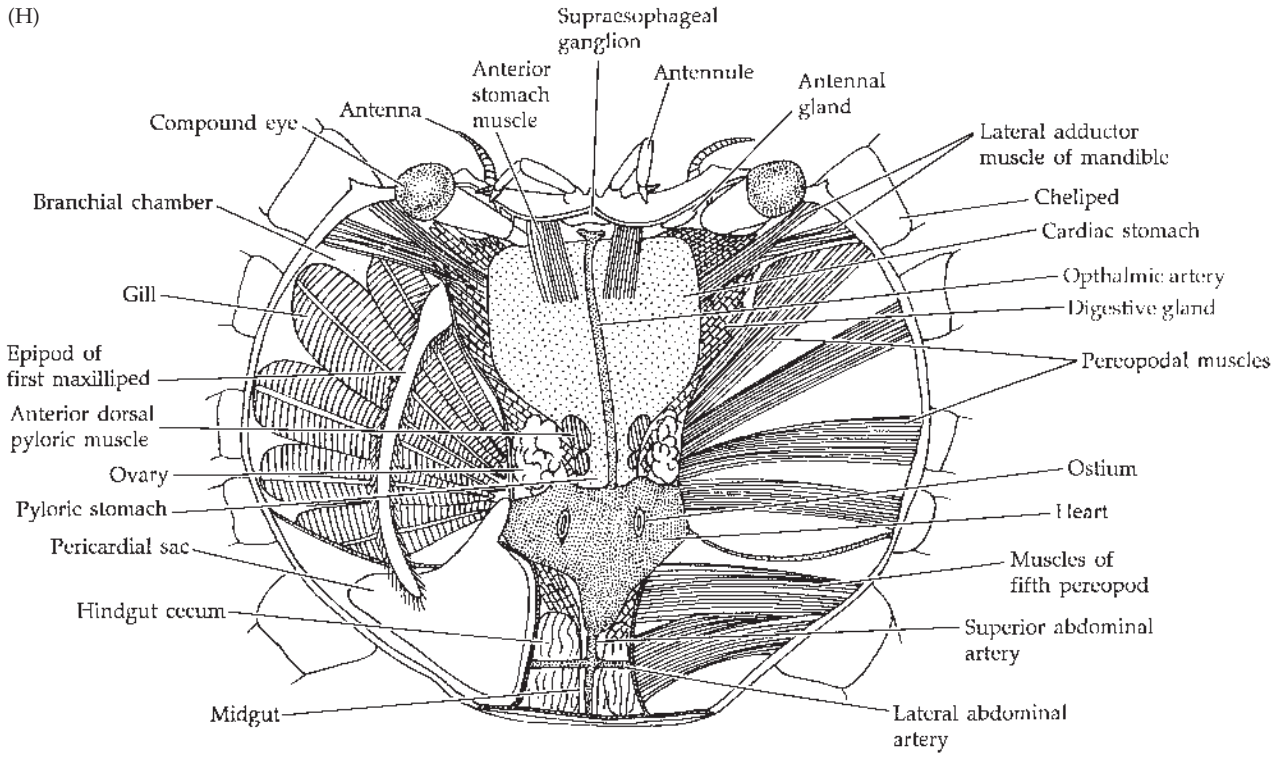
After ingestion, the food material is usually handled mechanically by the foregut. This may involve simply transporting the food to the midgut or, more commonly, processing the food in various ways prior to chemical digestion. For example, the complex foregut of decapods (Figure 21.27G) is divided into an anterior cardiac stomach and a posterior pyloric stomach. Food is stored in the enlarged portion of the cardiac stomach

for more ebook/ testbank/ solution manual Requests email 960126734@qq.com



and then moved a bit at a time to a region containing a gastric mill, which usually bears heavily sclerotized teeth. Special muscles associated with the stomach wall move the teeth, grinding the food into smaller particles. The macerated material then moves into the back part of the pyloric stomach, where sets of filtering setae prevent large particles from entering the midgut. This type of foregut arrangement is best developed in macrophagous decapods (scavengers, predators, and some herbivores). Thus the food can be taken in quickly, in big bites, and mechanically processed afterward.

Circulation and Gas Exchange

The basic crustacean circulatory system usually consists of an elongate, dorsal, ostiate heart within a pericardial cavity and variously developed vessels emptying into an open hemocoel (Figure 21.28). But the open hemocoel, which in the past led to descriptions of crustaceans as having an open circulatory system, has become highly modified in many groups, and in most there is a complex and intricate arrangement of true vessels (arteries) and lacunar canals that has only recently begun to be recognized. A distinct heart is absent in most ostracods, many copepods, and many cirripedes. In some groups the heart is replaced or supplemented by accessory pumping structures derived from muscular vessels. But in all cases, the organs and tissues are exposed to the hemolymph, which fills the body cavities. The circulating hemolymph helps regulate pH and inorganic ions, and it transports amino acids, proteins, carbohydrates and lipids, and other nutrients, as well as waste products and oxygen (via hemocyanin or hemoglobin). Hemolymph also contributes to wound healing through the clotting of hemocytes and other cells.

The primitive heart structure in crustaceans is a long tube with segmental ostia, a condition retained in part in cephalocarids and in some branchiopods, leptostracans, and stomatopods. However, the general shape of the heart and the number of ostia are closely related to body form and the location of gas exchange structures. The heart may be relatively long and extend through much of the postcephalic region of the body, as it does in the remipedes, anostracans, and leptostracans, or it may tend toward a globular or box shape and be restricted to the thorax (e.g., as in cladocerans), where it may be associated with the thoracic gills (e.g., as in decapods). The intimate coevolution of the circulatory system with body form and gill placement is best exemplified when closely related groups are compared. Although isopods and amphipods, for instance, are both peracarids, their hearts are located largely in the pleon and in the pereon, respectively, corresponding to the pleopodal and pereopodal gill locations.

The number and length of blood vessels and the presence of accessory pumping organs are related to body size and to the extent of the heart itself. In most nonmalacostracans, for example, there are no arterial vessels at all; the heart pumps blood directly into the hemocoel from both ends. These animals tend to have short bodies, long hearts, or both, an arrangement that facilitates circulation of the blood to all body parts. Sessile forms, such as most cirripedes, have lost the heart

altogether, although it is replaced by a pumping vessel in the thoracicans. Large malacostracans tend to have well-developed vessel systems (Figure 21.27D,E). Studies using corrosion casting techniques and microCT scanning have shown how complex these vessel systems can be and have even called into question the paradigm of "open" vs. "closed" circulatory systems in invertebrates. Large or active crustaceans may also possess an anterior accessory pump called the **cor frontale**, which helps maintain blood pressure, and often a venous system for returning blood to the pericardial chamber.

Crustacean blood contains a variety of cell types, including phagocytic and granular amebocytes and special wandering explosive cells that release a clotting agent at sites of injury or autotomy. In nonmalacostracans, oxygen is either carried in solution or attached to dissolved hemoglobin. Most malacostracans possess hemocyanin in solution (although some contain hemoglobin within tissues). Hemoglobin uses iron as the oxygen-binding site, whereas hemocyanin uses copper. The latter can give a bluish color to the hemolymph; carotenoid pigments frequently give hemolymph a pale brown or orange color. Oxygen-binding pigments are never carried in corpuscles, as they are in the vertebrates.

We have mentioned the form and position of gas exchange organs (gills) for some groups of crustaceans in the taxonomic synopses. Some small forms (e.g., copepods, some ostracods) lack distinct gills and rely on cutaneous exchange, which is facilitated by their relatively thin cuticles and high surface-area-to-volume ratio. In the small forms of other groups, a thin, membranous inner lining of the carapace serves this purpose (e.g.,

for more ebook/ testbank/ solution manuals requests email 9601267344@qq.com

Cladocera, Cirripedia, Leptostraca, Cumacea, Mysida, Spinicaudata, and even some members of the Decapoda).

Most crustaceans, however, possess distinct gills of some sort (Figure 21.28). These structures are commonly derived from epipods (exites) on the thoracic legs that have been modified in various ways to provide a large surface area. The inner hollow chambers of these gills are confluent with the hemocoel or its vessels. Although the gills vary considerably in structure (recall the various decapod gills described earlier), they all operate on the basic principles of gas exchange organs addressed in Chapter 3 and throughout this text: the circulatory fluid is brought close to the oxygen source in an organ with a relatively high surface area. The gills provide a thin, moist, permeable surface between the internal and external environments. The gills of stomatopods and isopods (Figure 21.28H,I) are formed from the abdominal pleopods. In the first case they are branched processes off the bases of the pleopods, but in the isopods the flattened pleopods themselves are vascularized and provide the necessary surface area for exchange. Stomatopods also have epipodal gills on the thoracopods, but these are not large.

For gills to be efficient, a flow of water must be maintained across them. In stomatopods and aquatic isopods a current is generated by the beating of the pleopods. Similarly, the pereopodal gills of euphausiaceans are constantly flushed by water as the animals swim. In many crustaceans, however, the gills are concealed to various degrees and require special mechanisms in order to produce the ventilating currents. In most decapods, for example, the gills are contained in branchial chambers formed between the carapace and the body wall (Figure 21.28). Thus the delicate gills, while still technically outside the body, appear to be (and are protected as though they were) internal organs. While such an arrangement provides protection from damage to the fragile gill filaments, the openings to the chambers are generally small, restricting the passive flow of water. Not surprisingly, the solution to this dilemma comes once again from the evolutionary plasticity of crustacean appendages. Most decapods have elongate exopods on the maxillae, called gill bailers or **scaphognathites**, that vibrate to create ventilating currents through the branchial chambers (Figure 21.28A). These currents typically enter from the sides and rear through small openings around the coxae of the pereopods (called in crabs **Milne-Edwards openings**, after their discoverer), and they exit anteriorly from under the carapace in the vicinity of the mouth field (and antennal glands). They can be easily seen by observing a crab or lobster in quiet water. The flow rate of the currents can be altered, depending on environmental factors, and can also be reversed, thus allowing certain decapods to burrow in sand or mud with only their front ends exposed to the water.

The positioning of the gills in branchial chambers protects them from desiccation during exposure to air and thus enables many crustaceans to live in littoral habitats; diffusion of respiratory gases commonly continues even during low tides. Some decapods have even invaded land, especially certain crayfish and the anomuran and brachyuran crabs known as land crabs (e.g., certain Gecarcinidae, the hermit crab *Coenobita*, the coconut crab *Birgus*; Figure 21.1H). In these semiterrestrial species the gills are typically reduced in size. In *Birgus* the original gills are very small, and the vascularized cuticular surface of the gill chamber is used for gas exchange. Although young *Birgus* may carry shells (or coconuts) to protect the soft abdomen, adults do not and the abdomen is well sclerotized and hardened. Some land crabs in the genus *Gecarcinus*, which have been reported living at up to 3,000 m elevation (in Jamaica), have **nephritic pads** onto which the urine is deposited; microbes living on the pads cleanse the urine of its nitrogenous waste compounds before the fluid is reabsorbed by the crab. Interestingly, at least three species of *Drosophila* have adapted to this habitat, where they feed on the microbes and spend their entire lives in association with their crab hosts. Another striking decapod adaptation to life in air is displayed by the sand-bubbler crabs of the Indo-Pacific region (family Dotillidae: *Scopimera, Dotilla*). These crabs possess membranous discs on their legs or sternites that were once thought to be auditory organs but are now thought to function as gas exchange surfaces.

The most successful crustaceans on land are not the decapods, however, but the familiar sowbugs and pillbugs. The success of these oniscidean isopods (e.g., *Porcellio*) is due in part to the presence of aerial gas exchange organs called **pseudotrachea** (Figure 21.28H,I). These organs are inwardly directed, moderately branched, thin-walled, blind sacs located in some of the pleopodal exopods, connected to the outside via small pores (similar to the tracheae and spiracles of other terrestrial arthropods, such as some arachnids, myriapods, and hexapods). Air circulates through these sacs, and gases are exchanged with the blood in the pleopods. Thus, in these animals the original aquatic pleopodal gills have been refashioned for air breathing by moving the exchange surfaces inside, where they remain moist. The superficially similar tracheal systems of isopods, insects, myriapods, and arachnids evolved independently, by convergence, in association with other adaptations to life on land.

Excretion and Osmoregulation

Like other fundamentally aquatic invertebrates, crustaceans are ammonotelic, whether in fresh water or seawater or on land. They release ammonia both through nephridia and by way of the gills. As discussed in Chapter 20, most crustaceans possess nephridial excretory organs in the form of either antennal glands or maxillary glands (Figures 21.6A and 21.27). These are serially homologous structures, constructed similarly but differing in the position of their associated pores (at the base of the second antennae or the second maxillae,

respectively). The inner blind end is a coelomic remnant of the nephridium called the sacculus, which leads through a variably coiled duct to the pore. The duct may bear an enlarged bladder near the opening. Antennal glands are sometimes called "green glands."

Most crustaceans have only one pair of these nephridial organs, but lophogastridans and mysidans have both antennal and maxillary glands, and a few others (cephalocarids, and a few tanaidaceans and isopods) have well-developed maxillary and rudimentary antennal glands. Most nonmalacostracans have maxillary glands, as do stomatopods, cumaceans, and most tanaidaceans and isopods. Adult ostracods have maxillary glands, but antennal glands also occur in freshwater species. All of the other malacostracans have antennal glands.

Blood-filled channels of the hemocoel intermingle with branched extensions of the sacculus epithelium, creating a large surface area across which filtration occurs. The cells of the sacculus wall also actively take up and secrete material from the blood into the lumen of the excretory organ. These processes of filtration and secretion are to some degree selective, but most of the regulation of urine composition is accomplished by active exchange between the blood and the excretory tubule. These activities not only regulate the loss of metabolic wastes, but also are extremely important in water and ion balance, particularly in freshwater and terrestrial crustaceans.

The excretion and osmoregulation carried out by antennal and maxillary gland activity are supplemented by other mechanisms. The cuticle itself acts as a barrier to exchange between the internal and external environments and is especially important in preventing water loss on land or excessive uptake of water in fresh water. Moreover, thin areas of the cuticle (especially the gill surfaces) serve as sites of waste loss and ionic exchange. The epipods on the legs of Branchiopoda were long assumed to function in gas exchange (as "gills"), but they are now known to serve primarily as sites of osmoregulation (hence, the taxonomic name Branchiopoda, meaning "gill-footed," is a misnomer!). Phagocytic blood cells and certain regions of the midgut are also thought to accumulate wastes. In some terrestrial isopods, ammonia actually diffuses from the body in gaseous form.

Nervous System and Sense Organs

The central nervous system of crustaceans is constructed in concert with the segmented body structure, along the same lines as seen in other arthropods (Figure 21.29). In

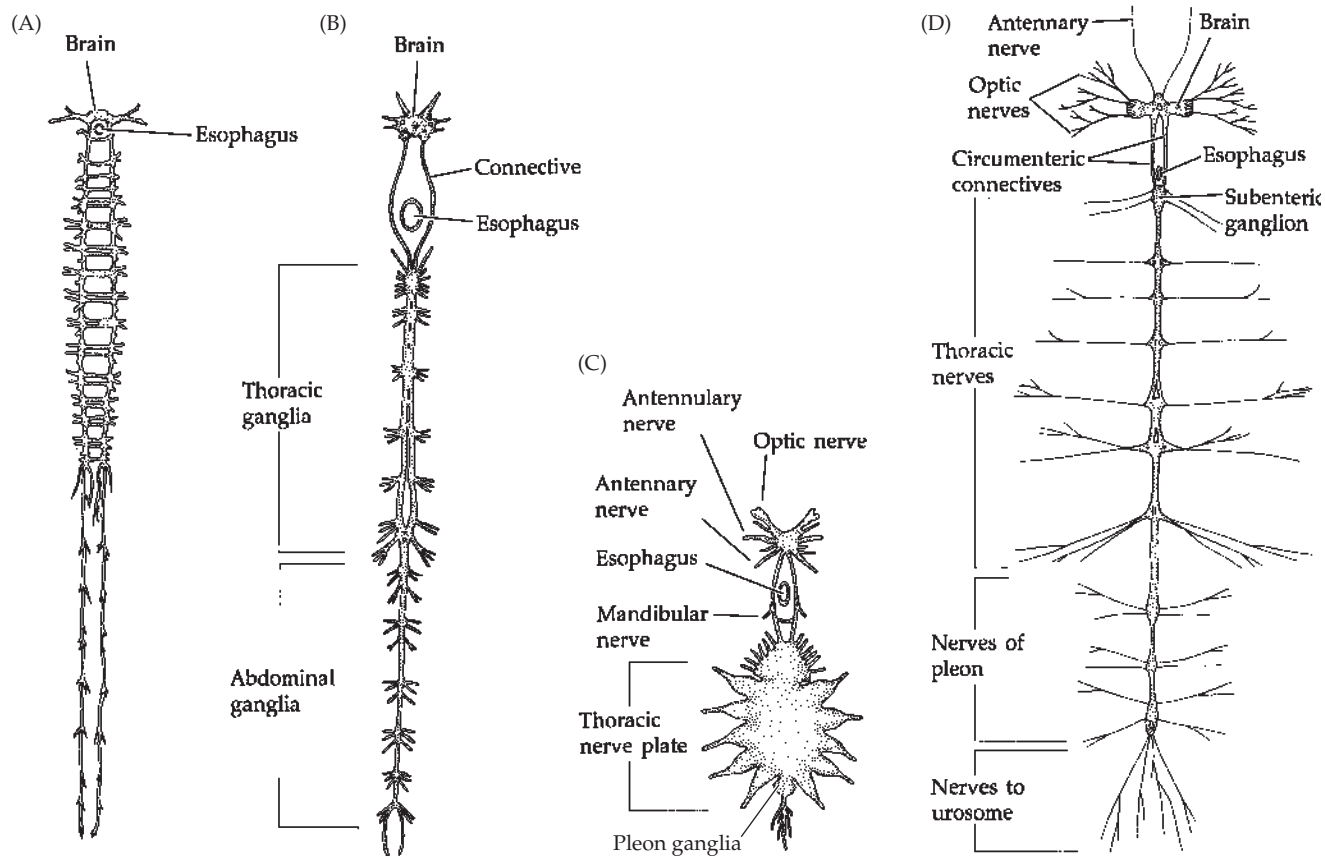

FIGURE 21.29 Central nervous systems of four crustaceans. (A) The ladderlike system of an anostracan. Note the absence of well-developed ganglia in the posterior, apodous, portion of the trunk. (B) Elongate metameric system of a crayfish. (C) Highly compacted system of a brachyuran crab, wherein all thoracic ganglia have fused and the abdominal ganglia are reduced. (D) Nervous system of a hyperiid amphipod. Note the loss of the urosomal ganglia typical of all amphipods. (D after G. J. Brusca. 1981. *J Crust Biol* 1: 358–375.)

for more ebook/ testbank/ solution manuals Requests email 960126734@qq.com

many groups the nervous system is ladderlike, the segmental ganglia being largely separate and linked by transverse commissures and longitudinal connectives (Figure 21.29A). The crustacean brain is composed of three fused ganglia, or neuromeres, the two anterior being the dorsal (supraesophageal) protocerebrum and deutocerebrum, which are thought to be preoral in origin. From the protocerebrum, optic nerves innervate the eyes. Mushroom bodies have been identified in many crustacean brains. From the deutocerebrum, antennulary nerves run to the antennules, while smaller nerves innervate the eyestalk musculature. The third ganglion of the brain is the tritocerebrum, which presumably represents the first postoral somite ganglion. The tritocerebrum forms a pair of circumenteric connectives that extend around the esophagus to a subesophageal or subenteric ganglion and link the brain with the ventral nerve cord bearing the segmental body ganglia. From the tritocerebrum also arise the antennary nerves as well as certain sensory nerves from the anterior region of the head. In tantulocarids, bizarre minute parasites on other crustaceans, the central nervous system has a dorsal brain and ventral nerve cord that runs through the thorax. The brain is formed of very small, tightly packed cells, and a neuropil is present (constituting almost half of the brain volume). The neuropil extends inside the ventral nerve cord.

The nature of the ventral nerve cord often clearly reflects the influence of body tagmosis. In crustaceans with relatively homonomous segmentation (e.g., remipedes, cephalocarids, and anostracan and notostracan branchiopods), the ganglia associated with each postantennary segment remain separate along the ventral nerve cord. In more heteronomous forms, however, a single large subenteric ganglionic mass is formed by the fusion of ganglia associated with the postoral cephalic segments (e.g., those of the mandibles, maxillules, maxillae, and, when present, maxillipeds). The ganglia of the thorax and abdomen may also be variably fused, depending on segment fusion and body compaction. For example, in most long-bodied decapods (lobsters and crayfish), the thoracic and abdominal ganglia are largely fused across the body midline but remain separate from one another longitudinally (Figure 21.29B). However, in short-bodied decapods (e.g., crabs), all of the thoracic segmental ganglia are fused to form a large ventral nerve plate, and the abdominal ganglia are much reduced (Figure 21.29C).

Most crustaceans have a variety of sensory receptors that transmit information to the central nervous system in spite of the imposition of the exoskeleton (as explained in Chapter 20) (Figure 21.30). Among the most obvious of these sensory structures are the many innervated setae or **sensilla** that cover various regions of the body and appendages (Figure 21.31). Studies of these structures suggest most function as both mechanoreceptors (sensing touch and currents) and chemoreceptors. Most crustaceans also possess special chemoreceptors in the form of clumps or rows of soft, tubular, cuticular processes called **aesthetascs** (Figure 21.30A) located on the antennules. In decapods, hundreds of neurons can innervate each aesthetasc. Thermoreceptors probably occur in many crustaceans (those living near hydrothermal vents in the deep sea would seem likely candidates) but are not yet documented. However, behaviors related to thermal avoidance and temperature preferences have been shown. A pair of unique sensory structures whose function is unknown, called **frontal processes**, occurs on the head of remipedes. Many crustaceans have dorsal organs, poorly understood glandular-sensory structures on the head, which actually constitute several different types of sensory structures that may or may not be homologous.

Like all arthropods, crustaceans contain well-developed proprioceptors that provide information about body and appendage position and movement during locomotion. A few taxa within the class Malacostraca possess statocysts, which either are fully closed and contain a secreted statolith (e.g., mysidans, some anthurid isopods) or are open to the outside through a small pore and contain a statolith formed of sand grains (e.g., many decapods and some asellote isopods) (Figure 21.30B,C). In the case of the decapods, the statocyst not only serves as a georeceptor, but also detects the angular and linear acceleration of the body relative to the surrounding water as well as the movement of water past the animal (i.e., the statolith is rheotactic). And in some shrimps the statocyst is apparently also engaged in hearing.

There are two types of rhabdomeric photoreceptors among crustaceans, median simple eyes and lateral compound eyes, and both are innervated by the protocerebrum. Many species possess both kinds of eyes, either simultaneously or at different stages of development. The compound eyes may be sessile or stalked. Stalked compound eyes occur in the Anostraca, many Malacostraca, and perhaps some Cumacea (and in anomalocaridids, and perhaps also some trilobites).

The median eye generally first appears during the nauplius larval stage, and for that reason it is often called a **naupliar eye**. Like the nauplius larva itself, the median eye is thought to be an ancestral (defining) feature of the Crustacea. Median eyes are in a sense "compound" in that they are composed of more than one photoreceptor unit (Figure 21.30D). There are typically three such units in the median eyes of nauplii and up to seven in the eyes of adults in which they persist. Except for their basic rhabdomeric nature, however, the structure of median eye units is unlike that of the ommatidia of true compound eyes. The former are inverse pigment cups, each with relatively few retinular (photoreceptor) cells. Cuticular lenses are present over the median eyes of most ostracods and some copepods. Simple crustacean eyes probably function only to detect light direction and intensity. Such information is of particular value as a means of orientation in planktonic forms without compound eyes, such as nauplius larvae, many copepods, etc. In some branchiopods, a space above the median eye is connected

to the external environment by a small pore, perhaps indicating an invagination of the eye at some point in the distant past, although the nature and function of the pore is not known.

The structure and function of compound eyes (ommatidia) were reviewed in Chapter 20. In terms of visual capacity, much more work has been done on the eyes of insects than on those of crustaceans, and we are left with a good deal of speculation in terms of what crustaceans actually see. Although most probably lack the visual acuity of many insects, it has been shown that many crustaceans can discern shapes, patterns, and movement; color vision has been demonstrated in some species (various species have been shown to respond to light wavelengths ranging from the blue-green region to the ultraviolet and far-red spectra, at least to 470–570 nm). Stomatopods, in particular, have been shown to have extremely complex and sensitive eyes with a wide range of capabilities. Running through the center of each stomatopod eye is a distinct band comprising six rows of ommatidia—which in most species contain four rows that make up a color vision system with 12 visual pigments—as well as two rows that analyze both linearly and circularly polarized light (Figure 21.30E). The ommatidia that deal with color have a three-tier structure: the top tier contains an ultraviolet-sensitive pigment, and below this are two tiers with different pigments sensitive to wavelengths in the human visible

spectrum. The upper and lower halves of each eye also have overlapping visual fields, so each eye can act as a stereoscopic range finder. The 12 different photoreceptor types each sample a narrow set of wavelengths ranging from deep UV to far red (300 to 720 nm).

Although both insects and crustaceans have tetrapartite ommatidia, there are certain structural differences between the compound eyes of insects and those of crustaceans, probably as a result of adaptation to the requirements of aerial and aquatic vision. In water, light has a more restricted angular distribution, a lower intensity, and a narrower range of wavelengths than it does in air. Contrast is also somewhat reduced in water. All of these factors place a premium on enhancing the sensitivity and contrast perception of the eyes

of aquatic creatures. Mounting the eyes on stalks is one dramatic way in which many crustaceans increase the amount of information available to the eyes, by increasing the field of view and binocular range. Eyestalks are complex structural features with a dozen or so muscles controlling their movement.

Typical tetrapartite compound eyes are lacking in the small crustaceans formerly combined as "maxillopodans" (copepods, barnacles, etc.), but various forms of "compound eyes" do occur among the Branchiura, Ostracoda (Cypridinacea), and Cirripedia. Eyes in the first two taxa most closely resemble those of other crustaceans in general structure and may be homologous with them. In the Cirripedia, the median eye and two lateral eyes are all derived from a single tripartite ocellar eye of the nauplius larva, which splits into its three components, each forming an adult photoreceptor following metamorphosis of the nauplius into a cypris larva. All three of these eyes thus appear to be composed of simple ocelli, although the lateral eyes have three photoreceptor cells and for this reason are often called "compound eyes." Rhizocephalan nauplii also have a tripartite nauplius eye, which persists into the cypris larval stage.

Compound eyes are lacking altogether in many crustacean taxa (e.g., Copepoda, Mystacocarida, Cephalocarida, Tantulocarida, Pentastomida, Remipedia, and some Ostracoda). Members of some other groups possess compound eyes only in late larval stages and lose them at metamorphosis (e.g., some cirripedes). Reduction or loss of eyes is also common in many deep-sea species, burrowers, cave dwellers, and parasites.

Crustaceans have complex endocrine and neurosecretory systems, although our understanding of these systems is far from complete. In general, the phenomena of molting (see Chapter 20), chromatophore activity, and various aspects of reproduction are under hormonal and neurosecretory control. Interesting recent work indicates that juvenile hormone–like compounds, long thought to occur only in insects, may also occur in at least some crustaceans. (Juvenile hormones are a family of compounds that regulate adult metamorphosis and gametogenesis in insects.) Crustaceans are masters of autotomy, or the dropping of limbs at specific breakage planes to escape potentially lethal threats. The process occurs via an intrinsic neuromuscular mechanism (i.e., it is a nonreflexive process), and the break point is capable of rapid sealing. In most crustaceans, loss of a limb stimulates rapid regeneration, usually accompanied by an initial molt. In snapping shrimps (Alpheidae) and some others with unequal chelae, autotomy of a cheliped commonly results in claw reversal during the induced molt, transforming the larger claw into a small one, and vice versa—a remarkable process that involves changes in morphology, underlying muscle types, and external setae.

Bioluminescence also occurs in several crustacean groups—it is common among pelagic decapods, and it has also been reported in certain myodocopan ostracods, hyperiid amphipods, and copepod larvae. Some copepods (e.g., male *Sapphirina metallina*) display an iridescence, which is created by a multilayered-membrane structure in the epidermal cells of the dorsal integument (see discussion of bioluminescent ostracods below).

Reproduction and Development

Reproduction We have often mentioned the relationships between an animal's reproductive and developmental pattern and its lifestyle and overall survival strategy. With the exception of purely vegetative processes such as asexual budding, the crustaceans have managed to exploit virtually every life history scheme imaginable. The sexes are usually separate, although hermaphroditism is the rule in remipedes, cephalocarids, most cirripedes, and a few decapods. Sequential hermaphroditism is not uncommon and usually is expressed as protandry (individuals first mature as males, then later become females), although protogyny occurs in a few species (e.g., the marine isopod *Gnorimosphaeroma oregonense* [Sphaeromatidae]). In addition, parthenogenesis is known in some branchiopods and certain ostracods. In one species of clam shrimp (*Eulimnadia texana*) a rare type of mixed mating system exists, called **androgonochorism** (i.e., androdioecy in plants), in which males coexist with hermaphrodites, but there are no true females. Androgonochorism is rare, but it is also known in the nematode *Caenorhabditis elegans*, some thoracican barnacles (e.g., *Balanus galeatus*, *Scalpellum scalpellum*), and several other branchiopod crustaceans.

The reproductive systems of crustaceans are generally quite simple (Figure 21.27). The gonads are derived from coelomic remnants and lie as paired elongate structures in various regions of the trunk. In many cirripedes, however, the gonads lie in the cephalic region. In some cases the paired gonads are partially or wholly fused into a single mass. A pair of gonoducts extends from the gonads to genital pores located on one of the trunk segments, either on a sternite, on the arthrodial membrane between the sternite and leg protopods, or on the protopods themselves. In many crustaceans the paired penes are fused into a single median penis (e.g., in tantulocarids, cirripedes, and some isopods). The female system sometimes includes seminal receptacles. The position of the gonopores varies among the classes.

The curious phenomenon of **intersex**—having both male and female secondary sexual characteristics—is widespread among crustaceans. Intersexual development is often associated with the presence of endoparasites such as bacteria and microsporidians, and it has also been correlated with the presence of endocrine-disrupting environmental pollutants that seem to induce opposing secondary sexual characteristics.

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

Most crustaceans copulate, and many have evolved courtship behaviors, the most elaborate and well known of which occur among the decapods. Although many crustaceans are gregarious (e.g., certain planktonic species, barnacles, many isopods and amphipods), most decapods live singly except during the mating season. More or less permanent, or at least seasonal, pairing is known among many crustaceans (e.g., stenopodid shrimps; certain parasitic and commensal isopods; pinnotherid "pea" crabs, which often live as pairs in the mantle cavities of bivalve molluscs or in burrows of axiid/lobster shrimps).

Even the parasitic pentastomids copulate (within the host's respiratory system) and have internal fertilization, relying on a transfer of sperm to the female's vagina by way of the male's cirri (penes). Pentastomid early embryos metamorphose into a so-called primary larva with two pairs of double-clawed legs and one or more piercing stylets (Figure 21.5E). The larvae may be autoinfective in the primary host, or they may migrate to the host's gut and pass out with the feces. In the latter case, an intermediate host is required, which may be almost any kind of vertebrate. The larvae bore through the gut wall of the intermediate host, where they undergo further development to the infective stage. Once the intermediate host is consumed by a definitive host (usually a predator), the parasite makes its way from the new host's stomach up the esophagus, or bores through the intestinal wall, eventually settling in the respiratory system.

Mating in nonpaired crustaceans requires mechanisms that facilitate location and recognition of partners. Among decapods, and perhaps many other crustaceans, scattered individuals apparently find one another either by distance chemoreception (pheromones) or through synchronized migrations associated with lunar periodicity, tidal movements, or some other environmental cue. Contact sex pheromones are also utilized. In one, unique lineage of myodocopan ostracods in the Caribbean, males produce complex bioluminescent displays similar to those of fireflies to attract females. Once prospective mates are near each other, recognition of conspecifics of the opposite sex may involve several mechanisms. Vision is known to be important in the stenopodid shrimps (most of which live in pairs), in certain anomurans (e.g., the family Porcellanidae), and in brachyurans (many grapsids and ocypodids).

A good deal of work has been done on fiddler crabs (Ocypodidae: *Uca*), of which over 100 species have been described. In these species, males engage in dramatic cheliped waving (of their greatly enlarged chela, or **major claw**, which can account for more than 50% of the male's total mass—more than the largest rack of a male elk!) to attract females and repel competing males (Figure 21.32A–D). In addition, males produce sounds by stridulation and substratum thumping, which are thought to attract potential mates. Mating generally takes place once the male has enticed the female into his burrow. Males of some fiddler crab species build sand structures at the entrance of their burrow, which have been shown to attract females.

Among many crustaceans, the external sexual characteristics are associated with the actual mating process. For example, the antennae of male anostracans and some cladocerans, ostracods, and copepods are modified for grasping the female. Additionally, many males bear special sperm transfer structures, in the form of either modified appendages or special penes such as those of the thoracican barnacles (Figure 21.32E), anostracans, and ostracods. Examples of modified appendages include the last trunk limbs of copepods and the anterior pleopods of most male malacostracans (called gonopods in most malacostracans, or **petasma** in Dendrobranchiata) (Figure 21.32F). Sperm are transferred either loose in seminal fluid or (in copepods, and many malacostracans) packaged in spermatophores. Motile flagellated sperm occur only in a few groups; in most the sperm are nonmotile. Crustacean sperm are highly variable in shape, even bizarre in many instances, often being large round or stellate cells that move by pseudopods or are, seemingly, nonmotile.[9] Sperm are deposited directly into the oviduct or into a seminal receptacle in or near the female reproductive system. In some crustaceans females can store sperm for long periods (e.g., several years in the lobster *Homarus*), thus facilitating multiple broods from a single insemination.

The great majority of crustaceans brood their eggs until hatching occurs, and a variety of brooding strategies have evolved. Peracarids brood the developing embryos in a marsupium, a ventral brood pouch formed from inwardly directed plates of the leg coxae called **oostegites** (thermosbaenaceans are an exception among the Peracarida and use the carapace as a brood chamber). Other crustaceans attach the embryos to endites on the bases of the legs or to the pleopods (Figure 21.32H), usually using mucus secreted by specialized glands. In some cladocerans, brooding takes place in a dorsal brood chamber formed by the carapace. However, the syncarids, almost all dendrobranchiate shrimps, and most euphausiaceans shed the zygotes directly into the water. A few others deposit their fertilized eggs in the environment, usually attaching them to some object (e.g., branchiurans, some ostracods, many stomatopods). These deposited embryos may be abandoned or, as is the case in stomatopods, carefully tended by the female. Nonetheless, parental protection of the embryos until they hatch as larvae or juveniles is typical in crustaceans. Thus, crustaceans usually engage in mixed or direct life histories (Table 21.2).

[9] The sperm of freshwater ostracods are the longest in the animal kingdom, relative to body size (up to 10× body length). Even though their sperm are aflagellate, they are filiform and range from several hundred microns to millimeters in length.

Development Although crustaceans are among the most widespread animals on Earth, we know surprisingly little about their embryogeny, which is extraordinarily diverse. The eggs are centrolecithal, with various amounts of yolk. The amount of yolk greatly influences the type of early cleavage and is often related to the time of hatching (see Chapter 4). As far as is known, the zygotes of most nonmalacostracans undergo some form of holoblastic cleavage, as do those of syncarids, euphausiaceans, penaeids, amphipods, and parasitic isopods. However, cleavage patterns are extremely variable, ranging from equal to unequal and from radial-like to unique. Early reports of modified spiral cleavage (see Figure 21.33A) in some crustaceans had once been viewed as evidence of close ties between the crustaceans and other spiralian groups such as the annelids. However, the generality of spiral-like cleavage among crustaceans has been called into question. Furthermore, evidence from molecular phylogenetics indicates arthropods belong to the Ecdysozoa clade of Protostomia, not the Spiralia (where annelids are nested). In fact, the cell lineages and germ layer origins in Crustacea are quite different from those of spirally cleaving embryos. For example, in barnacles the mesodermal germ layer arises from the 3A, 3B, and 3C cells, and the 4d cell contributes to ectoderm (Figure 21.33B)—whereas typical spiral cleavage involves a 4d origin of mesoderm. Euphausiaceans were long thought to have spiral cleavage, but recent work indicates they do not—only the oblique angle of the mitotic spindles during the transition from the two- to the four-cell stage superficially resembles spiral cleavage.

Meroblastic cleavage is the rule among many malacostracans. Here again, the exact pattern varies, but it generally involves intralecithal nuclear divisions followed by nuclear migration to the periphery of the embryo and subsequent partitioning of the nuclei into a cell layer around a central yolky mass (Figure 21.33C).

The form of the blastula and the method of gastrulation are dependent primarily on the preceding cleavage pattern and hence ultimately on the amount of yolk. Holoblastic cleavage may lead to a coeloblastula that undergoes invagination (as in syncarids) or ingression (as in many copepods and some cladocerans and anostracans). Other crustaceans form a stereoblastula followed by epibolic gastrulation (e.g., cirripedes). Most cases of meroblastic cleavage result in a periblastula and the subsequent formation of germinal centers.

As discussed above, crustaceans typically share a characteristic larval stage known as the nauplius larva, denoted by the appearance of the first three pairs of appendage-bearing somites (Figure 21.33D).[10] In those groups having little yolk in their eggs, the nauplius is generally free-living. In those species with yolky eggs, the nauplius stage is commonly passed through as part of a longer period of embryonic development (or a long brood period), and it is sometimes referred to as an **egg nauplius**. Free-living nauplii are usually planktotrophic, and their release corresponds to the depletion of stored yolk. However, in a few groups of crustaceans (e.g., euphausiaceans and dendrobranchiate shrimps), the nauplius exhibits lecithotrophy.

Crustacean development is either direct (the embryos hatch as juveniles that resemble miniature adults) or indirect (embryos hatch as a distinct larval stage) (Figure 21.32H). In direct development, the embryos are typically brooded. With indirect development, the embryos are typically released into the water (or in some cases deposited on the substratum). Some cases of indirect development can be viewed as "mixed development," in that embryos are brooded for a brief or prolonged period of time and early larval stages are passed within the brood. Larvae may pass through several phases, with each phase containing slightly different morphological steps called stages, before the adult condition is achieved. Direct development occurs in some cladocerans and branchiurans, and in all syncarids and peracarids. Ostracods also are typically viewed as having direct development. However, some ostracod species hatch with only the first three pairs of appendages present, a characteristic feature of nauplii, and thus some workers consider these to be naupliar larvae (even though they are in a bivalved carapace and add limbs gradually). The larval stages that have been recognized in the different crustacean groups have been assigned a plethora of names, and the homologies among these forms are not always understood. The more commonly encountered developmental forms are summarized below (also see Table 21.2 and Figure 21.33), but we do not attempt to describe them all.

[10] It was not until J. V. Thompson discovered the nauplius larvae of barnacles in the nineteenth century that this group was finally classified as Crustacea, a discovery that also marked the first use of larval features in understanding the phylogeny of marine invertebrates. An excellent atlas of crustacean larvae (Martin et al. 2014) includes historical notes on larval development in all major crustacean groups.

Crustacean development is sometimes described as being epimorphic, anamorphic, or metamorphic, a nomenclature more often used in myriapods (see Chapter 23). However, we caution readers that a clear evolutionary and functional understanding of crustacean developmental stages is still lacking, and thus the terms "indirect" and "direct" may be preferable, and less ambiguous, until we have a better understanding of these phenomena.

Anamorphic development is indirect, with larval stages, and the number of segments increases with each molt. **Epimorphic development** is direct, and in

for more ebook/ testbank/ solution manuals requests email 9601267734@qq.com

crustaceans it is thought to result from a delay in the hatching of the embryo, which causes the nauplius (and any other possible larval stages) to be suppressed or absent. In epimorphic development the hatchlings have a full complement of segments and appendages. **Metamorphic development** is the type of extreme development seen among the Eucarida; it includes dramatic transitions in body form from one life history stage to another. In general, up to five distinct preadult, or larval, phases may be recognized among crustaceans: **nauplius**, **metanauplius**, **protozoea**, **zoea**, and "**postlarva**." The zoeal phase shows the greatest diversity in form among the various taxa, and especially in decapods it has been given different names in different groups (e.g., acanthosoma, antizoea, mysis, phyllosoma, pseudozoea). It is common for the zoeal phase to contain a large number of stages, each differing only slightly from the one preceding it.[11] Regardless of name, the zoea is characterized by the presence of natatory exopods on some or all of the thoracic appendages and by the pleopods being absent (or rudimentary). Use of the term "postlarva" is unfortunate, as these stages differ dramatically from the preceding larvae as well as from the adults; they represent unique transitional stages (both morphologically and ecologically). Examples in the Decapoda include the **megalopa** of true crabs and the **puerulus** larva of spiny lobsters. In this phase of development, the role of swimming has switched from the thoracopodal limbs to the appendages of the abdomen.

Anamorphic development is a less extreme type of indirect development in which the embryo hatches as a nauplius (or later) larva, but the adult form is achieved through a series of gradual changes in body morphology as new segments and appendages are added. It is similar in many ways to hemimetabolous development

[11] The zoea larvae of palinurid lobsters (phyllosoma larvae) are large, bizarre-appearing creatures (Figure 21.33L), which can occur in such large numbers as to be a favorite food of tuna.

in insects in that the postnaupliar stages gradually take on the adult form with succeeding molts; the classic example of anamorphic development is often said to be the Anostraca. But it differs from insect development in that insects are born with the full complement of segments and appendages. Cephalocarida, Remipedia, many Branchiopoda, and Mystacocarida are anamorphic—the nauplius larva grows by a series of molts that add new segments and appendages gradually as the adult morphology appears. In many groups hatching is somewhat delayed, and the emergent nauplius larva is termed a metanauplius. The basic nauplius possesses only three body somites, while the metanauplius has a few more; however, both possess only three pairs of similar-appearing appendages (which become the adult antennules, antennae, and mandibles). The end of the naupliar/metanaupliar stage is defined by the appearance of the fourth pair of functional limbs, the maxillules. In copepods a postnaupliar stage called a **copepodite** (simply a small juvenile) is often recognized.

The most extreme forms of metamorphic, or mixed, development occur in the malacostracan superorder Eucarida. The most complex developmental sequences are seen among the dendrobranchiate shrimps, which hatch as a typical nauplius larva that eventually undergoes a metamorphic molt to become a protozoea larva, with sessile compound eyes and a full complement of head appendages. The protozoea, after several molts, becomes a zoea larva, with stalked eyes and three pairs of thoracopods (as maxillipeds). The zoea eventually yields a juvenile stage (the "postlarva," a better term for which is "decapodid") that resembles a miniature adult but is not sexually mature. In some other eucarid groups (Caridea and Brachyura) the postlarva is called a **megalopa**, and in the Anomura it is often called a **glaucothoe**; in both cases there are setose natatory pleopods on some or all of the abdominal somites. In other eucarids, some (or all) of these stages are absent.

Various other terms have been coined for different (or similar) developmental stages. For example, the modified zoeal stages of some stomatopods are called **antizoea** and **pseudozoea** larvae, and the advanced zoeal stage of many other malacostracans is often called a **mysis larva**. In euphausiaceans, the nauplius is followed by two stages, the **calyptopis** and the **furcilia**, which roughly correspond to protozoea and zoea stages, before the juvenile morphology is attained.

We've only just skimmed the surface of postembryonic larval, or developmental stage names; some 140 different larval names have been used for decapods alone! But, from this wealth of terms and diversity of developmental sequences, we can draw two important generalizations concerning the biology and evolution of the crustaceans. First, different developmental strategies reflect adaptations to different lifestyles. In spite of many exceptions, we can cite the early release of dispersal larvae by groups with limited adult mobility, such as thoracican barnacles, and by groups whose resources may not permit production of huge quantities of yolk, such as the copepods. At the other end of this adaptive spectrum is the direct development of peracarids—a major factor allowing the invasion of land by certain isopod lineages. Between these extremes we see all degrees of mixed life histories, with larvae being released at various stages following brooding and care. Second, because developmental stages also evolve, an analysis of developmental sequences can sometimes provide information about the radiation of the principal crustacean lineages. For example, the evolution of oostegites and of direct development combine as a unique synapomorphy of the Peracarida. Similarly, the addition of a unique larval form, such as the **cypris larva** that follows the nauplius in the cirripedes, can be viewed as a unique specialization that demarcates that group (Cirripedia). The cyprid either hatches as the only free-living larva or is the final larval stage after a series of lecithotrophic or planktotrophic nauplius larval stages.

It should also be noted that the branchiopods and some freshwater ostracods have evolved specialized ways of coping with the harsh conditions of many freshwater environments. Parthenogenesis, for example, is common in freshwater ostracods. Other adaptations include production of special overwintering forms, usually eggs or zygotes that can survive extreme cold, lack of water, or anoxic conditions. Perhaps most remarkable in this respect are the large-bodied branchiopods (fairy shrimps, tadpole shrimps, and clam shrimps) whose encysted embryos are capable of an extreme state of anaerobic quiescence, or diapause. During these resistant stages, the metabolic rate of the embryos may drop to less than 10% of their normal rate. Interestingly, there is a large group of Ediacaran microfossils, called acritarchs, that look remarkably similar to branchiopod resting stages, although further research is needed to confirm the identity of these fossils.

Many crustaceans have **indeterminate growth**, that is, they continue to molt throughout their life. In contrast, other species have **determinate growth** and cease molting following puberty (this life history stage is sometimes referred to as the terminal molt, or terminal anecdysis). In some species, the terminal molt is sex specific; for example, in American blue crabs (*Callinectes sapidus*) only females have a terminal molt.

Crustacean Phylogeny

Countless phylogenetic studies have been published on the topic of crustacean evolution, but recent large-scale phylogenomic studies of the Pancrustacea have largely agreed on the higher-level structure of the group's phylogeny. Thus our tree (Figure 21.34A) depicts Pancrustacea comprising two large sister groups, Oligostraca and Altocrustacea. Oligostraca houses the Ostracoda, Mystacocarida, Branchiura, and Pentastomida (though

the last has not yet been included in a phylogenomic analysis). The clade Oligostraca is a group of short-bodied crustaceans initially suggested by Zrzavý et al. (1998) based primarily on gene sequence data. The remainder of the Crustacea (Altocrustacea) houses two sister groups, one sometimes called the Allotriocarida (the "leaf-footed" crustacean lineages: Cephalocarida, Branchiopoda, and Remipedia, all of which have gradual, or anamorphic, development, plus Hexapoda), the other sometimes called Multicrustacea (Copepoda, Thecostraca, Malacostraca). Analyses support the monophyly of most traditionally recognized taxa, such as Malacostraca, Peracarida, Dendrobranchiata, Decapoda, Pleocyemata, Reptantia, Thecostraca, Copepoda, Branchiopoda, Cephalocarida, Remipedia, and Hexapoda. Relationships within the Branchiopoda reflect current thinking based largely on morphology. Relationships among the major decapod clades are not yet fully resolved, and the precise position of Copepoda (within the Multicrustacea) is still uncertain. Hexapoda is likely a sister group to the Remipedia, the two taxa together called Labiocarida (based on the likely homology of the "lower lip" in remipedes and the "labium" in hexapods). The former groups known as "Maxillopoda" and "Entomostraca" are not supported by molecular analyses.

Within the class Malacostraca there are two clades: Leptostraca, which have phyllopodous limbs and seven abdominal somites, and Eumalacostraca, which lack phyllopodous limbs, have six abdominal segments, and have the sixth abdominal appendages modified as uropods (which can work in conjunction with the telson as a tail fan). Relationships among the main eumalacostracan lines are shown in Figure 21.34B.

The class Branchiopoda is monophyletic in molecular analyses, but it is difficult to define on the basis of unique synapomorphies because it shows such great morphological variation. The extreme reduction of adult maxillae, as well as certain naupliar characters (e.g., reduced and tubular antennules, uniramous mandibles) strongly support monophyly, as do almost all studies employing molecular data. Apparently some branchiopods have secondarily lost the carapace, and others have secondarily lost most or all of the abdominal appendages.

That a group of crustaceans gave rise to the megadiverse group of arthropods called the Hexapoda (insects and their kin) is now almost universally agreed upon, based on a wide array of evidence that includes molecular sequence data, neuroanatomy, and other information. This realization renders the group called "Crustacea" paraphyletic. The monophyletic clade containing both crustaceans and insects is referred to as the Pancrustacea, or Tetraconata (a name that recognizes the unique presence and anatomy of four crystalline cone cells, known as Semper cells, in the ommatidia). Like the arthropods in general, crustaceans exhibit high levels of evolutionary parallelism and convergence and many apparent reversals of character states. This genetic flexibility is no doubt due in part to the nature of the segmented body, the serially homologous appendages, and the flexibility of developmental genes, which, as we have stressed, provide enormous opportunity for evolutionary experimentation. Any conceivable cladogram of crustacean phylogeny will require the acceptance of considerable homoplasy.

Fossil data (including the Cambrian Orsten fauna, Figure 21.35) seem to favor phyllopodous limbs as the primitive condition. However, developmental studies following the expression of *Distal-less* and other

for more ebook/ testbank/ solution manuals requests email 9601267734@qq.com

developmental genes suggest that the early embryogeny of limbs is very similar among crustaceans. For example, trunk limbs always emerge as ventral, subdivided limb buds. In phyllopodous limbs, the subdivisions of these limb buds grow to become the endites and the endopod of the natatory/filtratory adult limbs. In stenopodous limbs, the same limb bud subdivisions end up developing into the actual segments of the adult limb. Hence, the endites of phyllopodous limbs appear to be homologous to the segments of the stenopodous limbs. This discovery supports an emerging view of developmental plasticity in arthropod limbs, and it suggests that relatively simple genetic "switches" can account for major differences in adult morphologies. Thus, it is quite plausible that stenopodous limbs have evolved multiple times from phyllopodous ancestors, and this is the scenario depicted in the tree in Figure 21.34B.

Work by Klaus Müller and Dieter Waloszek on three-dimensionally preserved microscopic arthropods from the middle Cambrian Orsten (about 510 Ma) deposits of Sweden has documented a diverse fauna of minute crustaceans and their larvae. Among them, for example, is *Skara* (Figure 21.35C), a cephalocarid- or mystacocarid-like crustacean for which both naupliar larvae and adults have been recovered (the nauplius larvae are only a couple hundred microns long; adults are about 1 mm in length). *Skara* and many other Orsten crustaceans were probably meiofaunal animals not unlike modern marine meiofaunal forms (e.g., the mystacocarids). Dozens of Orsten microcrustaceans have so far been described (Figure 21.35). In 2001, a beautifully preserved fossil, *Ercaia minuscula*, was described from the middle Cambrian (520 Ma; Series 2) of South China. It has an untagmatized, 13-segmented trunk with serially repeated biramous appendages and a head with stalked eyes and five pairs of head appendages, including two pairs of antennae. *Ercaia minuscula* is only 2–4 mm long (hence the species name) and bears resemblances to both cephalocarids and "maxillopodans" (Figure 21.35F).

Studies on Cambrian fossils from the Swedish Orsten fauna (510 Ma), Burgess Shale–like deposits from around the world (520 Ma), and the Chengjiang fossils from China (530 Ma) have shown that Cambrian

(F) *Ercaia minuscula*, an early Cambrian (520 Ma) crustacean from South China.

crustaceans had all the attributes of modern ones, such as compound eyes, an ocular segment, distinct head and trunk tagmata, at least four head appendages, a carapace (or head shield), naupliar (or "head") larvae (with locomotory first antennae), and biramous appendages on the second and third head somites (the second antennae and mandibles). We thus know that the crustaceans are an ancient group. Their fossil record dates back to the early Cambrian (the Fortunian stage), or likely the Ediacaran period if some arthropod fossils from those strata are viewed as Crustacea. The earliest undisputed crustacean larval stage is a fossil of a slightly advanced nauplius (called a metanauplius) from the Terreneuvian (525 Ma) of China that in many ways resembles the naupliar larva of modern cirripedes. This is remarkable, as it confirms not only the great age of the Crustacea as a whole but also the age of groups within the Crustacea, such as the cirripedes, that were already becoming distinct.

Chapter Summary

The subphylum Crustacea is a paraphyletic group, because it excludes the Hexapoda (insects and their kin), which evolved from within Crustacea close to 500 million years ago. The sister group of Hexapoda may be Remipedia. Phylogenetically, Crustacea and Hexapoda comprise the clade Pancrustacea (sometimes called Tetraconata). As with the insects on land, crustaceans have been hugely successful in the aquatic world. Close to 60,000 living crustacean species have been described, but five or ten times that number probably await discovery. As with insects, the morphological disparity within Crustacea is staggering, with body sizes ranging from less than 100 μm in length to over 4 meters in width. Given that most of Earth is covered with water, and the great depths of world's seas, crustaceans are the most widespread animals on the planet! Crustaceans are well understood, in part, because of their economic importance, especially as seafood. A number of groups, notably isopods and amphipods, have successfully invaded the terrestrial world. The crustacean body is divided into a head (bearing 5 pairs of appendages) and trunk, the latter being subdivided into a thorax and abdomen in all but the class Remipedia. The head, and often some of the thoracic segments, are commonly covered by a dorsal shield called the carapace. Paralleling their morphological diversity, crustaceans exhibit a wide range of locomotory strategies that include swimming, walking, and hopping. They also have numerous modes of feeding, including suspension feeding, deposit feeding, active predation, and parasitism. The body is a hemocoel, but a dorsal ostiate (pumping) heart is usually present, as are small vessels that distribute the hemocoel. Excretion relies on various nephridially-derived structures and diffusion across the gills. The central nervous system follows the general arthropod plan, with a brain composed of three fused pairs of ganglia (protocerebrum, deutocerebrum, tritocerebrum), the tritocerebrum forming a pair of circumenteric connectives around the esophagus to a subenteric ganglion that links to the ventral nerve cord formed of paired segmental ganglia. Most crustaceans are gonochoristic, although hermaphroditism is not uncommon (usually expressed as protandry or protogyny). Parthenogenesis is known in some groups. Cleavage patterns in embryos are highly diverse and largely dependent on the amount of yolk present, ranging from equal to unequal. Crustacea have a characteristic first larval stage called the nauplius larva (suppressed or bypassed in some groups), denoted by three pairs of appendage-bearing somites. In some groups, various other postnaupliar larvae occur (e.g., metanauplius, protozoea, zoea, megalopa). A rich record of Cambrian fossil Crustacea has been described from Sweden, China, and elsewhere. We now know that Pancrustacea likely comprises three great clades: Oligostraca (Ostracoda, Mystacocarida, Branchiura, Pentastomida), Multicrustacea (Thecostraca, Copepoda, Malacostraca), and Allotriocarida (Cephalocarida, Branchiopoda, Remipedia, Hexapoda).

CHAPTER 22

Phylum Arthropoda

Subphylum Hexapoda: Insects and Their Kin

Arthropods stand out among all other invertebrates for being far and away the most diverse phylum of animals on Earth. This is due, entirely, to the hexapod class Insecta—their diversity and abundance nearly defy imagination. Insects are the only invertebrates that fly, and the only terrestrial invertebrate group whose members undergo either indirect development or complete metamorphosis.

The arthropod subphylum Hexapoda comprises the class Insecta and three other small, wingless, insectlike groups: Collembola, Protura, and Diplura. All hexapods have a distinct body plan consisting of a head, a 3-segmented thorax, and an abdomen of 11 segments (or fewer in groups that have a secondarily reduced abdomen). The thorax bears three pairs of legs and, in the Pterygota, two pairs of wings. The head bears a single pair of antennae (vestigial in Protura) and three sets of mouthparts (mandibles, maxillae, and labium). They have an aerial gas exchange system, composed of tracheae and spiracles, and Malpighian tubules formed as proctodeal (ectodermal) evaginations (Box 22A). The presence of a thorax fixed at three segments, each with a pair of walking legs, is an apomorphy of Hexapoda. Other apomorphies include the presence of a large fat body (mainly concentrated in the abdomen) and fusion of the second maxillae to form a lower lip (the labium).

Hexapods evolved on land; groups inhabiting aquatic environments today have secondarily invaded those habitats through physiological adaptations and modifications of their aerial gas exchange systems. The earliest undisputed fossils of hexapods are Early Devonian (412 Ma). However, there are Silurian trace fossils that are very hexapod-like, and molecular clock data suggest an Early Ordovician origin for Hexapods at about 480 million

BOX 22A Characteristics of the Subphylum Hexapoda

1. Body composed of 20 segments organized as a head (6 somites), thorax (3 somites), and abdomen (11 somites; or fewer in groups with a reduced abdomen); due to fusion of somites, body segments are not always externally obvious
2. Head bears the following structures (from anterior to posterior): compound eyes and ocelli, antennae, clypeolabrum, mandibles, maxillae, labium (fused second maxillae); ocelli (and compound eyes) secondarily lost in some groups
3. Legs uniramous, present on the three thoracic segments of adults. Legs composed of six articles: coxa, trochanter, femur, tibia, tarsus, and pretarsus; tarsus often subdivided, pretarsus typically clawed.
4. Gas exchange by spiracles and tracheae
5. Gut with gastric (digestive) ceca
6. Large fat body is mainly concentrated in abdomen
7. Fused exoskeleton of head forms a unique internal tentorium
8. Ectodermally derived Malpighian tubules (proctodeal evaginations)
9. Gonopores open on the last abdominal segment, or on abdominal segment 7, 8, or 9
10. Gonochoristic; development direct or indirect

years ago and an early Silurian origin about 440 million years ago for Insecta.

The most spectacular evolutionary radiation among the Hexapoda (in fact among all eukaryotic life) has, of course, been within the insects, which inhabit nearly every conceivable terrestrial and freshwater habitat and, less commonly, even the sea surface and the marine littoral region. Insects are also found in such unlikely places as oil swamps and seeps, sulfur springs, glaciers and glacial streams, and brine ponds. They often live where only few other animals or plants can exist. It is no exaggeration to say that insects rule the land.

We do not know how many species of Hexapoda there are on the planet, or even precisely how many have already been described. Published estimates of the number of described (living) species range from 890,000 to well over a million; we estimate there are nearly 996,000 described species of hexapods. An average of about 3,500 new species have been described annually since the publication of Linnaeus's *Systema Naturae* in 1758, although in recent years the average has climbed to around 7,000 new species annually. Estimates of the number of insect species remaining to be described range from 3 million to 100 million. The Coleoptera (beetles), with an estimated 387,000 described species, is far and away the largest insect order (more than a quarter of all described animal species are beetles). The beetle family Curculionidae (the weevils) contains about 65,000 described species (nearly 5% of all described animal species). The rich diversity of insects seems to have come about through a combination of advantageous features, including the evolutionary exploitation of developmental genes working on segmented and compartmentalized bodies, coevolution with plants (particularly the flowering plants), miniaturization, and their ability to fly.

Insects are not only diverse, but also incredibly abundant. For every human alive, there are an estimated 200 million insects. Howard Ensign Evans estimated that an acre of ordinary English pasture supports an astonishing 248,375,000 springtails and 17,825,000 beetles. In tropical rainforests, insects can constitute 40% of the total animal biomass (dry weight), and the biomass of the ants can be far greater than that of the combined mammal fauna (up to 15% of the total animal biomass). A single colony of the African driver ant *Anomma wilverthi* may contain as many as 22 million workers. Based on his research in the tropics, biodiversity sleuth Terry Erwin calculated that there are about 3.2×10^8 individual arthropods per hectare, representing more than 60,000 species, in the western Amazon. In Maryland, a single population of the mound-building ant *Formica exsectoides* comprised 73 nests covering an area of 10 acres and containing approximately 12 million workers. Termites have colonies of similar magnitudes. E. O. Wilson calculated that, at any given time, 10^{15} (a million billion) ants are alive on Earth! And in one 4 ha patch of cloud forest in Costa Rica an astounding 4,332 species of Diptera were found; this amounts to more than half the number of named species of flies for all of Central America!

In most parts of the world, insects are among the principal predators of other invertebrates. Insects are also key prey in the diets of many terrestrial vertebrates and other arthropods, especially arachnids and myriapods, and they play a major role as reducer-level organisms (detritivores and decomposers) in food webs. Due to their diversity and abundance, they constitute much of the fabric of terrestrial food webs. Their biomass and energy consumption exceed those of vertebrates in most terrestrial habitats. In deserts and in the tropics, ants replace earthworms as the most abundant earth movers (ants are nearly as important as earthworms even in temperate regions). Termites are among the chief decomposers of dead wood and leaf litter around the world, and without dung beetles African savannas would be buried under the excrement of the tens of thousands of large grazing mammals.

Without insects, life as we know it would cease to exist. In fact, E. O. Wilson stated, "So important are insects and other land-dwelling arthropods that if all were to disappear, humanity probably could not last more than a few months." Some 80% of the world's crop species, including food, medicine, and fiber crops, rely

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

on animal pollinators, nearly all of which are insects. Insects also play key roles in pollinating wild, native plants, and there is evidence (in mid-Cretaceous Burmese amber fossils) of specialized beetle-angiosperm pollination as early as 99 million years ago. Beekeeping began long ago, at least by 600 BCE in the Nile Valley and probably well before that. The first migratory beekeepers were Egyptians who floated hives up and down the Nile to provide pollination services to floodplain farmers while simultaneously producing a honey crop. Domestic honeybees (*Apis mellifera*), introduced to North America from Europe in the mid-1600s, are now the dominant pollinators of most food crops grown around the world, and they play some role in pollinating 80% of the crop varieties grown in the United States.[1]

Interactions between insects and flowering plants have been going on for a very long time, beginning over 100 million years ago with the origin of the angiosperms and accelerating with the ascendancy of these flowering plants during the early Cenozoic. Millions of years of plant-insect coevolution have resulted in flowers with anatomy and scents that are finely tuned to their insect partners. In exchange for pollination services, flowers provide insects with food (nectar, pollen), shelter, and chemicals used by the insects to produce such things as pheromones. In general, insect pollination is accomplished coincidentally, as the pollinators visit flowers for other reasons. But in a few cases, such as that of the yucca moths of the American Southwest (*Tegiticula* spp.), the insects actually gather up pollen and force it into the receptive stigma of the flower, initiating pollination. The moth's goal is to assure a supply of yucca seed for its larvae, which develop within the yucca's fruits. Some insects also play important roles as seed dispersers, especially ants. More than 3,000 plant species (in 60 families) are known to rely on ants for the dispersal of their seeds.

Like all other animals on Earth, insects are facing enormous threats of extinction. Certainly many thousands of species have become extinct over the past century as a result of rampant land use change and deforestation. With accelerating biodiversity losses worldwide, estimates of the number of insect species that have already gone extinct range into the millions. Further, widespread and often inappropriate use of pesticides (e.g., neonicotinoids) has created a "pollination crisis" in many parts of the world, as pollinating insects are locally extirpated and native plant and domestic crop pollination plummets.

As valuable as insects are to human life, some species seem to conspire to give the whole group a bad name. Some insect species are pests that consume about a third of our potential annual harvest, and some other species transmit devastating human diseases. Every year we spend billions of dollars on insect control. Malaria, transmitted by mosquitoes, kills 1 to 3 million people annually (mostly children), and each year nearly 500 million people contract the disease. It is the leading cause of death from infectious disease, and it has plagued humans for at least 3,000 years (Egyptian mummies have been found with malaria antigens in their blood). One of the most widespread and fastest-spreading human viral diseases, dengue, is transmitted by mosquitoes of the genus *Aedes*. Dengue is essentially an urban disease, almost entirely associated with anthropogenic environments because its main vectors, *A. albopictus* and *A. aegypti*, breed primarily in artificial containers (e.g., flower vases, discarded tires, water tanks). In recent years, these species have spread throughout the tropics, often following the international trade in used tires. Although these mosquitoes have not penetrated very far into the temperate zones, they have become established in the southern United States. Another variety of mosquitoes transmits the filarial nematode *Wuchereria bancrofti*, the causative agent of lymphatic filariasis ("elephantiasis") throughout the world's tropics. Chagas' disease (American trypanosomiasis) is transmitted by certain hemipteran bugs in the subfamily Triatominae (family Reduviidae) and causes chronic degenerative disease of the heart and intestine. The species of triatomine bugs that occur in the southwestern United States tend not to defecate when they feed, greatly reducing the possibility of humans contracting Chagas' disease in that area. However, global warming is now increasing the spread of *Aedes*, *Culex*, triatomines, and other tropical disease vectors.

Natural history writer David Quammen, speaking of the blood-sucking varieties of mosquitoes, notes that the average blood meal of a female (the only sex that feeds on blood) amounts to 2.5 times the original weight of the insect—the equivalent, Quammen notes, "of Audrey Hepburn sitting down to dinner and getting up from the table weighting 380 pounds, then, for that matter, flying away." But as Quammen also points out, mosquitoes have made tropical rainforests (the most diverse ecosystems on Earth) largely uninhabitable to humans, thus helping to preserve them!

The enormous diversification of Hexapoda is often attributed to the evolution of three key innovations: the ability to fly, the ability to fold back their wings, and hemimetabolous and holometabolous development. The persistence of the main lineages of insects since the Devonian and their ecological and morphological

[1] The study of bees is called "melittophily." The study of honeybees (*Apis* spp.) and their management is called "apiculture." The management of bumblebees (*Bombus* spp.) is "bombiculture." The ritualized keeping of stingless bees is "meliponiculture." The Asian honeybee, *Apis dorsata*, is a giant, reaching an inch in length. Its droppings are quite noticeable, and the mass defecations of these bees at sunset create a "golden shower" that provides significant nutrient enrichment to tropical soils. Their droppings were once confused with the dreaded "yellow rain," a deadly form of biochemical warfare that poisoned thousands of villagers during the Vietnam War.

versatility have undoubtedly contributed to making Hexapoda the dominant group in extant terrestrial ecosystems, with respect to species diversity, functional diversity, and overall biomass. Obviously, the subject of insect biology, or entomology, is a discipline in its own right, and a multitude of books and college courses on the subject exists. If we apportioned pages to animal groups on the basis of numbers of species, overall abundance, or economic importance, insect chapters could easily fill 85% of this textbook. The Selected References at the end of this book provide entry into some of the current literature on insects.

There are as many orders of Hexapoda as there are phyla of animals (31). Because hexapods comprise such a large and diverse assemblage of arthropods, we first present a brief classification of the recognized orders, followed by more detailed synopses, brief diagnoses, and comments on each order. These two sections serve as a preface to the body plan discussion that follows and also provide a reference that the reader can refer to as needed.

Classification of the Subphylum Hexapoda

Our classification scheme recognizes 31 orders of living hexapods. Three entognathous, or noninsect, hexapod orders (formerly classified as Entognatha) are basal to the monophyletic class Insecta. The Insecta comprise two monophyletic sister groups, the order Archaeognatha (with monocondylic mandibles) and all the others (with dicondylic mandibles). The subclass Pterygota, or flying insects, comprise two groups: the Palaeoptera (Ephemeroptera, Odonata), which may be a paraphyletic group, and the monophyletic infraclass Neoptera. We recognize three superorders within the modern winged insects, or Neoptera: the Polyneoptera (Blattodea, Dermaptera, Embioptera, Grylloblattodea, Mantodea, Mantophasmatodea, Orthoptera, Phasmida, Plecoptera, and Zoraptera), the Acercaria (Hemiptera, Psocodea, Thysanoptera), and the Holometabola (all the remaining orders). Within the Holometabola we recognize four well-supported, but unranked clades: Coleopetrida (Coleoptera, Strepsiptera), Neuropterida (Megaloptera, Neuroptera, Raphidioptera), Antliophora (Diptera, Mecoptera, Siphonaptera), and Amphiesmenoptera (Lepidoptera, Trichoptera). With nearly a million named species of Hexapoda, we have opted to include representative families of only the most diverse and common orders in the taxonomic synopses.

SUBPHYLUM HEXAPODA

(Note: Entognatha is a paraphyletic group; Diplura is the sister group of Insecta. Palaeoptera is likely a paraphyletic group.)

ENTOGNATHA

ORDER COLLEMBOLA Springtails

ORDER PROTURA Proturans

ORDER DIPLURA Diplurans

CLASS INSECTA (= ECTOGNATHA)

ORDER ARCHAEOGNATHA Jumping bristletails

DICONDYLIA

ORDER ZYGENTOMA Silverfish

SUBCLASS PTERYGOTA Winged insects

INFRACLASS PALAEOPTERA Ancient winged insects

ORDER EPHEMEROPTERA Mayflies

ORDER ODONATA Dragonflies and damselflies

INFRACLASS NEOPTERA Modern, wing-folding insects

SUPERORDER POLYNEOPTERA

ORDER PLECOPTERA Stoneflies

ORDER BLATTODEA Cockroaches and termites

ORDER MANTODEA Mantises

ORDER PHASMIDA (= PHASMATODEA) Stick and leaf insects

ORDER GRYLLOBLATTODEA Rock crawlers

ORDER DERMAPTERA Earwigs

ORDER ORTHOPTERA Locusts, katydids, crickets, grasshoppers

ORDER MANTOPHASMATODEA Heel-walkers or gladiators

ORDER EMBIOPTERA (= EMBIIDINA) Web-spinners

ORDER ZORAPTERA Zorapterans

SUPERORDER ACERCARIA (= PARANEOPTERA)

ORDER THYSANOPTERA Thrips

ORDER HEMIPTERA True bugs

ORDER PSOCODEA Book lice, bark lice, true lice

SUPERORDER HOLOMETABOLA

ORDER HYMENOPTERA Ants, bees, wasps

COLEOPTERIDA

ORDER COLEOPTERA Beetles, weevils, ladybugs, etc.

for more ebook/ testbank/ solution manuals requests: email 9012673 4@qq.com

ORDER STREPSIPTERA Twisted-wing parasites

NEUROPTERIDA

ORDER MEGALOPTERA Alderflies, dobsonflies, fishflies

ORDER RAPHIDIOPTERA Snakeflies

ORDER NEUROPTERA Lacewings, ant lions, mantisflies, owlflies

ANTLIOPHORA

ORDER MECOPTERA Scorpionflies, hangingflies, snow scorpionflies (possibly paraphyletic within Siphonaptera)

ORDER SIPHONAPTERA Fleas

ORDER DIPTERA True flies, mosquitoes, gnats, hoverflies

AMPHIESMENOPTERA

ORDER TRICHOPTERA Caddisflies

ORDER LEPIDOPTERA Butterflies, moths

Synopses of Hexapod Groups

Subphylum Hexapoda

Body differentiated into head (of six segments), thorax (3 segments), and abdomen (11 or fewer segments); head with 1 pair of lateral compound eyes and often with a triad or pair of medial ocelli; with 1 pair of uniramous multiarticulate antennae, mandibles, and maxillae; second pair of maxillae fused to form a complex labium; each thoracic segment with 1 pair of uniramous legs; wings often present on second and third thoracic segments (in pterygote insects); abdomen without fully developed legs, but "prolegs" (presumably homologous with the ancestral arthropod abdominal appendages) occur in at least 7 orders (in adults of some Diplura, Zygentoma, and Archaeognatha; in larvae of some Diptera, Trichoptera, Lepidoptera, and Hymenoptera); abdomen with a large fat body; gonopores open on the last abdominal segment or on the seventh, eighth, or ninth abdominal segment; paired cerci often present; males commonly with intromittent and clasping structures; development direct, involving relatively slight changes in body form (ametabolous or hemimetabolous), or indirect with striking changes (holometabolous). About 996,000 described, extant species.

Entognatha

Mouthparts with bases hidden within the head capsule ("ento-gnathous"); mandibles with single articulation; most or all antennal articles with intrinsic musculature; wingless; without, or with poorly developed, Malpighian tubules; legs with 1 (undivided) tarsus. The 3 orders of entognathous hexapods do not form a monophyletic group. Recent data from paleontology, comparative anatomy, and molecular phylogenetics suggest that Diplura is the sister group of Insecta and therefore more closely related to the Insecta than to the other entognathous orders.

Order Collembola Approximately 6,000 described species (Figure 22.1A,B). Small (most less than 6 mm); biting-chewing mouthparts; with or without small compound eyes; ocelli vestigial; antennae with 4 articles, first 3 with intrinsic muscles; tarsus of legs indistinct (perhaps fused with tibia); pretarsus of legs with single claw; abdomen with a reduced number of segments (6, or fewer in Symphypleona); first abdominal segment with ventral tube (collophore) of unknown function; third abdominal segment with small process (retinaculum); a forked tail-like appendage on fourth or fifth abdominal segment (furcula); without cerci; with gonopores on last abdominal segment; without Malpighian tubules; often without spiracles or tracheae.

The earliest known hexapods in the fossil record are collembolans. *Rhyniella praecursor* and other species from the Lower Devonian closely resemble some modern collembolan families. Unlike most other hexapods, which breathe using internal tubes called tracheae, springtails breathe air directly through their cuticle and epidermis. Their cuticle repels water, allowing them to live in moist environments without suffocating. They also have a remarkable system for escaping predators. While they are at rest, the furcula is retracted under the abdomen and held in place by the retinaculum. When the furcula and retinaculum disassociate, the furcula swings downwards with such force that it hits the substrate and quickly propels the collembolan high into the air. Many workers believe that springtails evolved via neoteny.

Order Protura Approximately 200 described species (Figure 22.1D). Minute (smaller than 2 mm); whitish; without eyes, abdominal spiracles, hypopharynx, or cerci; Malpighian tubules are small papillae; sucking mouthparts; styletlike mandibles; vestigial antennae; first pair of legs carried in an elevated position and used as surrogate "antennae"; pretarsus of legs with single claw; 11-segmented abdomen, with a telson (perhaps reminiscent of their crustacean ancestors); the segmental nature of this telson or twelfth "segment" has not been confirmed; first 3 abdominal segments with small appendages; without external genitalia, but male gonopores on protrusible phallic complex; gonopores on last abdominal segment; with or without tracheae; simple development.

Proturans are the only hexapods with anamorphic development, a type of development in which a new abdominal segment is added with each instar (or molt).

FIGURE 22.1 Representatives of the three orders of entognathous (noninsect) hexapods. (A) *Anurida granaria*, a springtail (order Collembola, suborder Poduromorpha). (B) *Ptenothrix* sp., a springtail (order Collembola, suborder Symphypleona). (C) A campodeid dipluran from New Zealand (order Diplura). (D) A proturan from British Columbia (order Protura).

All other insects have epimorphic development, in which segmentation is complete before hatching. Proturans are rare, and live in leaf litter, moist soils, and rotting vegetation.

Order Diplura Approximately 800 described species (Figure 22.1C); fossils date to the Carboniferous. Small (usually 0.3 to 1.0 cm in length, although the largest species reaches 5 cm); whitish; without eyes, ocelli, external genitalia, or Malpighian tubules; chewing mouthparts; 11-segmented abdomen, but embryonic segments 10 and 11 fuse before hatching; gonopores on ninth abdominal segment; 7 pairs of lateral abdominal leglets; 2 caudal cerci, enlarged and forming a pair of pincers in japygids; with tracheae and up to 7 pairs of abdominal spiracles; antennae multiarticulate, each article with intrinsic musculature; simple development. Most species live in mesic habitats beneath rocks, rotting logs, leaf litter, humus, and soil.

Class Insecta

Mouth appendages ectognathous (exposed and projecting from the head capsule); mandibles with 2 points of articulation (except Archaeognatha); intrinsic musculature of antennal articles greatly reduced; antennal pedicel with a mechanoreceptor that perceives the movement of the flagellum, called the Johnston's organ; head with a tentorial bridge connecting the posterior tentorial arms; tarsi subdivided into tarsomeres; with well-developed Malpighian tubules; ovipositor formed from modifications of the appendages of abdominal segments 8 and 9. The Insecta comprise 2 clades, the order Archaeognatha (with monocondylic mandibles) and all other insects (the clade Dicondylia, with dicondylic mandibles). Dicondylia also comprise two clades, the order Zygentoma and the subclass Pterygota (winged insects).

Order Archaeognatha Approximately 390 described species (Figure 22.2A,B). Small (to 15 mm), wingless (perhaps secondarily), resembling silverfish but body more cylindrical; ocelli present; compound eyes large and contiguous; body usually covered with scales; mandibles biting-chewing; with a single condyle (articulation point); maxillary palp large and leglike; 3-articulate tarsi; middle and hind coxae usually with exites ("styli"); 11-segmented abdomen, with 3 to 8 pairs of lateral leglets ("styli") and 3 caudal filaments; simple development. Jumping bristletails are usually found in grassy or wooded areas under leaves, bark, or stones.

Dicondylia

Includes Thysaura and the Pterygota (the winged insects). These two large insect clades are characterized by mandibles with two condyles (articulation points).

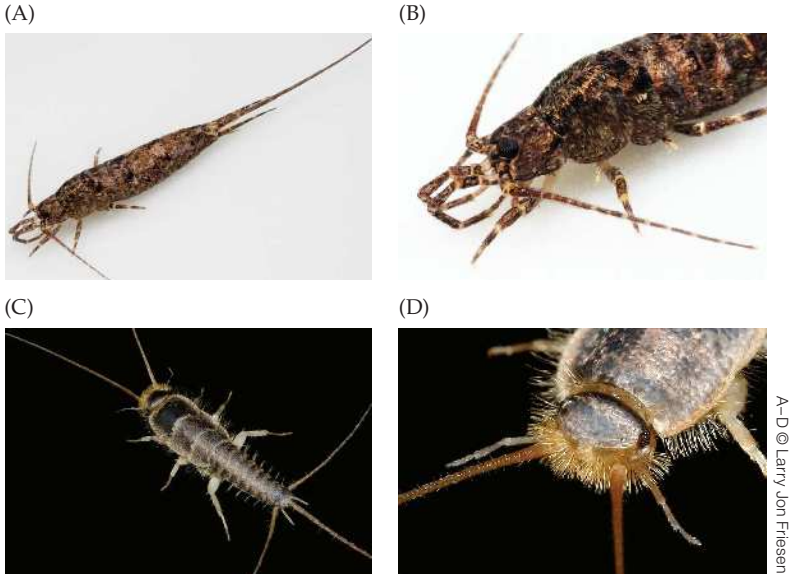

FIGURE 22.2 Representatives of the two orders of wingless Insecta. (A) Jumping bristletail (order Archaeognatha) and (B) close-up of jumping bristletail head (note the eyes are contiguous). (C) A silverfish (order Zygentoma). (D) Close-up of silverfish head. Note that eyes are not contiguous, but set wide apart, and that the bodies of both of these groups are covered with scales.

Order Zygentoma Approximately 450 described species (Figure 22.2C,D). Small, wingless, resembling Archaeognatha but with flattened body; with or without ocelli; compound eyes reduced, not contiguous; body usually covered with scales; mandibles biting-chewing; antennae multiarticulate, but only basal article with musculature; 3- to 5-articulate tarsi; 11-segmented abdomen, with lateral leglets (often called styli) on segments 2–9, 7–9, or 8–9; 3 caudal cerci; female gonopores on eighth abdominal segment, male gonopores on tenth; without copulatory organs; with tracheae; simple development. Silverfish occur in leaf litter or under bark or stones, or in buildings, where they may feed on wallpaper paste, bookbindings, and the starch sizing of some fabrics.

Subclass Pterygota

The winged insects, with a pair of wings on the second and third thoracic segments, the forewings (front wings) and hindwings; wings may be secondarily lost in one or both sexes, or modified for functions other than flight; adults without abdominal leglets except on genital segments; female gonopores on eighth abdominal segment, male on tenth; female often with ovipositor; molting ceases at maturity.

Palaeoptera

Wings cannot be folded, and when the individual is at rest, wings are held either straight out to the side or vertically above the abdomen (with dorsal surfaces pressed together); wings always membranous, with many longitudinal and cross veins; wings tend to be fluted, or accordion-like; antennae highly reduced or vestigial in adults; hemimetabolous development, but with aquatic young/immatures (naiads) that differ markedly from adults; larvae aquatic. Two extant orders; many extinct groups.

Order Ephemeroptera Approximately 2,500 described species (Figure 22.3A). Adults with vestigial mouthparts, minute antennae, and soft bodies; wings held vertically over body when at rest; forewings present; hindwings absent or present but much smaller than forewings; long, articulated cerci, usually with medial

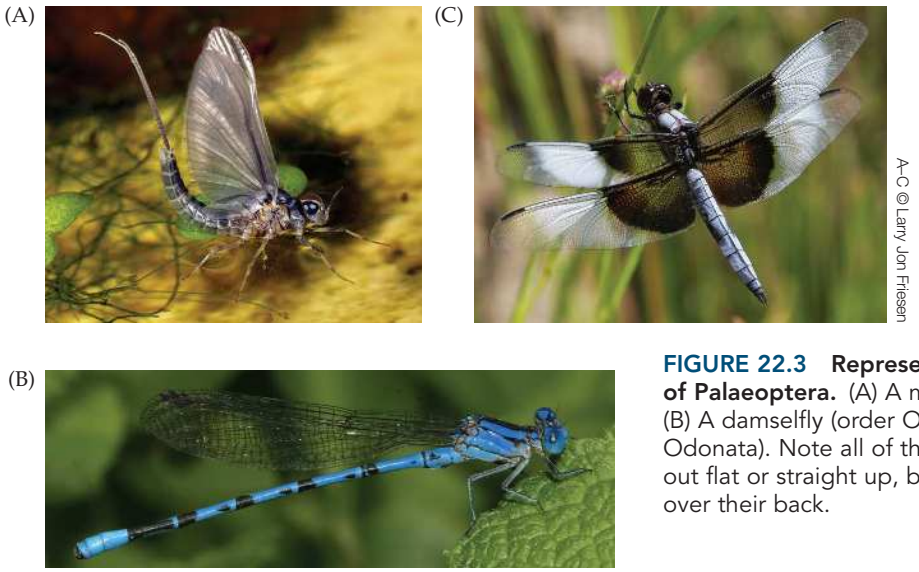

FIGURE 22.3 Representatives of the two orders of Palaeoptera. (A) A mayfly (order Ephemeroptera). (B) A damselfly (order Odonata). (C) A dragonfly (order Odonata). Note all of these insects hold their wings either out flat or straight up, but they cannot fold their wings over their back.

caudal filament; male with first pair of legs elongated for clasping female in flight; second and third legs of male, and all legs of female, may be vestigial or absent (Polymitarcyidae); 10-segmented abdomen; immature aquatic naiads with paired articulated lateral gills, caudal filaments, and well-developed mouthparts; adults preceded by winged subimago stage. The mayfly subimago (subadult) is the only winged insect known to undergo an additional molt. It is the one exception to the rule that an insect with wings is a mature adult insect and will never undergo another molt.

Mayflies are primitive winged insects in which the aquatic naiad stage dominates the life cycle. Larvae hatch in fresh water and become long-lived nymphs, passing through many instars. Mayfly nymphs are important food for many stream and lake fishes. Adults eclose in synchrony and live only a few hours or days (hence the name "ephemeral winged"), do not feed, and copulate in the air, sometimes in large nuptial swarms.

Order Odonata Approximately 6,000 described species (Figure 22.3B,C). Adults with small filiform antennae, large compound eyes, and chewing mouthparts with massive mandibles; larval labium modified into prehensile organ; adult with 2 pairs of large wings, held outstretched (dragonflies) or straight up over body (damselflies) when at rest; 10-segmented abdomen slender and elongate; male with accessory genitalia on second and third abdominal sternites; eggs and larvae aquatic, with caudal or rectal gills.

Dragonflies and damselflies are spectacular insects with broad public appeal, not only for their beauty but because they are fast, strong flyers and consume large numbers of insect pests, including mosquitoes. Naiads and adults are both highly active predators, with larvae consuming various invertebrates or small vertebrates, and adults capturing other flying insects. Many species are 7–8 cm long, while some extinct forms had a wingspan of over 70 cm.

Infraclass Neoptera

The modern, wing-folding insects. Modifications of the sclerites and an associated muscle at the base of the wings allow neopterans to rotate their wing joint and fold back their wings when they are not flying. This is one of the most important evolutionary innovations in hexapods. Wing folding allows insects to protect their fragile wings, especially from abrasion, thereby allowing them to live in tight spaces such as crevices under bark, under rocks, and in burrows, nests, and tunnels.

Superorder Polyneoptera

Polyneopterans are a morphologically diverse group of insects with biting-chewing mouthparts and hemimetabolous development (although Plecoptera have aquatic young called naiads). The phylogenetic relationships among the orders within Polyneoptera and the monophyly of the group itself have long been controversial. However, recent phylogenomic work based upon 1,478 single-copy nuclear genes recovered strong support that the 10 polyneopteran orders form a monophyletic group (Misof et al. 2014).

Order Plecoptera Approximately 1,700 described species (Figure 22.4A). Adults with reduced mouthparts, elongate antennae, (usually) long articulated cerci, soft bodies, and a 10-segmented abdomen; without ovipositor; wings membranous, pleated, folded over and around abdomen when at rest; wings with primitive venation; nymphs aquatic (naiads), with gills.

Stonefly naiads live in well-oxygenated lakes and streams where they are either herbivores, feeding on submerged leaves and benthic algae, or predators of other aquatic arthropods. They are an important food resource for fish. Plecopteran nymphs are intolerant of water pollution, and their presence is often used as a bioindicator of high water quality. Adults of most species are short-lived and die soon after mating.

Order Blattodea Approximately 7,000 described species (Figure 22.4B,C). Two major body forms: cockroaches and termites, the latter previously classified as Isoptera. Cockroaches have a dorsoventrally flattened body; large pronotum, with expanded margins extending over the head; forewings (when present) leathery; hindwings expansive and fanlike; ovipositor reduced; cerci multiarticulate; legs adapted for running; eggs laid in cases (ootheca). Termites are small, soft-bodied, eusocial species characterized by wings that are equal in size, elongate, membranous, and dehiscent (shed by breaking at basal line of weakness); antennae short, filamentous, with 11–33 articles; cerci small to minute; ovipositor reduced or absent; many with rudimentary or no external genitalia; marked polymorphism.

Of the 4,000 described species of cockroaches, fewer than 40 are domestic (household inhabitants). Some species are omnivores, while others are restricted in diet. Most species are tropical, but some live in temperate habitats, caves, deserts, and ant and bird nests. Some live in and feed on wood and have intestinal flora that aid in cellulose digestion (*Cryptocercus*). These wood-feeding cockroaches share a most recent common ancestor with the termites (infraorder Isoptera), a strictly social group of insects, usually with three distinct types of individuals, or castes, in a species: workers, soldiers, and alates (reproductive individuals). Workers are generally sterile, blind individuals with normal mandibles; they are responsible for foraging, nest construction, and caring for members of the other castes. Soldiers are blind, usually sterile, wingless forms with powerful enlarged mandibles used to defend the colony. Alates have wings and

(C) Termites (order Blattodea, infraorder Isoptera). (D) A mantid (order Mantodea). (E) A stick insect (order Phasmida). (F) A rock crawler (order Grylloblattodea). (G) Earwigs (order Dermaptera). (H) A horse lubber grasshopper (order Orthoptera). (I) A heel-walker (order Mantophasmatodea), inset SEM of the tarsus of a heel-walker showing enlarged arolium. (J) A webspinner (order Embioptera). (K) A zorapteran (order Zoraptera).

fully formed compound eyes. They are produced in large numbers at certain times of the year, whereupon they emerge from the colony in swarms. Mating occurs at this time, and individual pairs start new colonies. Wings are shed after copulation. Colonies form nests (termitaria) in wood that is in or on the ground. Workers harbor a variety of symbiotic cellulose-digesting flagellate protists in special chambers in the hindgut. Some families contain symbiotic bacteria that serve the same purpose. Termites often occur in enormous numbers; one spectacular estimate suggests that there are about three-quarters of a ton of termites for every person on Earth!

There is strong morphological and molecular evidence that order Blattodea is the sister group of the order Mantodea. Together these two groups are referred to as the Dictyoptera.

Order Mantodea Approximately 2,400 described species (Figure 22.4D). First pair of legs large and raptorial; prothorax elongate; head highly mobile due to cervical sclerites that lend structural and musculature support, with very large compound eyes, not covered by the pronotum; forewings thickened, hindwings membranous; 11-segmented abdomen, 10 visible segments and the fragmented epiproct (which is made up of a median and 2 lateral components); reduced ovipositor made up of 3 valvular structures; male genitalia made up of 3 phallomeric lobes; 1 pair of multiarticulate cerci; styli sometimes present in males.

Mantises are obligate predators, mostly on insects and spiders. While many species are highly cryptic in both color and structural morphology, some species feature brightly colored patches on the anteroventral surface of their forecoxae to use in threat displays or courtship displays. They have very good eyesight, which they use to locate and track prey before striking with their raptorial forelegs, using either an ambush or cursorial hunting strategy. Females lay many eggs together in an ootheca, a protective matrix of hardened foam, which is characteristic of this order. Mantises are distributed around the world, with their greatest diversity in the Indo-Malaysian, tropical African, and Neotropical regions.

Order Phasmida Approximately 3,000 described species (Figure 22.4E). Body cylindrical or markedly flattened dorsoventrally, usually elongate; biting-chewing mouthparts; prothorax short, with specialized glands for the excretion of noxious chemicals when disturbed; meso- and metathorax greatly elongate; forewings absent, or forming small to moderately elongate, leathery tegmina; hindwings absent, reduced to leathery tegmina, or fanlike; tarsomeres with ventral adhesive pads (euplantulae); short, unsegmented cerci; male with vomer—a specialized sclerite on venter of abdominal segment 10; ovipositor of female weak.

Stick and leaf insects ("walking sticks") and other phasmids are large, tropical, predominantly nocturnal herbivores and are some of the most spectacular and oddest of all the insects. Although resembling orthopterans in basic form, they are clearly a distinct radiation. Their ability to mimic plant parts is legendary, and many have evolved as perfect mimics of twigs, leaves, bark, broken branches, moss, or lichens. Stick and leaf insects are the only hexapods that can regenerate lost limbs while still immature (e.g., due to predation), as their crustacean ancestors could; regeneration occurs during molts, with the new legs markedly smaller than original limbs but increasing in relative size with each successive molt (as in Crustacea). Phasmids are the only insect order with species-specific egg morphology across the entire order. The eggs of some species even mimic angiosperm seeds and are spread via ant-mediated dispersal. The order includes the longest insects still extant, including the world's longest at just over 56 cm, though some are less than 4 cm. Sexual dimorphism is so striking that males and females have often mistakenly been given different species names. Phasmids are facultatively parthenogenetic; in the absence of males, females can produce viable eggs that are genetic clones of their mother, and this is why some species now thrive in the pet industry.

Order Grylloblattodea Approximately 33 species (Figure 22.4F). Slender, elongate, cylindrical, wingless insects, usually 15–30 mm long. Body usually pale or golden and finely pubescent; compound eyes small or absent; no ocelli; mouthparts mandibulate; antennae long and filiform, of 23–45 antennomeres, cerci long, 8-segmented; terminal sword-shaped ovipositor of similar length as cerci.

Rock crawlers were not discovered until 1914, and today 33 species are known, roughly half of which are from North America. They inhabit cold, rocky habitats, including snow fields below glaciers and ice caves. Most species cannot tolerate warm temperatures but thrive at below freezing temperatures. Due to the cold temperature at which they live, growth and development are very slow. Rock crawlers may require up to 7 years to complete a single generation. They are nocturnal scavengers on dead insects and other organic matter.

Order Dermaptera Approximately 1,800 described species (Figure 22.4G). Cerci usually form heavily sclerotized posterior forceps; forewings (when present) form short, leathery tegmina, without veins and serving as covers for the semicircular, membranous hindwings (when present); ovipositor reduced or absent.

Earwigs are common in urban environments. Most appear to be nocturnal scavenging omnivores. The forceps are used in predation, for defense, to hold a mate during courtship, for grooming the body, and for folding the hindwings under leathery forewings. Some species eject a foul-smelling liquid from abdominal glands when disturbed. Most species are tropical, although many also inhabit temperate regions.

Order Orthoptera Approximately 23,000 described species (Figure 22.4H). Pronotum unusually large, extending posteriorly over mesonotum; forewings with thickened and leathery region (tegmina), occasionally modified for stridulation or camouflage; hindwings membranous, fanlike; hindlegs often large, adapted for jumping; auditory tympana present on forelegs and abdomen; tarsomeres with ventral adhesive pads (euplantulae); ovipositor large; male genitalia complex; cerci distinct, short, and jointed.

Grasshoppers, crickets, and their kin are common and abundant insects at all but the coldest latitudes. This order includes some of the largest living insects.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Most are herbivores, but many are omnivorous, and some are predatory. Stridulation, which is common among males, is usually accomplished by rubbing the specially modified forewings (tegmina) together or by rubbing a ridge on the inside of the hind femur against a special vein of the tegmen. No orthopterans stridulate by rubbing the hindlegs together, as is often thought. Common families include Acrididae (short-horned grasshoppers), Gryllotalpidae (mole crickets), Tetrigidae (pygmy grasshoppers), Gryllidae (crickets), Tettigoniidae (long-horned grasshoppers, katydids).

Order Mantophasmatodea Approximately 21 species (Figure 22.4I). Head hypognathous, with generalized mouthparts; antennae long, filiform; ocelli absent; wings entirely lacking; coxae elongate; tarsi with 5 tarsomeres, pretarsus of all legs with an unusually large arolium; cerci short, with 1 segment.

The Mantophasmatodea is the most recently described order of insects (2002) and the only new insect order described since 1914. The order includes several living species (from Namibia, South Africa, Tanzania, and Malawi) and six fossil species (five from Baltic amber and one fossil from China). They resemble a mix between praying mantises and phasmids, but molecular evidence indicates that they are most closely related to the Grylloblattodea.

Mantophasmatodeans have several distinct characteristics, including a hypognathous head, and most strikingly, when walking, all species keep the fifth tarsomere and pretarsus (a greatly enlarged arolium plus two tarsal claws) of each leg turned upwards and off the substrate, giving them the appearance of "walking on their heels." Both sexes are wingless. They are highly flexible along their longitudinal body axis, enabling them to clean their external genitalia with their mouthparts. During the day they hide in bushes, rock crevices, or clumps of grass and prey on spiders and insects at night. Males and females produce percussive signals by tapping their abdomens on the substrate to locate mates.

Order Embioptera (Embiidina) Approximately 430 described species (Figure 22.4J). Males somewhat flattened; females and young cylindrical. Most about 10 mm long; however, Southeast Asian species in the genus *Ptilocerembia* are approximately 20 mm long. Antennae filiform; ocelli lacking; chewing mouthparts; head prognathous; legs short and stout; 3-articulate tarsi; hind femora greatly enlarged. The basal article of the front tarsus is enlarged and contains glands that produce silk, which is spun from a dense field of hollow hairlike structures on the ventral surface. Males of most species are winged, but some are wingless; females and nymphs are always wingless. Abdomen has 10 segments, with rudiments of the eleventh segment, and a pair of short cerci.

Webspinners are small, slender, chiefly tropical insects. They live gregariously in silken galleries that they construct in leaf litter, under or on stones, in soil cracks, in bark crevices, and in epiphytic plants. Wings are made rigid for flight and flexible in galleries by regulation of the hemocoelic fluid pressure in the radial blood sinuses in both pairs of wings. They feed mostly on dead plant material and also graze on the outer bark of trees and on mosses and lichens.

Order Zoraptera Approximately 40 species (Figure 22.4K). Minute (to 3 mm); similar to termites; colonial; wingless or with wings; wings eventually shed; 9-articulate antennae moniliform; 10-segmented abdomen short, oval; chewing mouthparts; simple hemimetabolous development. These uncommon insects are usually found in gregarious colonies in dead wood, but they do not have a division of labor or polymorphism (as in termites and ants). They feed chiefly on mites and other small arthropods. All extant species are classified in the single genus *Zorotypus*. The sister-group relationship of this order remains controversial and elusive.

Superorder Acercaria

The superorder Acercaria is sometimes referred to as the Paraneoptera or the "hemipteroids." These insects are characterized by (usually) short antennae, enlarged cibarial (feeding) muscles, visible externally as an enlarged portion of the head; lacinia slender and elongate; sucking mouthparts, tarsi with 3 or fewer tarsomeres, absence of abdominal cerci, lack of true male gonopods, wings (when present) with reduced venation, and hemimetabolous development (although life cycles in several groups includes 1 or 2 inactive pupalike stages).

Order Thysanoptera Approximately 5,000 described species (Figure 22.5D). Slender, minute (0.5–1.5 mm) insects with long, narrow wings (when present) bearing long marginal setal fringes; mouthparts form a conical, asymmetrical sucking beak; left mandible a stylet, right mandible vestigial; with compound eyes; antennae with 4–10 flagellomeres; 10-segmented abdomen; without cerci; tarsi with 1–2 segments, with a pretarsal eversible adhesive sac, or arolium. Thrips are mostly herbivores or predators, and many pollinate flowers. They are known to transmit plant viruses and fungal spores. "Thrips" is both singular and plural.

Order Hemiptera Approximately 85,000 species (Figure 22.5A,B). Piercing-sucking mouthparts form an articulated beak, styletlike mandibles and first maxillae lying in dorsally grooved labium; forewings either completely membranous or hardened basally and membranous only distally; hindwings membranous; pronotum large.

Hemipterans occur worldwide and in virtually all habitats. Hemipterans are liquid feeders. Most feed on the xylem or phloem of plants, although many feed on the hemolymph of arthropods or blood of vertebrates, and some are specialized ectoparasites. They are of considerable economic importance because many are serious crop pests. Members of one subfamily of Reduviidae (Triatominae, the assassin or kissing bugs) transmit Chagas' disease. Others have more positive economic importance to humans, such as the cochineal bugs (Dactylopiidae), from which a safe red dye (cochineal) is extracted for use in the food industry. Shellac is made from lac, a chemical produced by members of the family Kerriidae (lac insects). Two of the most famous hemipterans are the periodical 13-year and 17-year cicadas of eastern North America (genus *Magicicada*), which have a very long life cycle and synchronized development and can reach plaguelike levels of abundance (to 3.7 million individuals per hectare). Common predacious hemipteran families include Nepidae (water scorpions), Belostomatidae (giant water bugs or "toe biters"), Corixidae (water boatmen), Notonectidae (backswimmers), Gerridae (water striders), Saldidae (shore bugs), Cimicidae (bedbugs), and Reduviidae (assassin bugs).

Many others are plant feeders (hence the common name "plant bugs"). Heavy infestations of these insects on plants may cause wilting, stunting, or even death, and some are vectors of important plant diseases. Common herbivorous families include the Cicadidae (cicadas), Cicadellidae (leafhoppers), Fulgoridae (planthoppers), Membracidae (treehoppers), Cercopidae (spittle bugs and froghoppers), Aleyrodidae (whiteflies), and Aphididae (aphids), as well as members of the large superfamily Coccoidea (coccoids, scale insects, mealybugs, and many others).

Order Psocodea Approximately 8,500 described species (Figure 22.5C). Until recently, species in this order were classified in 2 separate orders: the Psocoptera (the book and bark lice) and the Phthiraptera (the true lice). Psocopterans are small (1–10 mm long), with long, filiform, multiarticulate antennae; short prothorax; meso- and metathorax often fused; chewing mouthparts; 9-segmented abdomen; without cerci. Phthirapterans are even smaller (less than 5 mm), wingless, blood-sucking, obligate ectoparasites of birds and mammals; thoracic segments completely fused; cuticle largely membranous and expandable to permit engorgement; compound eyes absent or of 1–2 ommatidia; ocelli absent; piercing-sucking mouthparts retractable into a buccal pouch; antennae short (5 or fewer flagellomeres), exposed or concealed in grooves beneath the head; with 1 pair dorsal thoracic spiracles and 6 or fewer abdominal spiracles; without cerci; females lack ovipositor.

Psocids—the book and bark lice—generally feed on algae and fungi and occur in suitably moist areas (e.g., under bark, in leaf litter, under stones, in human habitations where humid climates prevail). They are often pests that get into various stored food products or consume insect and plant collections; some species live in books and eat the bindings. Commonly called sucking

for more ebook/ testbank/ solution manual requests: email 960126734@qq.com

lice ("Anoplura") and biting lice ("Mallophaga"), phthirapterans spend their entire life on one host. A number of phthirapteran species are specialized to feed on the feathers and skin of birds (feather-feeding insects of uncertain taxonomic affinity have been described in association with dinosaur feathers from mid-Cretaceous Burmese amber). Eggs (nits) are usually attached to the hair or feathers of the host, although the human body louse (a "sucking louse") may attach eggs to clothing. No biting lice are known to infest humans. Posthatching development comprises three "nymphal" instars. Some species that infest domestic birds and mammals are of economic significance.

Superorder Holometabola

Holometabola is a monophyletic group strongly supported by both morphological and molecular data. One of its key apomorphies is holometabolous development, with distinct egg, larval, pupal, and adult states. During the pupal stage, most tissues undergo a complete reorganization (e.g., larval eyes [stemmata] disintegrate, and adult compound eyes and ocelli form de novo). Another key apomorphy is the presence of internal wing buds (imaginal discs) in the larval stage; these clusters of early embryonic cells arise from localized invaginations of the ectoderm in the early embryo and form adult structures during pupation. Holometabola contains the 4 most diverse orders of insects (Hymenoptera, Coleoptera, Diptera, and Lepidoptera), and thus this type of development is considered by many as a key innovation in insect evolution, perhaps even more important than the origin of flight.

Order Hymenoptera Approximately 115,000 described species (Figure 22.6A). Mouthparts often elongate and modified for ingesting floral nectar, although mandibles usually remain functional; labium often (bees) distally expanded as paired lobelike structures called glossae and paraglossae; 3 ocelli; usually with 2 pairs of membranous wings; hindwings small, coupled to forewings by hooks (hamuli); wing venation highly reduced; antennae well developed, of various forms and with 3–70 flagellomeres, reduced metathorax usually fused to first abdominal segment; males with complex genitalia; females with ovipositor (in most), modified for sawing, piercing, or stinging.

The earliest fossil Hymenoptera date from the Upper Triassic (220–207 Ma). Ants, bees, wasps, sawflies, and their relatives are all active insects with a tendency to form polymorphic social communities. Two suborders are generally recognized. Suborder Symphyta contains the primitive, wasplike, "thick-waisted" hymenopterans (sawflies, horntails, and their kin). They rarely show conspicuous sexual dimorphism and are always fully winged. The first and second abdominal segments are broadly joined. Larvae are mostly caterpillar-like, with a well-developed head capsule, true legs, and often also with abdominal prolegs. The suborder Apocrita contains the "narrow-waisted" hymenopterans (true wasps, bees, and ants), in which the first and second abdominal segments are joined by a distinct and often elongate constriction. Adults tend to be strongly social and display marked polymorphism. Social communities often include distinct castes of queens, haploid males, parthenogenetic females, and individuals with other sex-related specializations, as well as nonreproducing worker and soldier forms. Common families of Hymenoptera include the Apidae (bumblebees and honeybees), Formicidae (ants), Vespidae (yellow jackets, hornets, paper wasps, and potter wasps), Halictidae (sweat bees), Sphecidae (sand wasps, digger wasps, and mud daubers), and three large groups of parasitic wasps (Ichneumonidae, Braconidae, Chalcidoidea). One of the major trends in the evolution of parasitoid wasps is miniaturization, which has produced the smallest known insects, species of *Megaphragma* (family Trichogrammatidae), some of which are smaller than some unicellular organisms with an adult body length of just 170 µm.

Coleopterida

The Coleopterida includes 2 orders: the Coleoptera (beetles) and the Strepsiptera (twisted-wing parasites). This clade includes the most diverse order of insects (Coleoptera) and an order with the most highly modified and morphologically and developmentally aberrant groups of parasites (Strepsiptera). Largely due to their bizarre combination of morphological characters and the high rate of molecular evolution in many strepsipteran genes, the sister-group relationship of the Strepsiptera eluded researchers until very recently. In the past, Strepsiptera were considered at various times to be close relatives of either Hymenoptera, Diptera, or Coleoptera. Recent genome-wide analyses and new morphological evidence strongly suggest that they are in fact the sister group to the Coleoptera.

Order Coleoptera Approximately 387,100 described species (Figure 22.6B). Body usually heavily sclerotized; forewings sclerotized and modified as rigid covers (elytra) over hindwings and body; membranous hindwings fold both transversely and longitudinally and are often reduced or absent; biting-chewing mouthparts; antennae usually with 8–11 flagellomeres; prothorax large and mobile; mesothorax reduced; abdomen typically of 5 (or up to 8) segments; without ovipositor; male genitalia retractable.

Coleoptera is the largest order of insects. Many hypotheses have been proposed to explain the extraordinary diversity of beetles: (1) The oldest fossils date to the early Permian, but they most probably arose in the late Carboniferous (300 Ma). (2) Their

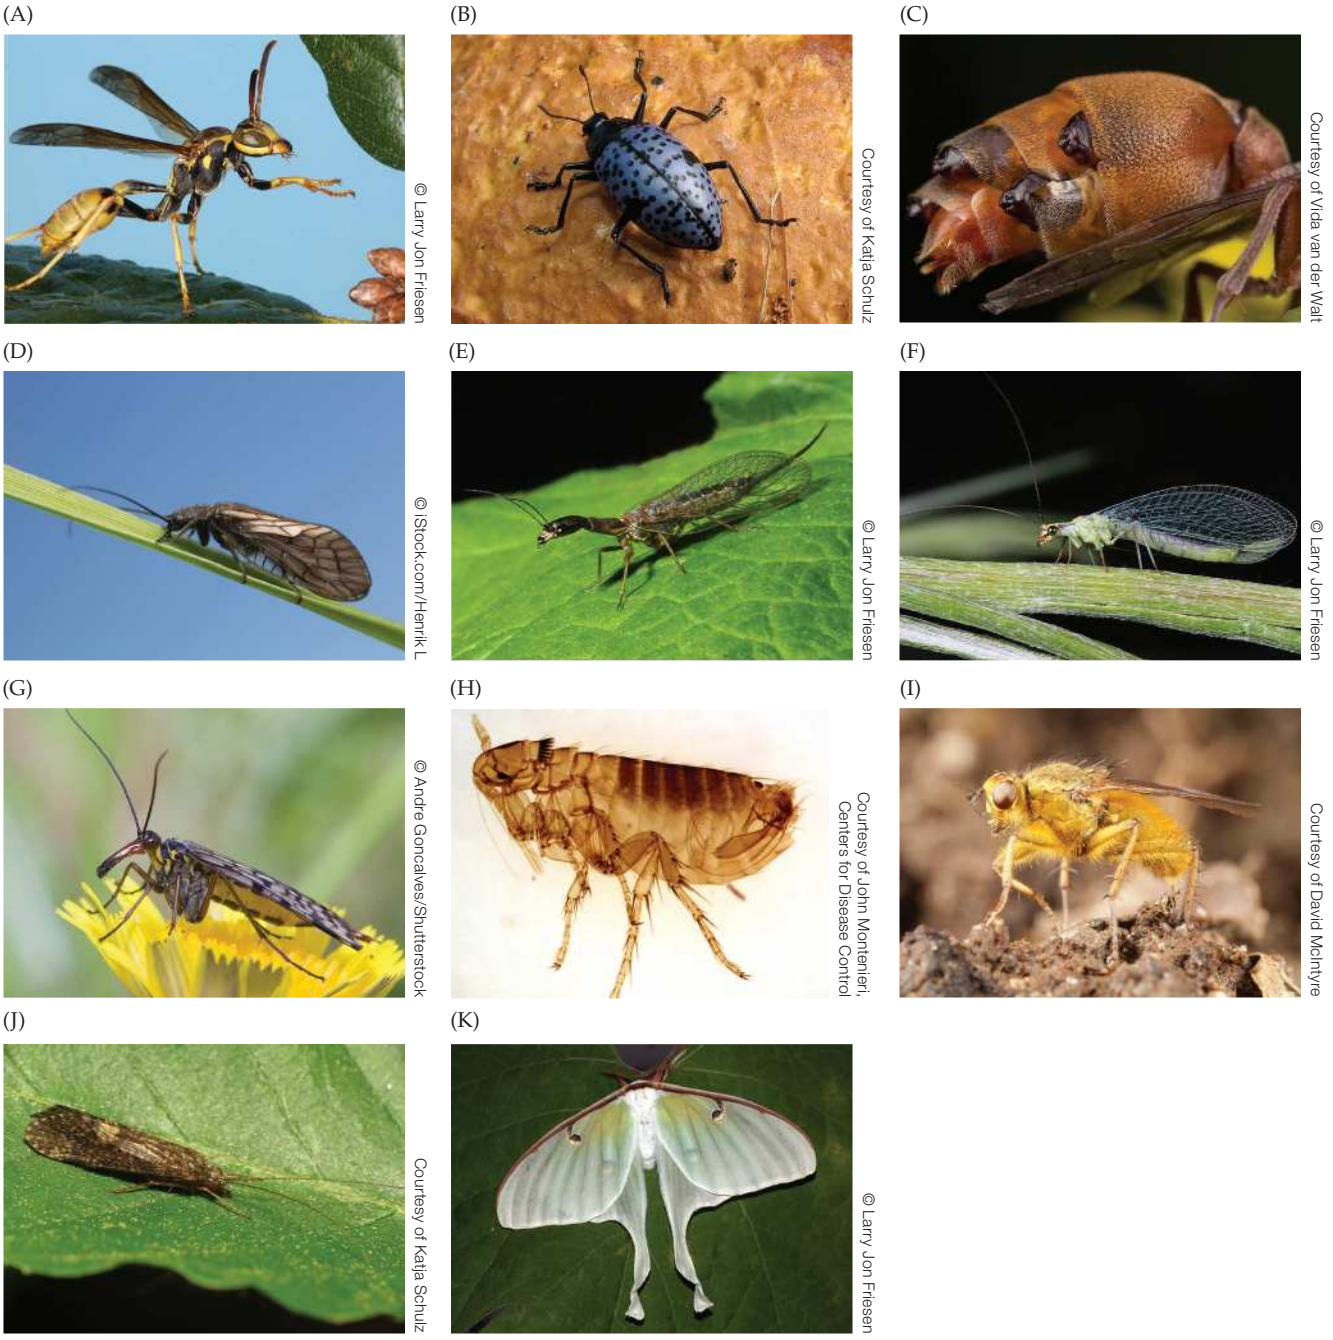

FIGURE 22.6 Representatives of the 11 orders of Holometabola. (A) A paper wasp (order Hymenoptera). (B) A pleasing fungus beetle, *Gibbifer californicus* (order Coleoptera). (C) Female twisted-wing parasites (order Strepsiptera) visible between the abdominal sclerites of a wasp (order Hymenoptera). (D) An alderfly (order Megaloptera). heavily sclerotized bodies, including their protective elytra, and general lack of exposed membranous surfaces facilitated their adaptation to a wide variety of tight narrow spaces and reduced their risk of predation and desiccation. (3) They co-evolved with the great angiosperm radiation in the Cretaceous Period. Today, beetles range from minute (0.30 mm, *Nanosella fungi*) to very large (20 cm, *Titanus giganteus*) and occur in all the world's environments (except the open sea). Some of the world's strongest animals are beetles: rhinoceros beetles can carry up to 100 times their own weight for short distances, and 30 times their weight indefinitely (equivalent to a 150-pound man walking with a Cadillac on his head—without tiring). Humans have had a long fascination with beetles, and beetle worship can be traced back to at

for more ebook/ testbank/ solution manual requests: email 9601267346@qq.com

least 2500 BCE. (The venerated scarab of early Egyptians was actually a dung beetle.)

Some common coleopteran families include Carabidae (ground beetles), Dytiscidae (predaceous diving beetles), Gyrinidae (whirligig beetles), Hydrophilidae (water scavenger beetles), Staphylinidae (rove beetles), Cantharidae (soldier beetles), Lampyridae (fireflies and lightning bugs), Phengodidae (glowworm beetles), Elateridae (click beetles), Buprestidae (metallic wood-boring beetles), Coccinellidae (ladybugs or ladybird beetles), Meloidae (blister beetles), Tenebrionidae (darkling beetles), Scarabaeidae (scarab beetles, dung beetles, June "bugs"), Cerambycidae (long-horned beetles), Chrysomelidae (leaf beetles), Curculionidae (weevils), Brentidae (primitive weevils), and Ptiliidae (feather-winged beetles, the smallest of all free-living insects, some with body lengths of just 300 µm).

Order Strepsiptera Approximately 600 described species (Figure 22.6C). Extreme sexual dimorphism; males free-living and winged; females wingless, usually parasitic. Females of free-living species with distinct head, simple antennae, chewing mouthparts, and compound eyes. Females of parasitic species neotenous, larviform, usually without eyes, antennae, and legs; with indistinct body segmentation. Male antennae often with elongate processes on flagellomeres; forewings reduced to clublike structures resembling halteres of Diptera; hindwings large and membranous, with reduced venation; raspberry-like eyes.

Most of these minute insects are parasitic on other insects. Adult females of parasitic species are larviform and most commonly live between the abdominal sclerites of flying insects that pollinate flowers, such as bees and wasps. The winged male finds the female on the bee or wasp abdomen and mates with her there. The fertilized eggs hatch into first-instar larvae inside their mother's body. These larvae, called triungulins, have well-developed eyes and legs, and they actively crawl out of their mother to invade the soil and vegetation. The triungulins eventually locate a new host insect and enter it, wherein they molt into a legless wormlike larval stage that feeds in the host's body cavity. Pupation also takes place within the host's body, where the females remain for the rest of their lives; the free-living males emerge as fully formed flying adults.

Neuropterida

The three orders of Neuropterida have always been considered close relatives. Some workers subsume the Megaloptera and Raphidioptera within the Neuroptera, but all 3 groups are monophyletic, making such a taxonomic decision arbitrary. These 3 orders have 2 pairs of membranous wings with many cross veins, 5-segmented tarsi, adults with mandibles, and decticous pupae (with articulated mandibles).

Order Megaloptera Approximately 300 described species (Figure 22.6D). Ocelli present or absent; larvae aquatic, with lateral abdominal gills. Megalopterans (alderflies, dobsonflies, fishflies) strongly resemble neuropterans (and are often regarded as a suborder), but their hindwings are broader at the base than the forewings, and the longitudinal veins do not have branches near the wing margin. Larvae of some megalopterans (hellgrammites) are commonly used as fish bait.

Order Raphidioptera Approximately 260 described species (Figure 22.6E). Snakeflies strongly resemble neuropterans (and are often regarded as a suborder) but are unique in having the prothorax elongate (as in the mantises), but the forelegs are similar to the other legs. The head can be raised above the rest of the body, as in a snake preparing to strike. Adults and larvae are predators on small insects.

Order Neuroptera Approximately 6,000 described species (Figure 22.6F). Adults soft-bodied; with 2 pairs of similar, highly veined wings held tentlike over the abdomen when at rest; with biting-chewing mouthparts; 10-segmented abdomen; without cerci; larvae with mandibles and maxillae co-adapted to create a sucking tube; mouth closed off by modified labrum and labium; well-developed legs; larval midgut is closed off posteriorly (larval waste accumulates until the adult emerges); Malpighian tubules secrete silk, via the anus, to construct the pupal cocoon.

The lacewings, ant lions, mantisflies, spongillaflies, and owlflies form a complex group, the adults of which are often important predators of insect pests (e.g., aphids). The larvae of many species have piercing-sucking mouthparts, and those of other species are predaceous and have biting mouthparts. The pupae are often unusual in possessing free appendages and functional mandibles used for defense; they may actively walk about prior to the adult molt, but they do not feed. Common families include Chrysopidae (green lacewings), Myrmeleontidae (ant lions), Ascalaphidae (owlflies), and Mantispidae (mantidflies).

Antliophora

The Antliophora include 3 orders: the Mecoptera, Siphonaptera, and Diptera. There is strong molecular and morphological support for the monophyly of this group. The males of all members of Antliophora have a sperm pump, a structure that aids in sperm transfer during copulation. Many other characters also define this grouping, most of which have to do with relatively subtle aspects of the adult mouthparts.

Order Mecoptera Approximately 600 described species (Figure 22.6G). Two pairs of similar, narrow,

membranous wings, held horizontally from sides of body when at rest; antennae long, slender, and of many flagellomeres (about half the body length); head with ventral rostrum and reduced biting mouthparts; long, slender legs; mesothorax, metathorax, and first abdominal tergum fused; 11-segmented abdomen; female with 2 cerci; male genitalia prominent and complex, at apex of attenuate abdomen and often resembling a scorpion's stinger. The larvae of some species are remarkable in having compound eyes, a condition unknown among larvae of other insects having complete metamorphosis.

Mecopterans are usually found in moist places, often in forests, where most are diurnal flyers. They are best represented in the Holarctic region. Some feed on nectar; others prey on insects or are scavengers. There are several families, including Panorpidae (scorpionflies), Bittacidae (hangingflies), Boreidae (snow scorpionflies), and the enigmatic Nannochoristidae.

Order Siphonaptera Approximately 2,700 described species (Figure 22.6H). Small (less than 3 mm long); wingless; body laterally compressed and heavily sclerotized; short antennae lie in deep grooves on sides of head; piercing-sucking mouthparts; compound eyes often absent; legs modified for clinging and (especially hindlegs) jumping; 11-segmented abdomen; abdominal segment 10 with distinct dorsal pincushion-like sensillum, containing a number of sensory organs; without ovipositor; pupal stage passed in a cocoon.

Adult fleas are ectoparasites on mammals and birds, from which they take blood meals. They occur wherever suitable hosts are found, including the Arctic and Antarctic. Larvae usually feed on organic debris in the nest or dwelling place of the host. Host specificity is often weak, particularly among the parasites of mammals, and fleas regularly commute from one host species to another. Fleas act as intermediate hosts and vectors for organisms such as plague bacteria, dog and cat tapeworms, and various nematodes. Commonly encountered species include *Ctenocephalides felis* (cat flea), *C. canis* (dog flea), *Pulex irritans* (domestic flea), and *Oropsylla montanus* (western squirrel flea).

Siphonaptera has long been considered closely related to Mecoptera, and while the monophyly of Siphonaptera is not questioned, there is controversy about whether or not Siphonaptera arose from *within* Mecoptera, which would render Mecoptera paraphyletic. A recent study based on transcriptomic data concludes this is the case and that Siphonaptera is the sister group of the mecopteran family Nannochoristidae (Tihelka et al. 2020), while similar studies find less clear evidence for this relationship, depending upon whether the data are analyzed at the nucleotide or amino acid levels (Meusemann et al. 2020). Given the lack of conclusive evidence, we keep Siphonaptera as an order in this text, but note the potential for it to be subsumed under Mecoptera sometime in the future.

Order Diptera Approximately 159,295 described species (Figure 22.6I). Adults with one pair of membranous mesothoracic forewings and a metathoracic pair of clublike halteres (organs of balance); head large and mobile; compound eyes, large sometimes stalked; antennae primitively filiform, with 7–16 flagellomeres and often secondarily annulated (reduced to only a few articles in some groups); mouthparts adapted for sponging, sucking, or lapping; mandibles of blood-sucking females developed as piercing stylets; hypopharynx, laciniae, galeae, and mandibles variously modified as stylets in parasitic and predatory groups; labium forms a proboscis ("tongue"), consisting of distinct basal and distal portions, the latter in higher families forming a spongelike pad (labellum) with absorptive canals; mesothorax greatly enlarged; abdomen primitively 11-segmented, but reduced or fused in many higher forms; male genitalia complex; females without true ovipositor, but many with secondary ovipositor composed of telescoping posterior abdominal segments; larvae lack true legs, although ambulatory structures (prolegs and "pseudopods") occur in many.

The true flies (which include mosquitoes and gnats) are a large and ecologically diverse group, notable for their excellent vision and aeronautic capabilities. The mouthparts and digestive system are modified for a fluid diet, and several groups feed on blood or plant juice. Dipterans are vastly important carriers of human diseases, such as sleeping sickness, yellow fever, African river blindness, and various enteric diseases. It has been said that mosquitoes (and the diseases they carry) prevented Genghis Khan from conquering Russia, killed Alexander the Great, and played pivotal roles in both world wars. Myiasis—the infestation of living tissue by dipteran larvae—is often a problem for livestock and occasionally for humans. Many dipterans are also beneficial to humans as parasites or predators of other insects and as pollinators of flowering plants. Dipterans occur worldwide and in virtually every major environment (except the open sea). Some breed in extreme environments, such as hot springs, saline desert lakes, oil seeps, tundra pools, and even shallow benthic marine habitats.

Some common dipteran families include Asilidae (robber flies), Bombyliidae (bee flies), Calliphoridae (blowflies, bluebottles, greenbottles, screwworm flies, etc.), Chironomidae (midges), Culicidae (mosquitoes: *Culex*, *Anopheles*, etc.), Drosophilidae (pomace or vinegar flies; often also called "fruit flies"), Ephydridae (shore flies and brine flies), Glossinidae (tsetse flies), Muscidae (houseflies, stable flies, etc.), Sarcophagidae (flesh flies), Simuliidae (blackflies and buffalo gnats), Syrphidae (hover flies and flower flies), Tabanidae (horseflies,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

deerflies, and clegs), Tachinidae (tachinid flies), Tephritidae (fruit flies), and Tipulidae (crane flies).

Amphiesmenoptera

The Amphiesmenoptera contains the orders Trichoptera and Lepidoptera. Some characteristics that unite these 2 groups include the presence of hairy wings (with the hairs modified into scales in Lepidoptera), the females as the heterogametic sex, and the larval labium and hypopharynx being fused into a composite lobe with the opening of an associated silk gland at its apex.

Order Trichoptera Approximately 12,000 described species (Figure 22.6J). Adults resemble small moths, but with body and wings covered with short hairs; 2 pairs of wings, tented in oblique vertical plane (rooflike) over abdomen when at rest; compound eyes present; mandibles minute or absent; antennae usually as long or longer than body, setaceous; legs long and slender; larvae and pupae mainly in fresh water, adults terrestrial; larvae with abdominal prolegs on terminal segment.

The freshwater larvae of caddisflies construct fixed or portable "houses" (cases) made of sand grains, wood fragments, or other material bound together by silk emitted through the labium. Larvae are primarily herbivorous scavengers; some use silk to produce food-filtering devices. Most larvae inhabit benthic habitats in temperate streams, ponds, and lakes. Adults are strictly terrestrial and have liquid diets.

Order Lepidoptera Approximately 157,402 described species (Figure 22.6K). Minute to large; sucking mouthparts; mandibles usually vestigial; maxillae coupled, forming a tubular sucking proboscis, coiled between labial palps when not in use; head, body, wings, and legs usually densely scaled; compound eyes well developed; usually with 2 pairs of large and colorfully scaled wings, coupled to one another by various mechanisms; protibia with epiphysis used for cleaning antennae; male genitalia complex; females with ovipositor.

Butterflies and moths are among the best known and most colorful of all the insects. The adults are primarily nectar feeders, and many are important pollinators, some of the best known being the large hawk, or sphinx, moths (Sphingidae). A few tropical species are known to feed on animal blood, and some even drink the tears of mammals. The larvae (caterpillars) feed on green plants, but a few are carnivorous. Caterpillars have three pairs of thoracic legs and a pair of soft prolegs on each of abdominal segments 3–6; the anal segment bears a pair of prolegs or claspers. Butterflies can be distinguished from moths by two features: their antennae are always long and slender, ending in a knob (moth antennae are never knobbed), and their wings are typically held together above the body at rest (moths never hold their wings in this position). Over 80% of the described Lepidoptera are moths.

Other common families include Psychidae (bag worms), Cossidae (carpenter worms), Pyralidae (snout moths), Saturniidae (silk moths), Hesperiidae (skippers), Geometridae (inch worms), Arctiidae (tiger moths), Noctuidae (owlet moths), Papilionidae (swallowtails), Nymphalidae (brush-footed butterflies), Pieridae (whites and sulphurs), Lycaenidae (gossamer-winged butterflies), and Riodinidae (metalmarks).[2]

The Hexapod Body Plan

General Morphology

In Chapter 20 we briefly discussed the various advantages and constraints imposed by the phenomenon of arthropodization, including those associated with the establishment of a terrestrial lifestyle. Departure from the ancestral aquatic environment necessitated the evolution of stronger and more efficient support and locomotory appendages, special adaptations to withstand osmotic and ionic stress, and aerial gas exchange structures. The basic arthropod body plan included many preadaptations to life in a "dry" world. As we have seen, the arthropod exoskeleton inherently provides physical support and protection from predators, and by incorporating waxes into the epicuticle, the insects, like the arachnids, acquired an effective barrier to water loss. Similarly, within the Hexapoda, the highly adaptable, serially arranged arthropod limbs evolved into a variety of specialized locomotory and food-capturing appendages. Reproductive behavior became increasingly complex, and in many cases highly evolved social systems developed. Within the class Insecta, many taxa underwent intimate coevolution with land plants, particularly angiosperms. The adaptive potential of insects is evident in the many species that have evolved striking camouflage, warning coloration, and chemical defense (Figure 22.7).

Non-insect hexapods (proturans, collembolans, and diplurans—the entognathous hexapods) differ from insects in several important ways. The mouthparts are not fully exposed (i.e., they are **entognathous**), the

[2]One of the best-known butterfly taxonomists was the great Russian novelist Vladimir Nabokov (*Lolita*, *Pale Fire*, *The Gift*), who left Saint Petersburg in 1917 to travel around Europe and eventually settled in the United States (first working at the American Museum of Natural History in New York, then at Cornell and Harvard Universities). Nabokov was a specialist on the blue butterflies (Polyommatini) of the New World and a pioneer anatomist, coining such alliterative anatomical terms as "alula" and "bullula." Butterflies, real and imaginary, flit through 60 years of Nabokov's fiction, and many lepidopterists have named butterflies after characters in his life and writings (e.g., species epithets include *lolita*, *humbert*, *ada*, *zembla*, and *vokoban*—a reversal of Nabokov). Nabokov's descriptions of Lolita were patterned after his species descriptions of butterflies (e.g., "her fine downy limbs").

FIGURE 22.7 Defense, warning coloration, and camouflage in insects. (A) A leaf-mimicking katydid (Orthoptera: Tettigoniidae) from Ecuador is perfectly camouflaged. (B) The bright coloration of the silkmoth caterpillar (Lepidoptera: Saturniidae: *Hyalophora euryalus*) warns potential predators of the defensive hairs on its back. (C) A bombardier beetle (Coleoptera: Carabidae: *Brachinus*) sprays noxious benzoquinones in defense while being "attacked" by forceps. (D) Close-up of an "eye spot" on a luna moth (see Figure 22.6K) (Lepidoptera: Saturniidae). Eyespots attract predators away from the moth's head and body and encourage focus on the moth's wings. Since butterflies and moths can fly even with slight wing damage, eyespots are a commonly used defense mechanism. (E) A spittlebug (Hemiptera: Cercopoidea) produces a cover of frothed-up plant sap resembling saliva, which hides the nymph from the view of predators and parasites.

mandibles have a single point of articulation, development is always simple (ametabolous), the abdomen may have a reduced number of segments, and they never developed flight.

Insects are primitively composed of 20 somites (as in the eumalacostracan Crustacea; Chapter 21), although these are not always obvious. The consolidation and specialization of these body segments (i.e., tagmosis) has played a key role in hexapod evolution and has opened the way for further adaptive radiation. The body is always organized into a head, thorax, and abdomen (Figures 22.8 and 22.9), comprising 6, 3, and 11 (or fewer) segments, respectively. In contrast to marine arthropods, a true carapace never develops in hexapods. In the head, all body sclerites are more or less fused as a solid head capsule. In the thorax and abdomen, the adult sclerites usually develop embryologically such that they overlap the primary segment articulations, forming secondary segments, and these are the "segments" we typically see when we examine an insect externally (e.g., the tergum and sternum of each adult abdominal secondary segment actually overlap its adjacent anterior primary segment) (Figure 22.10). The primitive (primary) body segmentation can be seen in unsclerotized larvae by the insertions of the segmental muscles and transverse grooves on the body surface.

Most insects are small, between 0.5 and 3.0 cm in length. The smallest are the thrips, feather-winged beetles, and certain parasitic wasps, which are all nearly microscopic. The largest are certain beetles, orthopterans, and stick insects, the last attaining lengths greater than 56 cm. However, certain Paleozoic species grew to twice that size. To familiarize you with the hexapod body plan and its terminology, we briefly discuss each of the main body regions (tagmata) here.

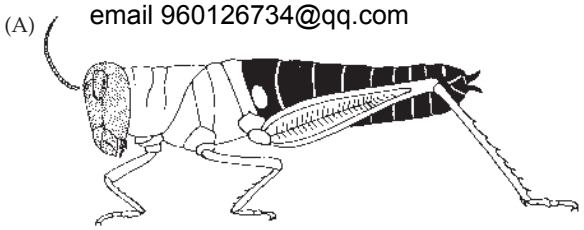

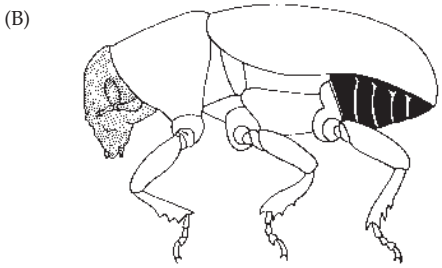

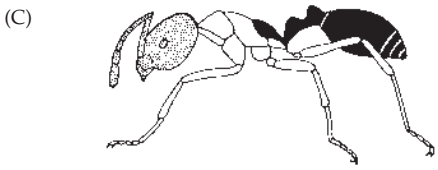

FIGURE 22.8 The principal body regions of hexapods, illustrated by three kinds of insects. (A) A grasshopper (wings removed). (B) A beetle. (C) An ant. In each case, the stippled region is the head; the white region is the thorax; the black region is the abdomen.

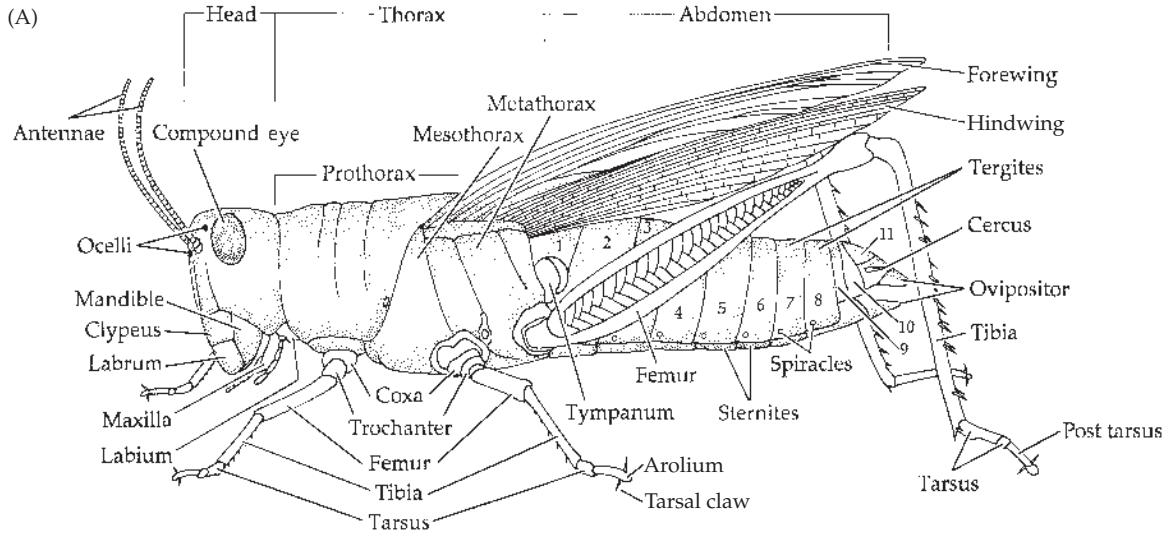
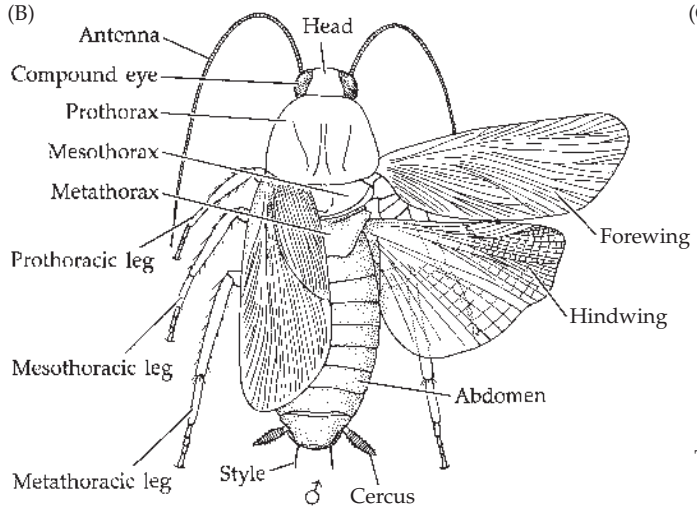
The hexapod head The hexapod head comprises six segments, bearing (from anterior to posterior) the eyes, antennae, clypeolabrum, and three pairs of mouth appendages (mandibles, maxillae, labium) (Figure 22.11). Compound eyes, as well as three **simple eyes** (**ocelli**), are typically present in adult hexapods. The median (anterior) ocellus is thought to have arisen through the fusion of two separate ocelli. The internal manifestation of the fused exoskeleton of the head forms a variety of apodemes, braces, and struts collectively called the **tentorium**. Externally, the head may also bear lines that may demarcate its original segmental divisions, and others that represent the dorsal (and





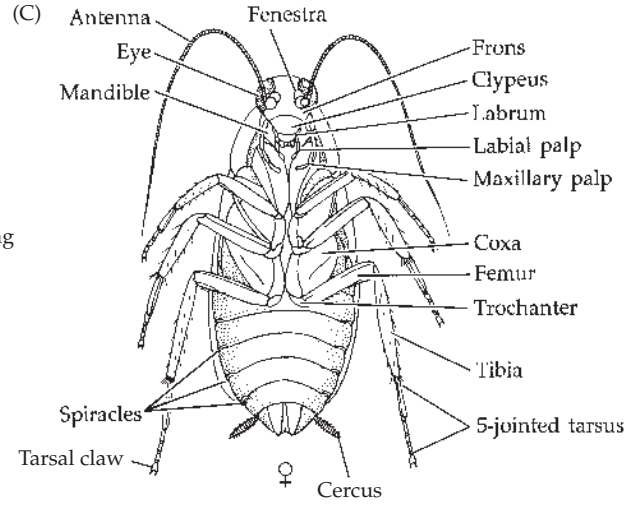


FIGURE 22.9 General body anatomy of insects. (A) A grasshopper (order Orthoptera). (B,C) Dorsal and ventral views of a cockroach (order Blattodea).

ventral) ecdysial lines, where the head capsule splits in immature insects and which persist as unpigmented lines in some adults. Still other lines represent inflections of the surface associated with internal apodemes.

The antennae (Figure 22.12) are composed of three regions: the scape, pedicel, and multijointed sensory flagellum. The **scape** and **pedicel** constitute the **protopod**; the **flagellum** represents the telopod. Among the entognathous insects, muscles intrinsic to the scape, pedicel, and flagellum are retained. But in the class Insecta, the intrinsic muscles of the antennae have been lost except for those in the scape. In addition, in many insects the joints, or **flagellomeres**, of the flagellum may have been secondarily subdivided (or annulated), producing additional unmuscled joints and increasing the length and flexibility of the antenna.

The mouth is bordered anteriorly by the clypeolabrum, posteriorly by the labium, and on the sides by the mandibles and maxillae. In the entognathans, the mouthparts are sunk within the head capsule and largely hidden from view. In contrast, the mouthparts of insects are exposed (**ectognathous**) and ventrally

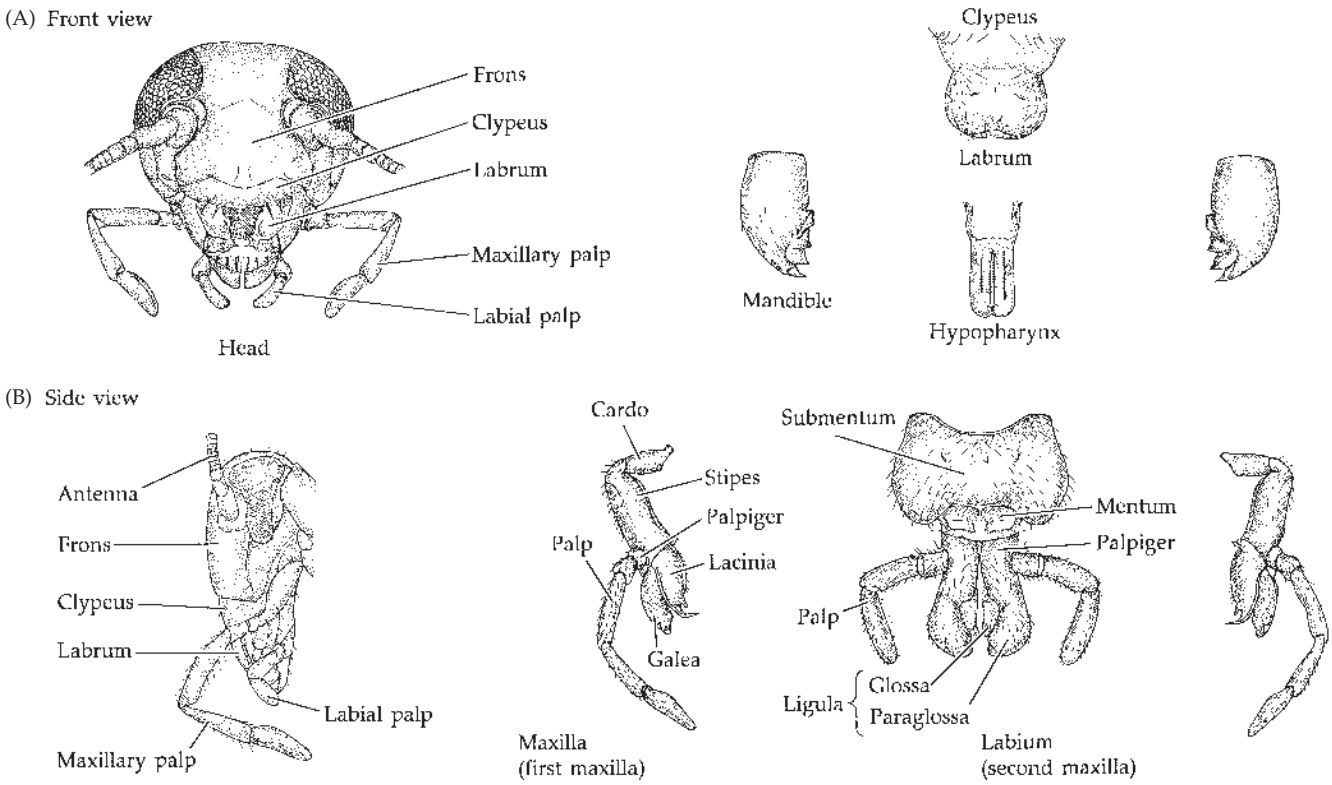

FIGURE 22.11 The mouth appendages of a typical biting-chewing insect: a grasshopper (order Orthoptera). (A) Front view. (B) Side view.

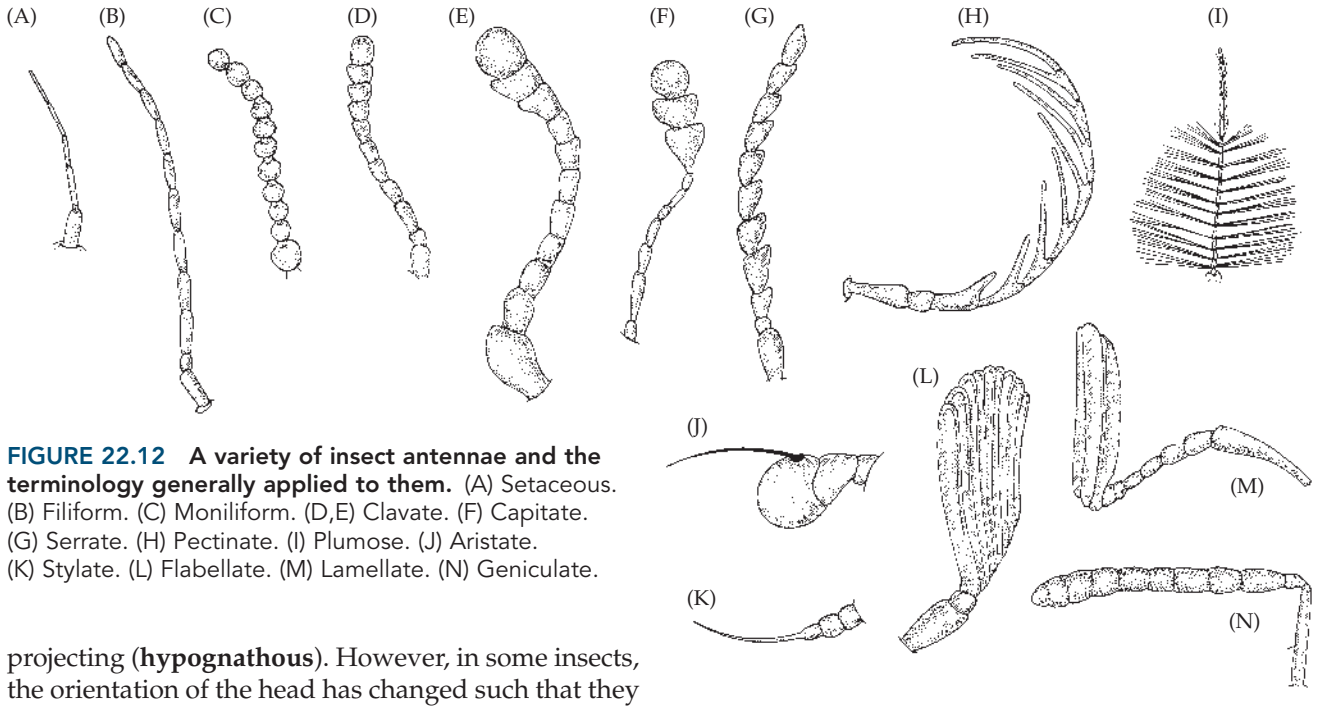

FIGURE 22.12 A variety of insect antennae and the terminology generally applied to them. (A) Setaceous. (B) Filiform. (C) Moniliform. (D,E) Clavate. (F) Capitate. (G) Serrate. (H) Pectinate. (I) Plumose. (J) Aristate. (K) Stylate. (L) Flabellate. (M) Lamellate. (N) Geniculate.

projecting (**hypognathous**). However, in some insects, the orientation of the head has changed such that they are **prognathous** (projecting anteriorly) or **opisthognathous** (projecting posteriorly) (Figure 22.13).

The labrum is a movable plate attached to the margin of the clypeus (a projecting frontal head piece), and together they form the **clypeolabrum**. Some workers regard the clypeolabrum to be an independently derived structure of the exoskeleton; others believe it could be derived from fused head appendages. The mandibles (Figure 22.14) are strongly sclerotized, usually toothed, and they lack a palp. In most insects the mandible is of one article, but in some primitive groups (and fossil taxa) it is composed of several articles. However, the gene *Distal-less* (*Dll*) is apparently never expressed in the embryogeny of hexapodan mandibles, suggesting that they are fully gnathobasic (i.e., protopodal). The maxillae are generally multiarticulate and bear a palp of one to seven articles. The labium comprises the fused second maxillae and typically bears two palps. In addition to these appendages, there is a median, unpaired, tonguelike organ called the hypopharynx that projects forward from the back of the preoral cavity. The salivary glands open through the hypopharynx.[3]

[3]Study of the *Dll* gene reveals that it was probably primitively expressed in the distal parts of all arthropod appendages. It is also expressed in the endites, or inner lobes, of arthropod limbs (e.g., in the phyllopodous limbs of Branchiopoda and in the maxillae of Malacostraca). In crustaceans and myriapods there is an initial *Dll* expression in the mandibular limb buds that is displaced laterally and continues in the mandibular palp in crustaceans. In insects, no *Dll* expression at all is seen in the mandibles—it has apparently been completely lost. Thus, the mandibles of all three groups are gnathobasic. The palp of the crustacean mandible represents the distal portion of the mandibular limb, altogether lost in hexapods and myriapods. The only real "whole-limb jaws" among the panarthropods are those of onychophorans. *Dll* is also expressed in the coxal endites of chelicerates and the pedipalp endites of arachnids. The complete loss of *Dll* expression in hexapod mandibles may be a synapomorphy for the group.

In the past, variations in feeding appendages were often used to define the major insect clades, and more recent molecular phylogenetic work has largely corroborated those ideas, although a number of cases of convergent evolution in mouthparts have also been revealed. In sucking insects both mandibles and maxillae may be transformed into spearlike structures (stylets), or the mandibles may be absent altogether (Figure 22.15 and 22.24). In most Lepidoptera, the maxillae form an elongate coiled sucking tube, the proboscis. In some insects (e.g., Hemiptera), the labium is drawn out into an elongate trough to hold the other mouthparts, and its palps may be absent; in others (e.g., Diptera), the labium is modified distally into a pair of fleshy porous lobes called labellae (sing. labellum).

The hexapod thorax The three segments of the thorax are the **prothorax**, **mesothorax**, and **metathorax** (Figure 22.9). Their tergites carry the same prefixes: **pronotum**, **mesonotum**, **metanotum**. In the winged insects (Pterygota), the mesothorax and metathorax are enlarged and closely united to form a rigid **pterothorax**. Wings, when present, are borne on these two segments and articulate with processes on the tergite (notum) and pleura of the somites. The prothorax is sometimes greatly reduced, but in some insects it is greatly enlarged (e.g., beetles) or even expanded into a large shield (e.g., cockroaches). The lateral, pleural sclerites are complex and thought to be derived, at least in part, from subcoxal (protopodal) elements of the ancestral legs that became incorporated into the lateral body wall. The sternites may be simple, or may be divided into multiple sclerites on each segment.

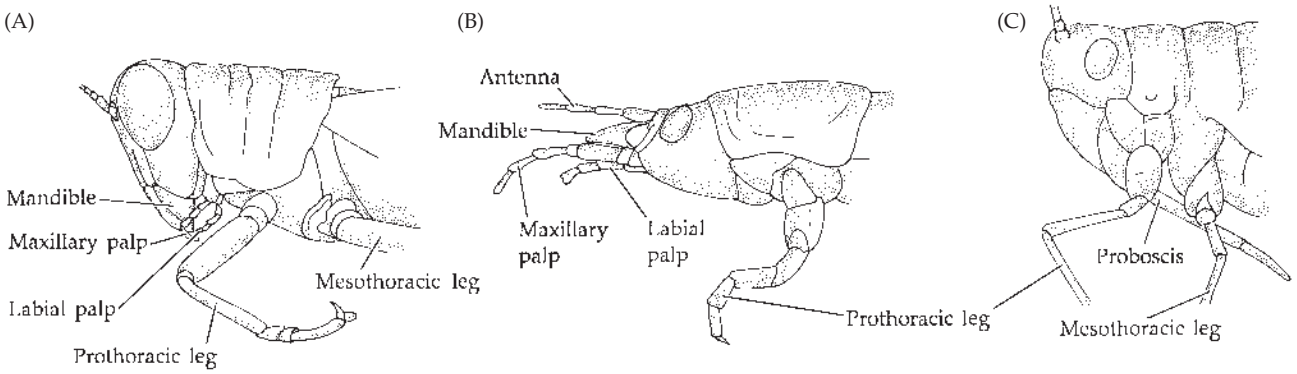

FIGURE 22.13 Different positions of head and mouthparts relative to the rest of the body. (A) Hypognathous condition (grasshopper). (B) Prognathous condition (beetle larva). (C) Opisthorhynchous condition (aphid). (After S. J. Simpson. 2012. In R. F. Chapman [Ed.] *The Insects*, 5th Ed., pp. 1–13. Cambridge University Press, Cambridge.)

Each of the three thoracic somites bears a pair of legs (Figure 22.9), composed of two parts, a proximal protopod and a distal telopod. The protopod (sometimes called a "coxopodite" by entomologists) is composed of two articles (**coxa**, **trochanter**), and the telopod is composed of four articles (**femur, tibia, tarsus, pretarsus**) (Figure 22.16). The tarsus is often subdivided into additional pseudoarticles called tarsomeres. The basal hexapods have a single tarsus (Protura and Diplura) or an indistinct tarsus (Collembola; probably fused with the tibia). In the Archaeognatha the tarsus is usually composed of three tarsomeres, and in the Pterygota it is composed of one, three, or five tarsomeres.[4] Whatever the number of tarsal articles, no intrinsic musculature occurs in them, and they are thus viewed as subdivisions of a single original article. The whole length of the tarsus is crossed by the tendon of the flexor muscle of the pretarsus, whose fibers usually arise on the tibia (Figure 22.17). The pretarsus is a minute article that usually bears a pair of lateral claws. In most adult hexapods, the pretarsus also bears a median **arolium** (which functions as an adhesive pad on smooth surfaces) or a median **unguitractor plate** or a median claw.

In insects, many adult organs derive from clusters of early embryonic cells called **imaginal discs**, which arise from localized invaginations of the ectoderm in the early embryo. The embryonic thorax contains three pairs of leg discs, and as development proceeds, these discs develop a series of concentric rings, which are the presumptive leg articles. The center of the disc corresponds to the distal-most articles (tarsus and pretarsus) of the future leg, while the peripheral rings correspond to its proximal region (coxa, trochanter). During embryogenesis, the leg telescopes out as it subdivides into the component articles. The gene *Distal-less* (*Dll*) is expressed in the presumptive distal region of the limb, while the gene *Extradenticle* (*Exd*) is necessary for the development of the proximal portion of the limb. Thus the protopod of the leg is under its own genetic control, as is the telopod, and this is why the mandible is considered gnathobasic, as it does not express *Dll* (see above).

Within the Pterygota, most species also have a pair of wings on the second and third thoracic segments. Wing morphology has been more extensively used in insect classification than the morphology of any other single structure. Wings are often the only remains of insects preserved as fossils. The wings of modern insects develop as evaginations of the integument, with thin cuticular membranes forming the upper and lower surfaces of each wing. Wing **veins**, which contain circulating hemolymph, anastomose and eventually

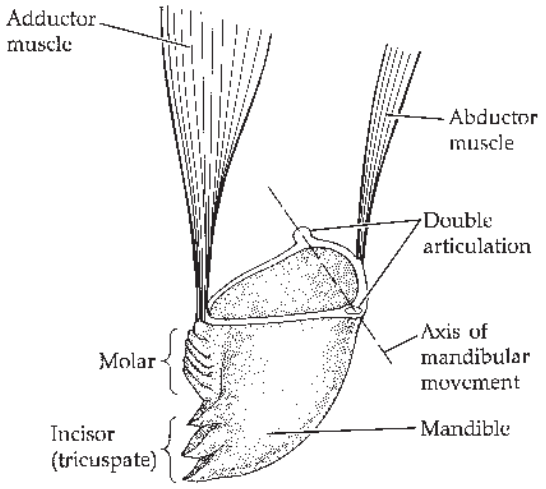

FIGURE 22.14 The musculature of an insect mandible.

[4]It is unclear whether having one or several tarsomeres is the primitive condition for the Hexapoda. Homologization of the leg articles among the various arthropod groups is a popular and often rancorous pastime. The issue is further confused when the number of articles differs from the norm (e.g., some insects have two trochanters, the number of tarsi varies from one to five, etc.). The protopods of myriapods, chelicerates, and trilobites all seem to consist of a single basal article (usually called the coxa). In the latter case, Kukalová-Peck hypothesizes that three "missing" protopodal articles were lost by fusion among themselves and with the pleural region. See Chapter 20 for a discussion of ancestral arthropod legs.

open into the body. The arrangement of veins in insect wings provides important diagnostic characters at all taxonomic levels. The origin and homologies of wing venation have been heavily debated over the decades. Most workers use a consistent naming system that recognizes six major veins: costa (C), subcosta (SC), radius (R), media (M), cubitus (CU), and anal (A) (Figure 22.18). Areas in the wings that are enclosed by longitudinal and cross veins are called **cells**, and these too have a somewhat complex nomenclature. In some groups (e.g., Orthoptera, Dermaptera) the forewings develop heavily sclerotized regions called **tegmina** (sing. tegmin), used for protection, stridulation, or other purposes. In many sedentary, cryptic, parasitic, and insular lineages the wings have become shortened (brachypterous) or lost (apterous). Insects often couple their wings together for flight by means of hooklike devices along the margin between the posterior border of the forewing and the anterior margin of the hindwing (e.g., **hamuli** in Hymenoptera; **frenula** in many Lepidoptera). In these insects the coupled wings function together as a single unit.

The hexapod abdomen The abdomen primitively comprises 11 segments, although the first is often reduced or even incorporated into the thorax, and the last segment may be vestigial. Abdominal pleura are greatly reduced or absent. The occurrence of true (though minute) abdominal leglets (sometimes called "prolegs" or "styli") on the pregenital segments is commonplace among the apterygotes and also occurs in the larvae of many pterygotes (e.g., the legs of caterpillars). In addition, transitory limb buds or rudiments appear fleetingly in the early embryos of some species, presumably harking back to the deep evolutionary past. Abdominal segments 8–9 (or 7–9) are typically modified as the **anogenital tagmata**, or **terminalia**, the exposed parts being the genitalia. The female median gonopore occurs behind sternum 7 in Ephemeroptera and Dermaptera, and behind sternum 8 or 9 in all other orders. The anus is always on segment 11 (which may be fused with segment 10).

There is enormous complexity in both clasping and intromittent organs among the Hexapoda, and a correspondingly sharp disagreement exists over the

Cambridge University Press, Cambridge.)

homologies and terminology of these structures. In general, females discriminate among males on the basis of sensory stimuli produced by the male genitalia; hence selection pressure has been a powerful force in the evolution of these structures (in both sexes). The most primitive male architecture can be seen in apterygotes and Ephemeroptera, in which the penes are paired and contain separate ejaculatory ducts. In most other insects, however, the intromittent organ develops late during embryogenesis by fusion of the genital papillae to form a median, tubular, often eversible endophallus, with the joined ejaculatory ducts opening at a gonopore at its base. The external walls may be sclerotized or modified in a wide variety of ways, and the whole organ is known as the **aedeagus**. Some workers consider the aedeagus to be derived from segment 9; others regard it as belonging to segment 10. A pair of sensory cerci (sing. cercus) often projects from the last abdominal segment.

Locomotion

Walking Like the other terrestrial arthropods, hexapods rely on their sclerotized exoskeleton for support on land. Their limbs provide the physical support needed to lift the body clear of the ground during locomotion. In order to accomplish this, the limbs must be long enough to hold the body high off the ground, but not so high as to endanger stability. Most hexapods maintain stability by having the legs in positions that suspend the body in a slinglike fashion and keep the overall center of gravity low (Figure 20.19).

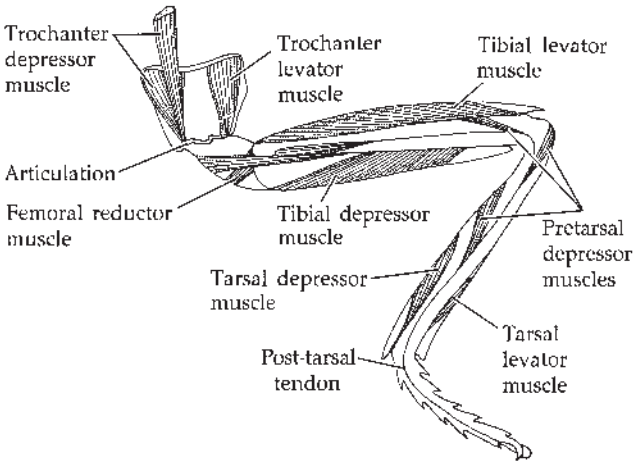

FIGURE 22.17 The musculature of an insect leg.

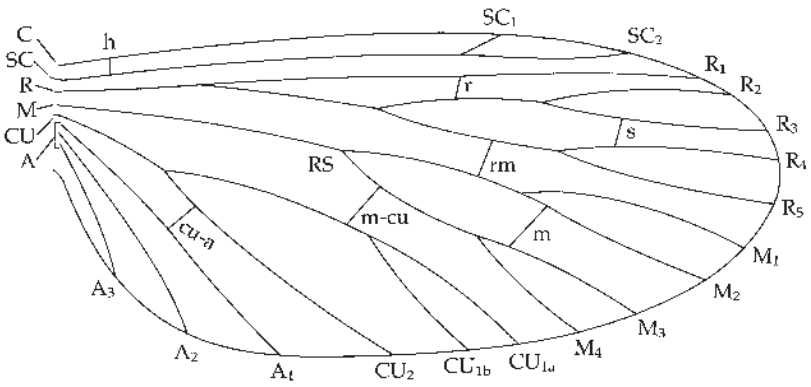

FIGURE 22.18 The nomenclature of basic wing venation in insects. Although the cells formed within the veins also have names, only the names of the veins are given here. Longitudinal veins are coded with capital letters, cross veins with lowercase letters. Longitudinal veins: costa (C); subcosta (SC); radius (R); radial sector (RS); media (M); cubitus (CU); anal (A). Cross veins: humeral (h); radial (r); sectorial (s); radiomedial (rm); medial (m); mediocubital (m-cu); cubitoanal (cu-a).

The basic structure of arthropod limbs was described in Chapter 20. In hexapods (and crustaceans) the anterior–posterior limb movements take place between the coxae and the body proper (in contrast to most arachnids, in which the coxae are immovably fixed to the body and limb movement occurs at more distal joints). Like the power controlled by the range of gears in a combustion engine automobile, the power exerted by a limb is greatest at low speeds and least at higher speeds. At lower speeds the legs are in contact with the ground for longer periods of time, thus increasing the power, or force, that can be exerted during locomotion. In burrowing forms the legs are short, and the gait is slow and powerful as the animal forces its way through soil, rotting wood, or other material. Longer limbs reduce the force but increase the speed of a running gait, as do limbs capable of swinging through a greater angle. Limbs long in length and stride are typical features of the fastest-running insects (e.g., tiger beetles, Carabidae, Cicindelinae).

One of the principal problems associated with increased limb length is that the field of movement of one limb may overlap that of adjacent limbs. Interference is prevented by the placement of the tips of adjacent legs at different distances from the body (Figure 22.19). Thus fast-running insects usually have legs of slightly different lengths. Insects usually move their legs in an alternating tripod sequence. Balance is maintained by always having three legs in contact with the ground.

Like many spiders, some insects can walk on water, and they do so in much the same way—by balancing the pull of gravity on their featherweight bodies with the physical principles of buoyancy and surface tension. Insects (and spiders) that walk on water don't get wet because their exoskeletons are coated with waxes that repel water molecules. The water surface, held taut by surface tension, bends under each leg to create a depression, or dimple, that works to push the animal upward in support. Water walking occurs in many insect groups, notably the Hemiptera (e.g., water striders), Coleoptera (e.g., whirligig beetles), and Collembola (some springtails).[5]

Many insects are superb jumpers (e.g., fleas, springtails, most orthopterans), but the click beetles (Elateridae) are probably the champions. It has been calculated that a typical click beetle (e.g., *Athous haemorrhoidalis*), when springing into the air to escape a predator, generates a g-force of 400, with a peak deceleration of 2,300 g.

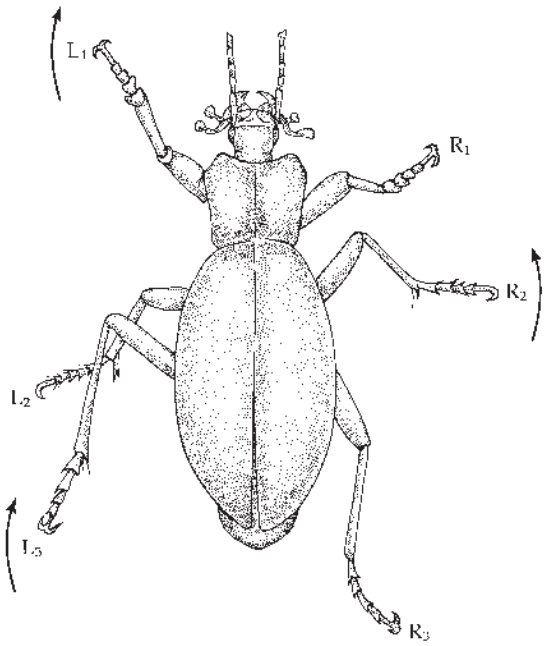

FIGURE 22.19 A beetle walking. The alternating tripod gait consists of alternate stepping with two sets of three legs; thus the body is always supported by a triad of legs. Here, three legs (L_1, R_2, and L_3) are moving forward while the other three (R_1, L_2, and R_3) are on the ground.

Flight Among the many remarkable advances of insects, flight is perhaps the most impressive. Insects were the first flying animals, and throughout the history of life on Earth, no other invertebrates have learned the art of true flight. The wingless insects belong to groups that have secondarily lost the wings (e.g., fleas, lice, certain scale insects), to life stages that have lost the wings, or to primitive taxa (the apterygotes) that arose prior to the evolution of wings. In three orders,

[5]On an undisturbed surface, water molecules are attracted to their neighbors beside and below, resulting in a flat skin of molecules that exerts only horizontal tensile forces; it is this "elasticity" of the surface that we call surface tension.

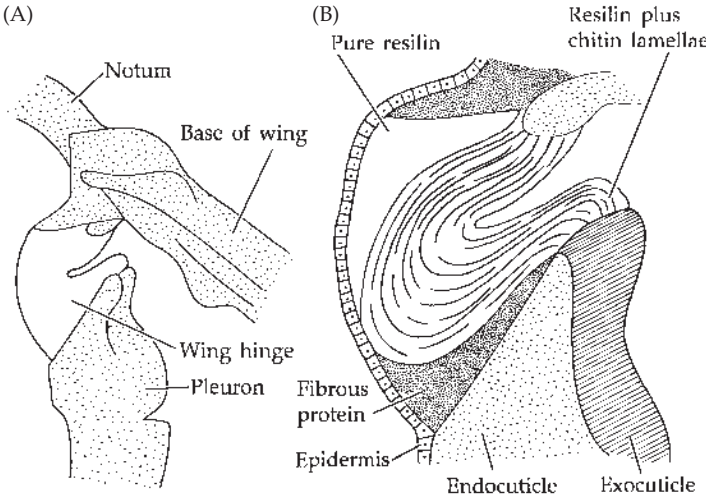

FIGURE 22.20 A typical insect wing hinge arrangement. This transverse section through the thoracic wall of a grasshopper shows the base of the wing and the wing hinge. (A) Entire hinge area. (B) Enlargement of hinge section.

the wings are effectively reduced to a single pair. In beetles, the forewings are modified as a protective dorsal shield (**elytra**). In dipterans, the hindwings are modified as organs of balance (**halteres**). The halteres beat with the same frequency as the forewings, functioning as gyroscopes to assist in flight performance and stability—flies fly very well. In strepsipteran males (females are wingless), the forewings are reduced to clublike structures resembling the halteres of Diptera.

Compared with an insect, an airplane is a simple study in aerodynamics. Planes fly by moving air over a fixed wing surface, the leading edge of which is tilted upward, forcing the air to travel farther (thus faster) over the top of the wing than the bottom, resulting in a vortex that creates a lift. But conventional fixed-wing aerodynamic theory is insufficient to understand insect flight. Insect wings are anything but fixed. Insects, of course, fly by flapping their wings to create vortices, from which they gain lift, but these vortices slip off the wings with each beat, and new vortices are formed with each alternate stroke. Beating insect wings trace a figure eight pattern, and they also rotate at certain crucial moments. Thus, each cycle of flapping creates dynamic forces that fluctuate drastically. By complex actions of wing orientation, insects can hover; fly forward, backward, and sideways; negotiate highly sophisticated aerial maneuvers; and land in any position. To complicate matters even more, in the case of small insects (and most are small, the average size of all insects being just 3–4 mm), the complex mechanics of flight take place at very low Reynolds numbers (see Chapter 3), such that the insect is essentially "flying through molasses." As a result of these complex mechanics, insect flight is energetically costly, requiring metabolic rates as high as 100 times the resting rate.

Each wing articulates with the edge of the notum (thoracic tergite), but its proximal end rests on a dorsolateral pleural process that acts as a fulcrum (Figure 22.20). The wing hinge itself is composed in large part of resilin, a highly elastic protein that allows for rapid, sustained movement. The complex wing movements are made possible by the flexibility of the wing itself and by the action of a number of different muscle sets that run from the base of the wing to the inside walls of the thoracic segment on which it is borne. These direct flight muscles serve to raise and lower the wing and to tilt its plane at different angles (somewhat like altering the blade angles on a helicopter) (Figure 22.21). However,

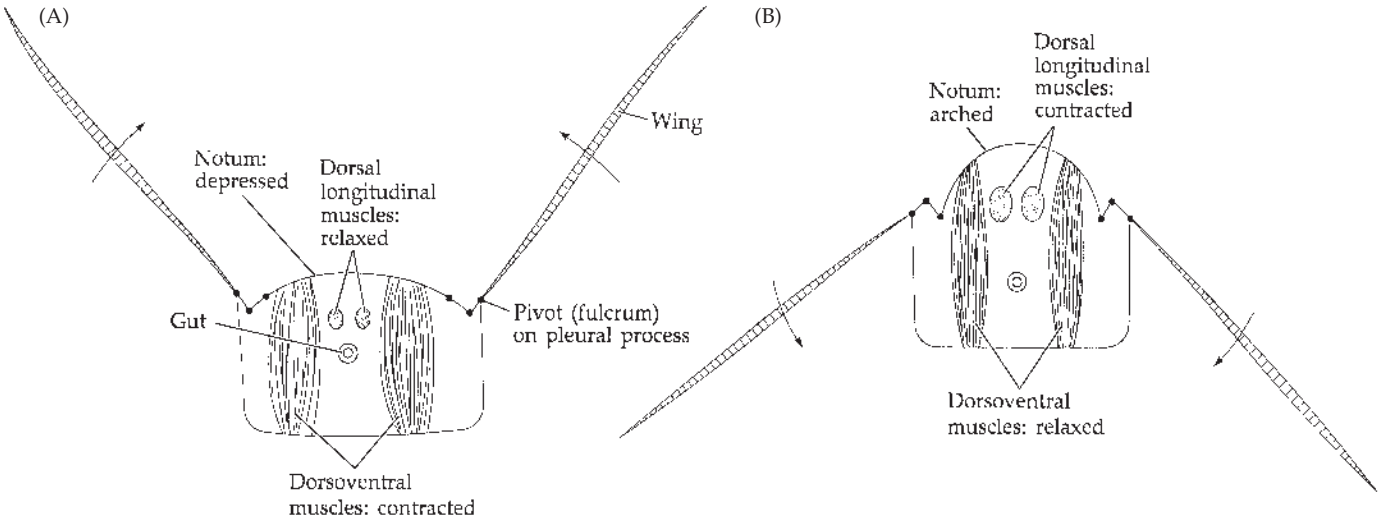

FIGURE 22.22 Wing movements of an insect such as a fly or hemipteran, in which both upward and downward movements of the wings are produced by indirect flight muscles. In these transverse sections of a thoracic segment, dots represent pivot points, and arrows indicate the direction of wing movement. Only two sets of muscles are shown. (A) The dorsoventral muscles contract, depressing the thoracic notum and forcing the wings into upstroke. (B) The dorsoventral muscles relax as the dorsal longitudinal muscles contract to "pop up" the notum, elevating it and forcing the wings into a downstroke.

except in palaeopterans (Odonata and Ephemeroptera), the direct flight muscles are not the main source of power for insect wing movements. Most of the force comes from two sets of indirect flight muscles, which neither originate nor insert on the wings themselves (Figures 22.21 and 22.22).

Dorsal longitudinal muscles run between apodemes at the anterior and posterior ends of each winged segment. When these muscles contract, the segment is shortened, which results in a dorsal arching of the segment roof and a downstroke of the wings. Dorsoventral muscles, which extend from the notum to the sternum (or to basal leg joints) in each wing-bearing segment, are antagonistic to the longitudinal muscles. Contraction of the dorsoventral muscles lowers the roof of the segment. In doing so, it raises the wings. Thus, wing flapping in most insects is primarily generated by rapid changes in the walls and overall shape of the mesothorax and metathorax. Other, smaller thoracic muscle sets serve to make minor adjustments to this basic operation.

Insects with low wing-flapping rates (e.g., dragonflies, orthopterans, mayflies, and lepidopterans) are limited by the rate at which neurons can repeatedly fire and muscles can execute contractions. However, in insects with high wing-flapping rates (e.g., dipterans, hymenopterans, and some coleopterans), an entirely different regulatory mechanism has evolved. Once flight has been initiated and a high wing-flapping rate attained (up to 100 beats/second), myogenic control takes over. This mechanism exploits the elastic-mechanical properties of the exoskeleton. When one set of indirect muscles contracts, the thorax is deformed. Upon relaxation of the muscles, there is an elastic rebound of the thoracic exoskeleton, which stretches the second set of indirect muscles and thus directly stimulates their contraction. This contraction establishes a second deformation, which in turn stretches and stimulates the first muscle group. Once initiated, this mechanism is nearly self-perpetuating, and the nonsynchronous firing of neurons serves only to keep it in action.

Not all insects utilize wings to travel through the air. Many small and immature insects are effectively dispersed by wind power alone. Some first-instar lepidopterans use silk threads for dispersal (as do spiders and mites). Tiny scale insects are commonly collected in aerial nets. In fact, studies have revealed the existence of "aerial plankton" consisting of insects and other minute arthropods, extending to altitudes as high as 14,000 feet. Most are minute winged forms, but wingless species are also common.

The Origin of Insect Flight

For many decades, two competing views of insect wing origin have dominated. In general, these views can be termed the novel structure hypothesis and the appendage hypothesis. The former holds that wings evolved by way of gene co-option to form a new structure (e.g., a gradual expansion of lateral, or paranotal, folds of the thoracic tergite, hence giving this view the name "tergal origin hypothesis"), which eventually became articulated and muscled to form wings. The latter hypothesizes that wings evolved from preexisting articulated structures on the thoracic appendages,

such as gills or protopodal exites on the legs. And some recent work has even suggested a "dual origin," with cells from both the tergal and pleural regions contributing to the wings.

The paranotal lobe hypothesis was first proposed by Müller in 1873, saw a resurgence of popularity in the middle of the twentieth century, and has lost favor in recent years. It suggests that wings originated as lateral aerodynamic flaps of the thoracic nota that enabled insects to alight right side up when jumping or when blown about by the wind. These stabilizing paranotal lobes later evolved hinged structures and muscles at their bases. The occurrence of fixed paranotal lobes in certain ancient fossil insects has been cited in support of the paranotal lobe hypothesis (Figure 22.23). However, recent studies suggest that these primitive paranotal lobes might have been used for other purposes, such as covering the spiracular openings or gills in amphibious insects, protecting or concealing the insects from predators, courtship displays, or thermoregulation by absorption of solar radiation.

The appendage hypothesis (also known as the "gill or branchial theory," "exite theory," or "leg theory") also dates back to the nineteenth century but was resurrected by the great entomologist V. B. Wigglesworth in the 1970s and was championed by J. Kukalová-Peck since the 1980s. It is the more favored hypothesis of wing origin today, based on recent paleontological work, microscopic anatomy, and molecular developmental biology. It suggests that insect wings are derived from thoracic appendages—from protopodal exites, in Wigglesworth and Kukalová-Peck's view. These proto-wing appendages might have first functioned as aquatic gills or paddles, or as terrestrial gliding structures. The paired abdominal gills of mayflies have been suggested as serial homologues of such "proto-wings." In Kukalová-Peck's version of this hypothesis, the first protopodal leg article (the epicoxa) fused with the thoracic pleural membrane early in the evolution of the Arthropoda, as did the second article (the precoxa) in the ancient hexapods, with both migrating dorsally off the leg and onto the body proper. In insects, the epicoxa eventually fused with the tergite, its exite enlarging to form the proto-wing and eventually the true wing. The precoxa formed the pleural sclerite providing the ventral articulation of the wing. Wing veins might have evolved from cuticular ridges that served to strengthen these structures and, eventually, to circulate blood through them.[6]

Kukalová-Peck's theory of wing evolution finds support in molecular developmental studies, which have shown that the cells that give rise to the wing primordium derive from the same cluster of cells that form the leg primordium, from which they segregate, migrating dorsally to a position below the tergum. Recent studies on gene expression also support the origin of wings from legs. The genes *pdm* and *apterous* are expressed in the wing (and leg) primordia of all insects. Expression of both genes appears to be necessary for normal wing formation. In malacostracan crustaceans (but not in branchiopod crustaceans) these same genes are expressed, in a similar manner, in the formation of the leg rami (the exopod and endopod).

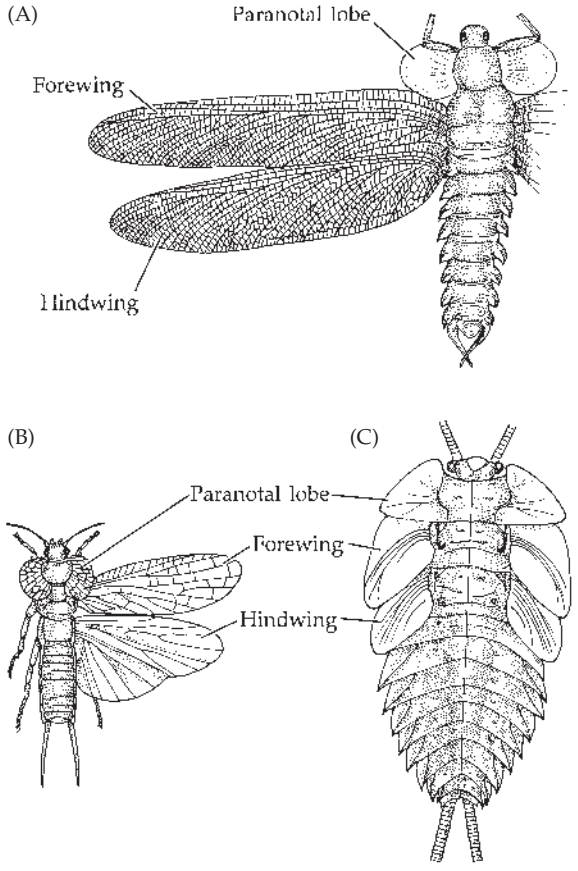

FIGURE 22.23 Fossil insects with paranotal lobes on the prothorax. (A) *Stenodictya lobata*, a Paleozoic palaeodictyopteran. (B) *Lemmatophora typa* (Mesozoic). (C) Nymphal stage of *Rochdalia parkeri*, a Paleozoic terrestrial palaeodictyopteran in which all three thoracic segments appear to have had "articulated" thoracic lobes.

Feeding and Digestion

Feeding Every conceivable kind of diet is exploited by species within the Hexapoda, whose feeding strategies include herbivory, carnivory, and scavenging, as well as a magnificent array of commensalism and parasitism. This "nutritional radiation" has played a key role in the phenomenal evolution among the Insecta. A comprehensive survey of insect feeding biology alone could easily fill a book this size. Setting aside symbiotic relationships for a moment, in the most general sense insects can be classified as (1) biters-chewers, (2) suckers, or (3) spongers (Figure 22.24).

[6]Unspecialized coxal exites can be seen on the legs of some living archaeognathans (bristletails) and in numerous extinct hexapods.

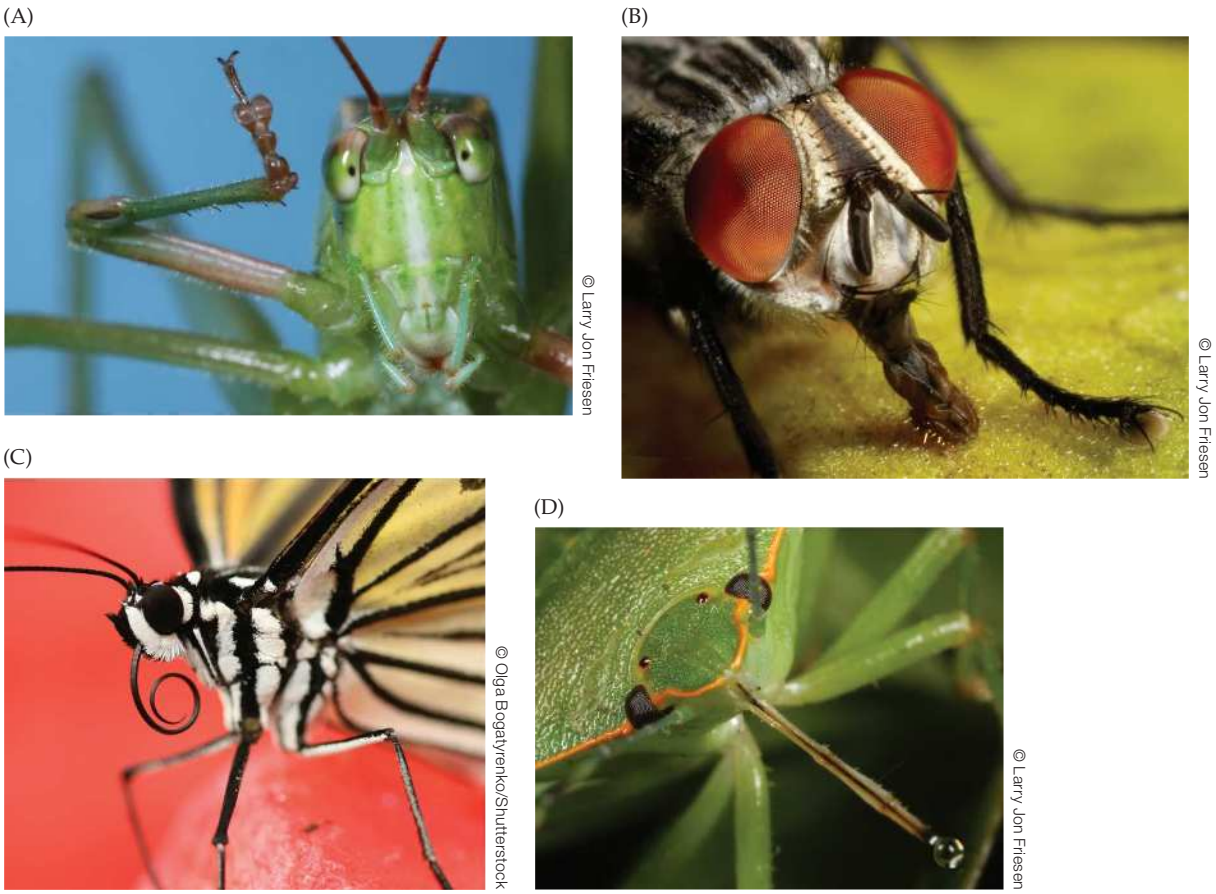

FIGURE 22.24 Mouthparts specialized for different modes of feeding. (A) Biting-chewing mouthparts of a grasshopper. Note the well-developed leglike palps. (B) Sponging mouthparts of a fly. (C) Sucking mouthparts of a butterfly. (D) Piercing mouthparts of a true bug.

Biters-chewers, such as the grasshoppers, have the least-modified mouthparts, so we describe them first. The maxillae and labium of these insects have well-developed leglike palps (Figure 22.24A) that help them hold food in place, while powerful mandibles cut off and chew bite-size pieces. The mandibles lack palps (in all hexapods) and typically bear small, sharp teeth that work in opposition as the appendages slide against each other in the transverse (side-to-side) fashion characteristic of most arthropod jaws. Biting-chewing insects may be carnivores, herbivores, or scavengers. In many plant eaters, the labrum bears a notch or cleft in which a leaf edge may be lodged while being eaten. Some of the best examples of this feeding strategy are seen among the Orthoptera (locusts, grasshoppers, crickets), and most people have witnessed the efficient fashion in which these insects consume their garden plants! Equally impressive are the famous leafcutter ants of the Neotropics, which can denude an entire tree in a few days. Leafcutter ants have a notable feeding adaptation: when cutting leaf fragments, they produce high-frequency vibrations with an abdominal stridulatory organ. This stridulation is synchronized with movements of the mandible, generating complex vibrations. The high vibrational acceleration of the mandible appears to stiffen the material being cut, just as soft material is stiffened with a vibratome for sectioning in a laboratory. Leafcutters don't eat the leaves they cut; instead, they carry them into an underground nest, where they use them to grow a fungus on which they feed. Several other insect groups have evolved associations with fungi, and in almost every case these relationships are mutualistic and obligate—neither partner can live without the other.

In sucking insects the mouthparts are markedly modified for the consumption of liquid foods, generally plant saps, nectars, animal blood, or cell fluids (Figure 22.24C,D). Sucking mouthparts and liquid diets have clearly evolved many times in different insect lines—further testimony to the frequency of evolutionary convergence in arthropods and the developmental adaptability of their appendages. In some sucking insects, such as mosquitoes, feeding is initiated by piercing the victim's epidermal tissue; this mode of feeding is referred to as piercing-sucking. Other insects, such as the butterflies and moths that feed on flower nectar, do not pierce anything and are merely suckers—but some carnivore lepidopterans, like the vampire moths, do pierce to draw blood!

In all sucking insects the mouth itself is very small and hidden. The mouthparts, instead of being adapted for handling and chewing solid pieces of food, are elongated into a needlelike beak adapted for a liquid diet. Different combinations of mouth appendages constitute the beak in different taxa. True bugs (Hemiptera), which are piercer-suckers, have a beak composed of five elements: an outer troughlike element (the labium) and, lying in the trough, four very sharp stylets (the two mandibles and two maxillae). The stylets are often barbed to tear the prey's tissues and enlarge the wound. The labrum is in the form of a small flap covering the base of the grooved labium. When piercer-suckers feed, the labium remains stationary, and the stylets do the work of puncturing the plant (or animal) and drawing out the liquid meal.

Different variations of piercing-sucking mouthparts are found in other insect taxa. In mosquitoes, midges, and certain biting flies (e.g., horseflies) there are six long, slender stylets, which include the labrum-epipharynx and the hypopharynx as well as the mandibles and first maxillae (Figure 22.15A). Other biting flies, such as the stable fly, have mosquito-like mouthparts but lack mandibles and maxillae altogether. Fleas (Siphonaptera) have three stylets: the labrum-epipharynx and the two mandibles. Thrips have unusual mouthparts: the right mandible is greatly reduced, making the head somewhat asymmetrical, and the left mandible, first maxillae, and hypopharynx make up the stylets.

Most lepidopterans are nonpiercing sucking insects in which the paired first maxillae are enormously elongated, coiled, and fused to form a tube through which flower nectar is sucked (Figure 22.24C); the mandibles are vestigial or absent (Figure 22.15D). The mouthparts of bees are similar: the first maxillae and labium are modified together to form a nectar-sucking tube, but the mandibles are retained and used for wax manipulation during hive construction (Figure 22.15C). The collected nectar is stored in a special "sac" in the foregut and carried back to the hive, where it is converted into honey, which is stored as a food reserve. Bees in an average hive consume about 500 pounds of honey per year—we humans get the leftovers.

Associated with sucking mouthparts are various mechanisms for drawing liquid food into the mouth. Most piercer-suckers rely largely on capillary action, but others have developed feeding "pumps." Often the pump is developed through elongation of the preoral cavity, or **cibarium**, which by extension of the cuticle around the mouth becomes a semiclosed chamber connecting with the alimentary canal (Figure 22.25). In these cases, cibarial muscles from the clypeus are enlarged to make a powerful pump. In lepidopterans, dipterans, and hymenopterans the cibarial pump is combined with a pharyngeal pump, which operates by means of muscles arising on the front of the head. Specialized salivary glands are also often associated with sucking mouthparts. In some hemipterans a salivary pump forces saliva through the feeding tube and into the prey, softening tissues and predigesting the liquid food. In mosquitoes, saliva carries blood thinners and anticoagulants (and often parasites such as *Plasmodium*, which causes malaria).

In spongers, such as most flies (order Diptera), the labium is typically expanded distally into a **labellum** (Figures 22.15E and 22.24B). Fluid nutrients are transported by capillary action along minute surface channels from the labellae to the mouth. In many spongers,

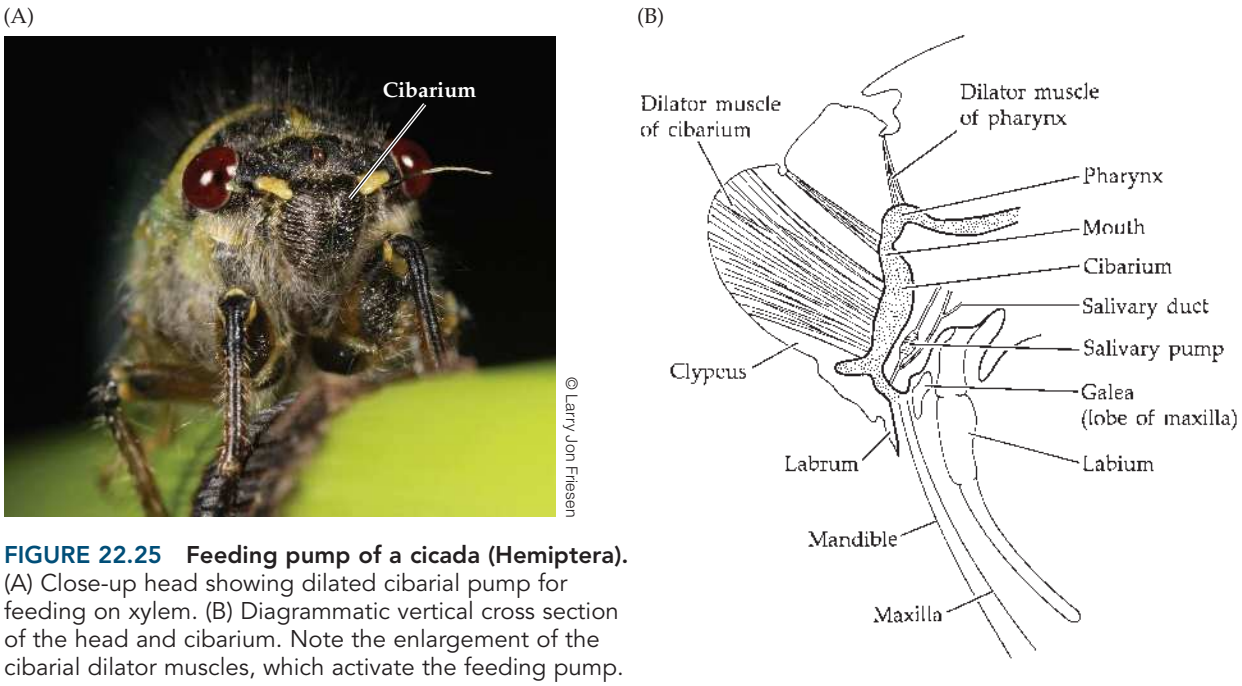

FIGURE 22.25 Feeding pump of a cicada (Hemiptera). (A) Close-up head showing dilated cibarial pump for feeding on xylem. (B) Diagrammatic vertical cross section of the head and cibarium. Note the enlargement of the cibarial dilator muscles, which activate the feeding pump.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

such as houseflies, saliva is exuded onto the food to partly liquefy it. In strict spongers, the mandibles are absent. In biting spongers, such as horseflies, the mandibles serve to slice open a wound in the flesh, thus exposing the blood and cellular fluids to be sponged up by the labellae.

Many insects are scatophagous, feeding on animal feces. Most of these groups have biting mouthparts, but some (such as certain flies) have sucking mouthparts. Perhaps the most famous of the scatophagous insects are the dung beetles, or tumblebugs (certain beetles in the families Scarabaeidae and Histeridae). These remarkable insects harvest animal dung by biting or slicing off pieces with specialized head or leg structures and working them into a ball. They may roll the dung ball a considerable distance and eventually bury it in the soil, whereupon females deposit eggs within it. Larvae are thus assured of a ready food supply. Dung balls may even be maneuvered by a pair of dung beetles pushing and pulling in a cooperative effort.

There are many symbiotic insects, and two orders are composed entirely of wingless parasites, most of which spend their entire lives on their hosts: some Psocodea (lice) and Siphonaptera (fleas). Bird lice are common, and lice are also found on dogs, cats, horses, cattle, and other mammals. Biting lice have broad heads and biting mouthparts used to chew epithelial cells and other structures on the host's skin. Sucking lice have narrow heads and piercing-sucking mouthparts, which they use to suck blood and tissue fluids from their host, always a mammal. Unlike most arthropod parasites, lice (of both types) spend their entire lives on the bodies of their hosts, and transmission to new hosts is by direct contact. For this reason most lice show a high degree of host specificity. Eggs, or nits, are attached by the female to the feathers or hair of the host, where they develop without a marked metamorphosis. Many lice, particularly those whose diet is chiefly keratin, possess symbiotic intracellular bacteria that appear to aid in the digestion of their food. These bacteria are passed to the offspring by way of the insects' eggs. Similar bacteria occur in ticks, mites, bedbugs, and some blood-sucking dipterans.

None of the biting lice are known to infest people or to transmit human disease microorganisms, although one species acts as an intermediate host for certain dog tapeworms. The sucking lice, on the other hand, include two genera that commonly infest humans (*Pediculus* and *Phthirus*). The latter genus includes the notorious *P. pubis*, the human pubic crab louse (which often occurs on other parts of the body as well). The genus *Pediculus* includes four species that parasitize primates, including *P. humanus* and its two morphotypes, the body louse and the head louse. A number of sucking lice are vectors for human disease organisms. The most common reaction to infestation with lice—a condition known as **pediculosis**, or being lousy—is simple irritation and itching caused by the anticoagulant injected by the parasite during feeding. Chronic infestation with lice among certain footloose travelers is manifested by leathery, darkened skin—a condition known as **vagabond's disease**.

Fleas (order Siphonaptera) are perhaps the best known of all insect parasites. Nearly 1,500 species from birds and mammals have been described. Unlike lice, fleas are holometabolous, passing through egg, larval, pupal, and adult stages. Some species of fleas live their entire lives on their host, although eggs are generally deposited in the host's environment and larvae feed on local organic debris. Larvae of domestic fleas, including the rare human flea (*Pulex irritans*), feed on virtually any organic crumbs they find in the household furniture or carpet. Upon metamorphosis to the adult stage, fleas may undergo a quiescent period until an appropriate host appears. A number of serious disease organisms are transmitted by fleas, and at least 8 of the 60 or so species of fleas associated with household rodents are capable of acting as vectors for bubonic plague bacteria.

Other insect orders contain primarily free-living insects but include various families of parasitic or micropredatory forms, or groups in which the larval stage is parasitic but the adults are free-living. Most of these "parasites" do not live continuously on a host and have feeding behaviors that fall into a gray zone between true obligate parasitism and predation. Such insects are sometimes classed as intermittent parasites, or micropredators. Bedbugs (Hemiptera, Cimicidae), for example, comprise about 100 species of minute flattened insects that feed on the blood of birds and mammals. However, most live in the nest or sleeping area of their host, emerging only periodically to feed. The common human bedbugs (*Cimex lectularius* and *C. hemipterus*) hide in bedding, in cracks, in thatched roofs, or under rugs by day and feed on their host's blood at night. They are piercer-suckers, much like the sucking lice. Bedbugs are not known to transmit any human diseases, although when present in large numbers, they can be troublesome (in South America, as many as 8,500 bugs have been found in a single adobe house). Mosquitoes (family Culicidae), on the other hand, are vectors for a large number of disease-causing microorganisms, including *Plasmodium* (responsible for malaria), yellow fever, viral encephalitis, dengue, and lymphatic filariasis (with its gross symptom, elephantiasis, resulting from blockage of lymph ducts). Kissing bugs (Hemiptera, Reduviidae, Triatominae) also have a casual host relationship. They live in all kinds of environments but often inhabit the burrows or nests of mammals, especially rodents and armadillos, as well as birds and lizards. They feed on the blood of these and other vertebrates, including dogs, cats, and people. Their host specificity is low. Several species are vectors of mammalian trypanosomiasis (*Trypanosoma cruzi*, the causative agent of Chagas' disease). The tendency of

some species to bite on the face (where the skin is thin) has resulted in the common name, "kissing bugs."

In the dipteran family Calliphoridae, larvae are saprophagous, coprophagous, wound feeding, or parasitic. The parasitic species include among their hosts earthworms, locust egg cases, termite colonies, and nestling birds, and several species parasitize humans and domestic stock (e.g., *Cochliomyia americana*, the tropical American screwworm).

Many insect parasites of plants cause an abnormal growth of plant tissues, called a gall. Some fungi and nematodes also produce plant galls, but most are caused by mites and insects (especially hymenopterans and dipterans). Parasitic adults may bore into the host plant or, more commonly, deposit eggs in plant tissues, where they undergo larval development. The presence of the insect or its larva stimulates the plant tissues to grow rapidly, forming a gall. The adaptive significance (for insects) of galls remains unclear, but one popular theory is that their production interferes with the production of defensive chemicals by the plant, thus rendering gall tissues more palatable. A somewhat similar strategy is used by leaf miners, specialized larvae from several orders (e.g., Coleoptera, Diptera, Hymenoptera) that live entirely within the tissues of leaves, burrowing through and consuming the most digestible tissues.

An interesting predatory strategy is that of New Zealand glowworms (*Arachnocampa luminosa*), which live in caves and in bushes along riverbeds. These larvae of small flies produce a bright bioluminescence in the distal ends of the Malpighian tubules, which lights up the posterior end of the body. (The light peaks at 485 nm wavelength.) Each larva constructs a horizontal web from which up to 30 vertical "fishing lines" descend, each with a regularly spaced series of sticky droplets. Small invertebrates (e.g., flies, spiders, small beetles, hymenopterans) attracted to the light are caught by the fishing lines, hauled up, and eaten. Harvestmen (Opiliones), the main predators of glowworms, use the light to locate their prey!

Digestive system Like the guts of all arthropods, the long, usually straight hexapod gut is divisible into an ectodermal foregut, endodermal midgut, and ectodermal hindgut (Figure 22.26). Salivary glands are associated with one or several of the mouth appendages (Figure 22.27). The salivary secretions soften and lubricate solid food, and in some species they contain enzymes that initiate chemical digestion. In moth caterpillars and in larval bees and wasps, the salivary glands secrete silk used to make pupal cells.

All hexapods, as well as most other arthropods that consume solid foods, produce a **peritrophic membrane** in the midgut (Figure 22.26B). This sheet of thin chitinous material may line the midgut or pull free to envelop and coat the food particles as they pass through the gut. The peritrophic membrane serves to protect the delicate midgut epithelium from abrasion. It is permeated by microscopic pores that allow passage of enzymes and digested nutrients. In many species, production of this membrane also takes place in the hindgut, where it encapsulates the feces as discrete pellets.

Along with their vast range of feeding habits, insects have evolved a number of specialized digestive structures. The foregut is typically divided into a well-defined pharynx, esophagus, crop, and proventriculus (Figures 22.26 and 22.27). The pharynx is muscular, particularly in the sucking insects, in which

it commonly forms a **pharyngeal pump**. The crop is a storage center whose walls are highly extensible in species that consume large but infrequent meals. The **proventriculus** regulates food passage into the midgut, either as a simple valve that strains the semifluid foods of sucking insects or as a grinding organ, called a gizzard or gastric mill, that masticates the chunks ingested by biting insects. Well-developed gastric mills have strong cuticular teeth and grinding surfaces that are gnashed together by powerful proventricular muscles.

The midgut (= stomach) of most insects bears gastric ceca that lie near the midgut-foregut junction and resemble those of crustaceans. These evaginations serve to increase the surface area available for digestion and absorption. In some cases the ceca also house mutualistic microorganisms (bacteria and protists). The insect hindgut serves primarily to regulate the composition of the feces and perhaps to absorb some nutrients. Digestion of cellulose by termites and certain wood-eating roaches is made possible by enzymes produced by protists and bacteria that inhabit the hindgut.

Clusters of fat cells create a **fat body** in the hemocoel of many insects, which is most conspicuous in the abdomen but also extends into the thorax and head. The fat body is an organ unique to the insects and is often likened to the vertebrate liver and the chloragogenous tissue in annelids. The fat body not only stores lipids, proteins, and carbohydrates, but also synthesizes proteins. Many insects do not feed during their adult life; instead, they rely on stored nutrients accumulated in the larval or juvenile stages and stored in the fat body.

Circulation and Gas Exchange

The hexapod circulatory system includes a dorsal tubular heart that pumps the hemocoelic fluid (blood) toward the head. The heart narrows anteriorly into a vessel-like aorta, from which blood enters the large hemocoelic chambers, through which it flows posteriorly, eventually returning to the pericardial sinus and then to the heart via paired lateral ostia (Figure 22.28). In most insects the heart extends through the first nine abdominal segments; the number of ostia is variable. Accessory pumping organs, or **pulsatile organs**, often occur at the bases of wings and of especially long appendages, such as the hindlegs of grasshoppers, to assist in circulation and maintenance of blood pressure.

The heart is a rather weak pumping organ, and blood is moved primarily by routine muscular activity of the body and appendages. Hence, circulation is slow and system pressure is relatively low. Like many arachnids, some hexapods use the hydraulic pressure of the hemocoelic system in lieu of extensor muscles. In this way, for example, butterflies and moths unroll their maxillary feeding tubes.

Many types of hemocytes (blood cells) have been reported from insects and several are apparently important in wound healing and clotting. Nutrients, wastes, and hormones can be efficiently carried by this system, but most insects do not have oxygen-transporting proteins in their blood. However, hemocyanin does occur in several hexapod groups, especially in embryonic stages or in hypoxic environments. Hemocyanin is apparently absent in Protura, Diplura, Ephemeroptera,

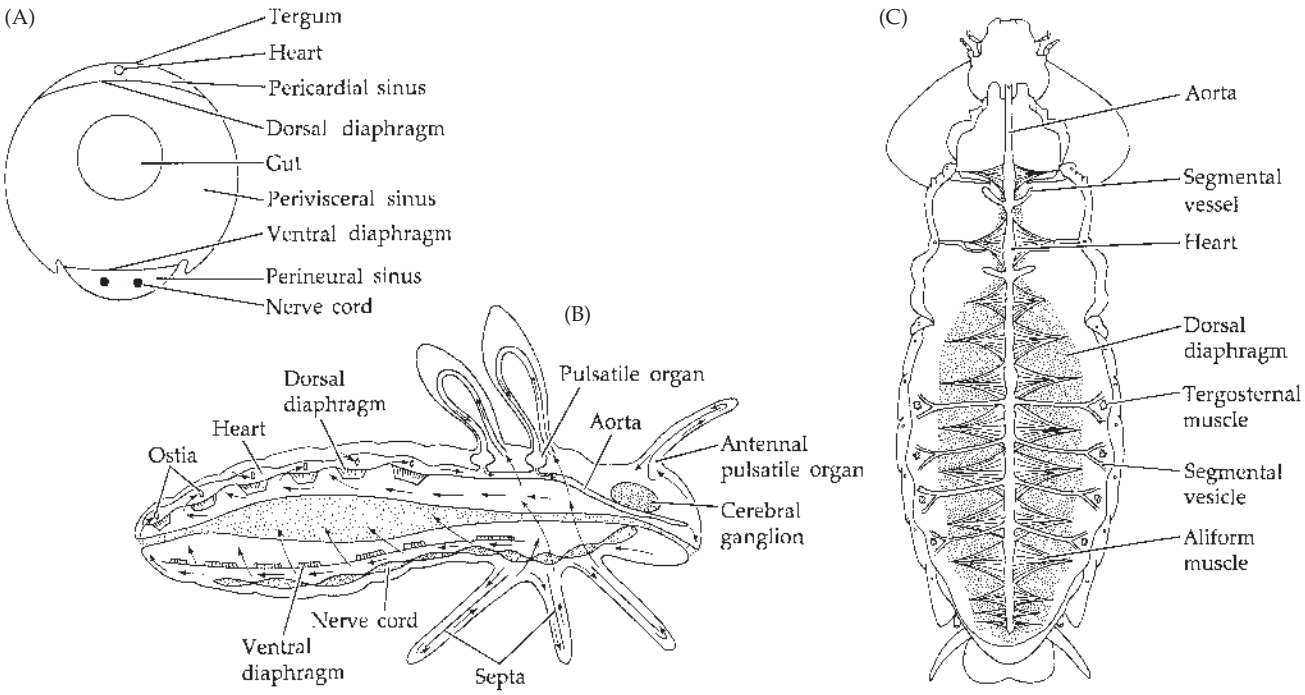

FIGURE 22.28 The circulatory system of insects. (A) An insect abdomen (cross section). Note the division of the hemocoel into three chambers (a dorsal pericardial sinus, a ventral perineural sinus, and a central perivisceral sinus). These chambers are separated by diaphragms lying on frontal planes. (B) Blood circulation in an insect with a fully developed circulatory system (longitudinal section). Arrows indicate the circulatory course. (C) A cockroach (ventral dissection). Note the dorsal and segmental vessels. The dorsal diaphragm and aliform (heart) muscles are continuous over the ventral wall of the heart and vessels, but they are omitted from the diagram for clarity. (B after V. B. Odonata, Hemiptera, and all holometabolous insect orders. The active lifestyles of these terrestrial animals require special structures to carry out the tasks of respiratory gas exchange and excretion. These structures are the tracheal system and the Malpighian tubules, described below.

Desiccation is one of the principal dangers faced by terrestrial invertebrates. Adaptations to terrestrial life always involve some degree of compromise between water loss and gas exchange with the atmosphere. Even though the general body surface of insects may be largely waterproof, the gas exchange surfaces cannot be.

In some minute hexapods, such as Collembola, gas exchange occurs by direct diffusion across the body surface. However, the vast majority of hexapods rely on a tracheal system (Figure 22.29). As explained in Chapter 20, **tracheae** are extensive tubular invaginations of the body wall, opening through the cuticle by pores called spiracles. Up to ten pairs of spiracles can occur on the pleural walls of the thorax and abdomen. Since tracheae are epidermal in origin, their linings are shed with each molt. The cuticular wall of each trachea is sclerotized and usually strengthened by rings or spiral thickenings called **taenidia**, which keep the tube from collapsing but allow for changes in length that may accompany body movements. The tracheae originating at one spiracle commonly anastomose with others to form branching networks penetrating most of the body. In some insects it appears that air is taken into the body through the thoracic spiracles and released through the abdominal spiracles, thus creating a flow-through system.

Each spiracle is usually recessed in an atrium, whose walls are lined with setae or spines (**trichomes**) that prevent dust, debris, and parasites from entering the tracheal tubes (Figure 22.29C). A muscular valve or other closing device is often present and is under control of internal partial pressures of O_2 and CO_2. In resting insects most of the spiracles are generally closed. Ventilation of the tracheal system is accomplished by simple diffusion gradients, as well as by pressure changes induced by the animal itself. Almost any movement of the body or gut causes air to move in and out of some tracheae. Telescopic elongation of the abdomen is used by some insects to move air in and out of the tracheal tubes. Many insects have expanded tracheal regions called tracheal pouches, which function as sacs for air storage.

Because the blood of hexapods does not transport oxygen, the tracheae must extend directly to each organ of the body, where their ends actually penetrate the tissues. Oxygen and CO_2 thus are exchanged directly

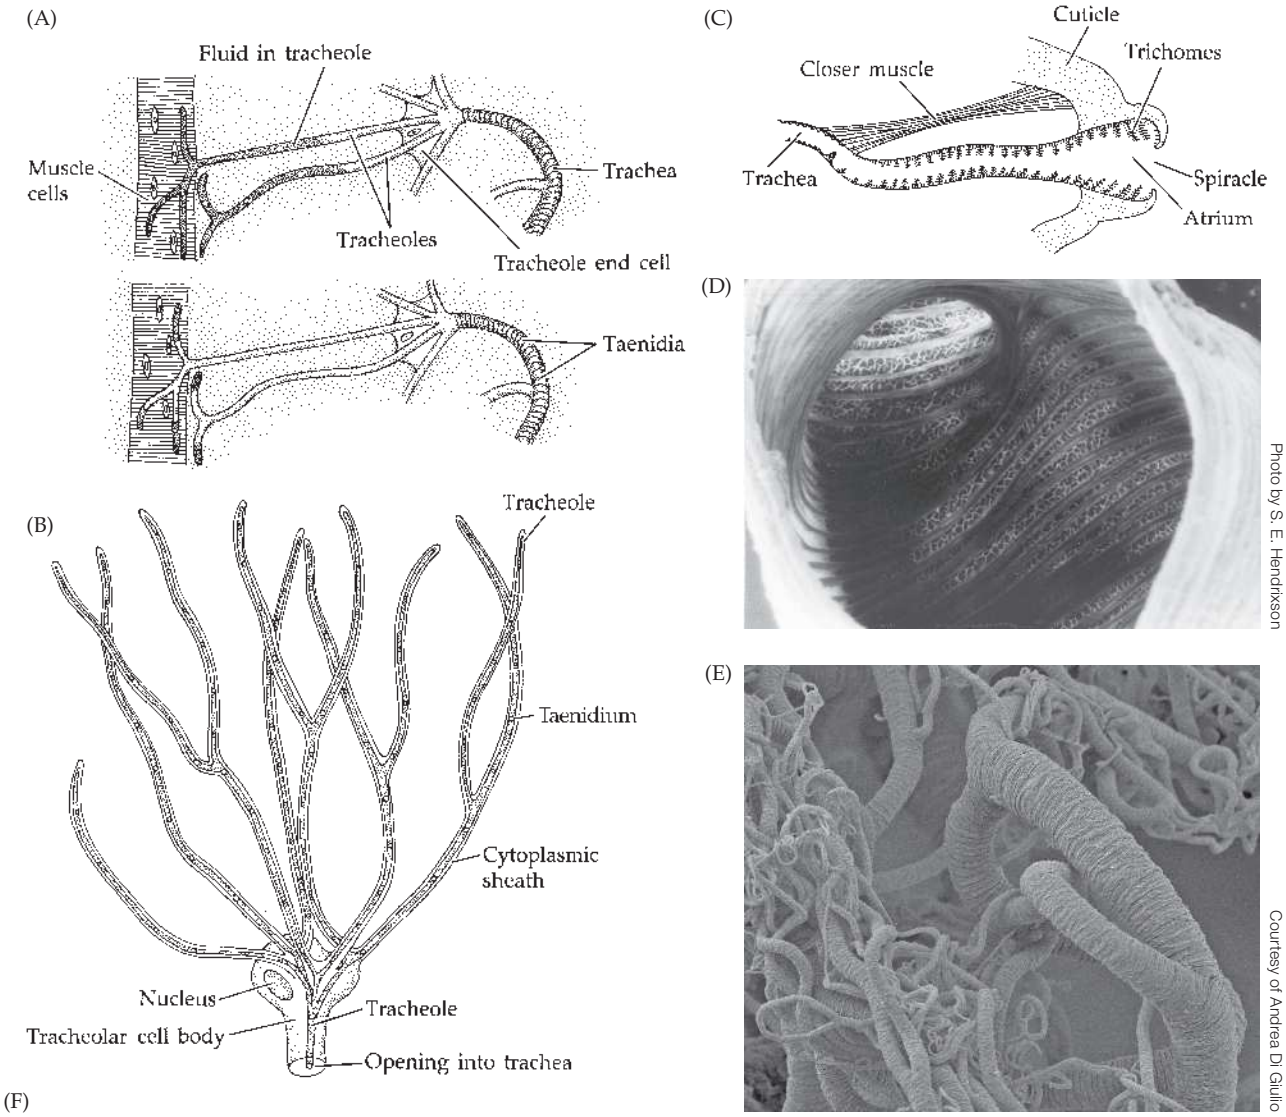

FIGURE 22.29 The tracheal system of insects. (A) Tracheoles and flight muscle cells. Note the region where the tracheoles become functionally intracellular within the muscle fibers. The upper figure depicts a situation in which the muscle cells are well oxygenated, oxygen demand is low, and fluid accumulates in the tracheoles. The lower figure depicts muscle cells that are oxygen deficient. Decreased fluid volumes in the tracheoles allow the tissues increased access to oxygen. (B) A tracheole end cell. The taenidia are rings that serve to keep the lumen of the tracheoles open. (C) A generalized insect spiracle (longitudinal section). Note the dust-catching spines (trichomes) within the atrium. (D) View inside a prothoracic trachea of the honeybee, *Apis mellifera*. (E) SEM of trachea and tracheoles of a carabid beetle. (F) Dragonfly nymph molting into an adult. Note the long white tracheae being pulled out of the exuvia by the emerging adult.

between cells and the small ends of the tracheae, the tracheoles. In the case of flight muscles, where oxygen demand is high, the tracheal tubes invade the muscle fibers themselves. **Tracheoles**, the innermost parts of the tracheal system, are thin-walled, fluid-filled channels that end as a single cell, the tracheole end cell (= tracheolar cell) (Figure 22.29). The tracheoles penetrate every organ in the body. Unlike tracheae, tracheoles are not shed during ecdysis. The tracheoles are so minute (0.2–1.0 μm) that ventilation is impossible, and gas transport here relies on aqueous diffusion. This ultimate constraint on the rate of gas exchange may be the primary reason terrestrial arthropods never achieved extremely large sizes.

FIGURE 22.30 Aquatic nymph of a mayfly, *Paraleptophlebia* (Ephemeroptera), with lateral abdominal gills.

In aquatic insects the spiracles are usually nonfunctional, and gases simply diffuse across the body wall directly to the tracheae. A few species retain functional spiracles; they hold an air bubble over each opening, through which oxygen from the surrounding water diffuses. The air bubbles are held in place by secreted waxes and by patches of hydrophobic hairs in densities that may exceed 2 million per square millimeter. Most aquatic insects, particularly larval stages, have **gills**—external projections of the body wall that are covered by thin, unsclerotized cuticle and contain blood, tracheae, or air bubbles (Figure 22.30). The gills contain channels that lead to the main tracheal system. In some aquatic insects, such as dragonfly nymphs, the rectum bears tiny branched tubules called **rectal accessory gills**. By pumping water in and out of the anus, these insects exchange gases across the increased surface area of the thin gut wall. There are analogous examples of hindgut respiratory irrigation in other, unrelated invertebrate groups (e.g., thalassematids, holothurians).

Excretion and Osmoregulation

The problem of water conservation and the nature of the circulatory and gas exchange systems in terrestrial arthropods necessitated the evolution of entirely new structures to remove metabolic wastes. Like the gas exchange surfaces, the excretory system is a site of potential water loss because nitrogenous wastes initially occur in a dissolved state. These problems are compounded in small terrestrial organisms, such as many hexapods, because of their large surface-area-to-volume ratios. And water loss problems are even more severe in flying insects because flight is probably the most metabolically demanding of all locomotor activities.

In most terrestrial arthropods, the solution to these problems is Malpighian tubules. In the Hexapoda, these unbranched outgrowths of the gut arise near the junction of the midgut and hindgut (Figures 22.26, 22.27, and 22.31). Their blind distal ends extend into the hemocoel and lie among various organs and tissues. Up to several hundred Malpighian tubules may be present.

In the absence of sufficient blood pressure for typical excretory filtration, hexapods use osmotic pressure to achieve the same result. Various ions, especially potassium ions, are actively transported across the Malpighian tubule epithelium from the blood into the tubule lumen (Figure 22.31). The osmotic gradient maintained by this ion transport mechanism enables water and solutes to move from the body cavity into the tubules, and thence into the gut. Water and other metabolically valuable materials are selectively reabsorbed into the blood across the wall of the hindgut, while the Malpighian filtrate left behind is mixed with the other gut contents. Reabsorption of water, amino acids, salts, and other nutrients may be enhanced by the action of special cells in thickened regions called rectal glands. The soluble potassium urate from the Malpighian tubules has, at this point in the gut, been precipitated out as solid uric acid as a result of the low pH of the hindgut (pH 4–5). Uric acid crystals cannot be reabsorbed into the blood; hence they pass out of the gut with the feces. Insects also possess special cells called nephrocytes or pericardial cells that move about in certain areas of the hemocoel, engulfing and digesting particulate or complex waste products.

The hexapod cuticle is sclerotized or tanned to various degrees, adding a small measure of waterproofing. Some insects have mineralized cuticular areas, and one

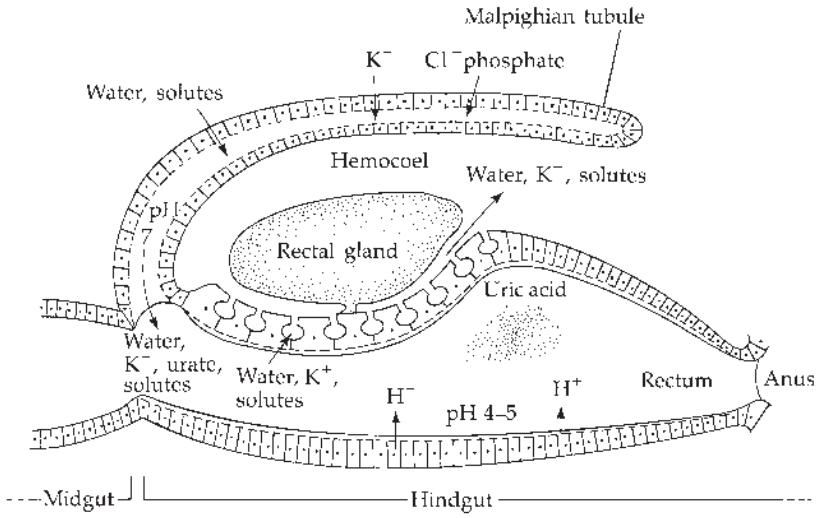

FIGURE 22.31 A single Malpighian tubule opening into the hindgut at its junction with the midgut. Arrows indicate the flow of materials.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

leafcutter ant has been shown to be fully calcified (*Acromyrmex echinatior*). But more importantly, a waxy layer occurs within the epicuticle, which greatly increases resistance to desiccation and frees insects to fully exploit dry environments. In many terrestrial arthropods (including primitive insects) an eversible coxal sac (not to be confused with the coxal glands of arachnids) projects from the body wall near the base of each leg. It is thought that the coxal sacs assist in maintaining body hydration by taking up water from the environment (e.g., dewdrops). Many insects collect environmental water by various other devices. Some desert beetles (Tenebrionidae) collect atmospheric water by "standing on their heads" and holding their bodies up to the moving air so that humidity can condense on the abdomen and be channeled to the mouth for consumption.

Insects that inhabit desert environments have a much greater tolerance of high temperatures and body water loss than do insects in mesic environments, and they are particularly good at water conservation and producing insoluble nitrogenous waste products. They also have behavioral traits, such as nocturnal activity cycles and dormancy periods that enhance water conservation. Upper lethal temperatures for desert species commonly range to 50°C. The spiracles are often covered by setae or depressed below the cuticular surface. Many xeric insects also undergo periods of dormancy (i.e., diapause or aestivation) during some stage of the life cycle, characterized by a lowering of the basal metabolic rate and cessation of movement, which allow them to withstand prolonged periods of temperature and moisture extremes. Some even utilize evaporative cooling to reduce body temperatures. The long-chain hydrocarbons that waterproof the epicuticle also are more abundant in xeric insects.

Nervous System and Sense Organs

The hexapod nervous system conforms to the basic arthropod plan described in Chapter 20 (Figures 22.32 and 22.33). The two ventral nerve cords, as well as the segmental ganglia, are often largely fused. In dipterans, for example, even the three thoracic ganglia are fused into a single mass. The largest number of free ganglia occurs in the primitive wingless insects, which have as many as eight unfused abdominal ganglia. Giant fibers have also been reported from several insect orders.

Like the "brains" of other arthropods, the paired cerebral ganglia of insects comprise three distinct regions: the protocerebrum (which innervates the eyes), the deutocerebrum (innervates the antennae), and the tritocerebrum (which does not innervate any appendages and thus was called the intercalary segment). The subesophageal ganglion is composed of the fused ganglia of the fourth, fifth, and perhaps the sixth head segments and innervates the mouthparts, salivary glands, and some other local musculature.

Insects possess a hypocerebral ganglion between the cerebral ganglion and the foregut. Associated with this ganglion are two pairs of glandular bodies called the **corpora cardiaca** and the **corpora allata** (Figure 22.33). These two organs work in concert with the prothoracic glands and certain neurosecretory cells in the protocerebrum. The whole complex is a major endocrine center that regulates growth, metamorphosis, molting, and other functions (see Chapter 20).

Hexapods typically possess simple ocelli in the larval, juvenile, and often adult stages. When present in adults, they usually form a triad or a pair on the anterodorsal surface of the head. The compound eyes are well developed, resembling those of Crustacea; they are image-forming eyes. Most adult insects have a pair of compound eyes (Figure 22.34), which bulge out to some extent, giving these animals a wide field of vision in almost all directions. Compound eyes are greatly reduced or absent in parasitic groups and in many cave-dwelling forms. The general anatomy of the arthropod compound eye was described in Chapter 20, but several distinct structural trends are found in hexapod eyes, as we describe here.

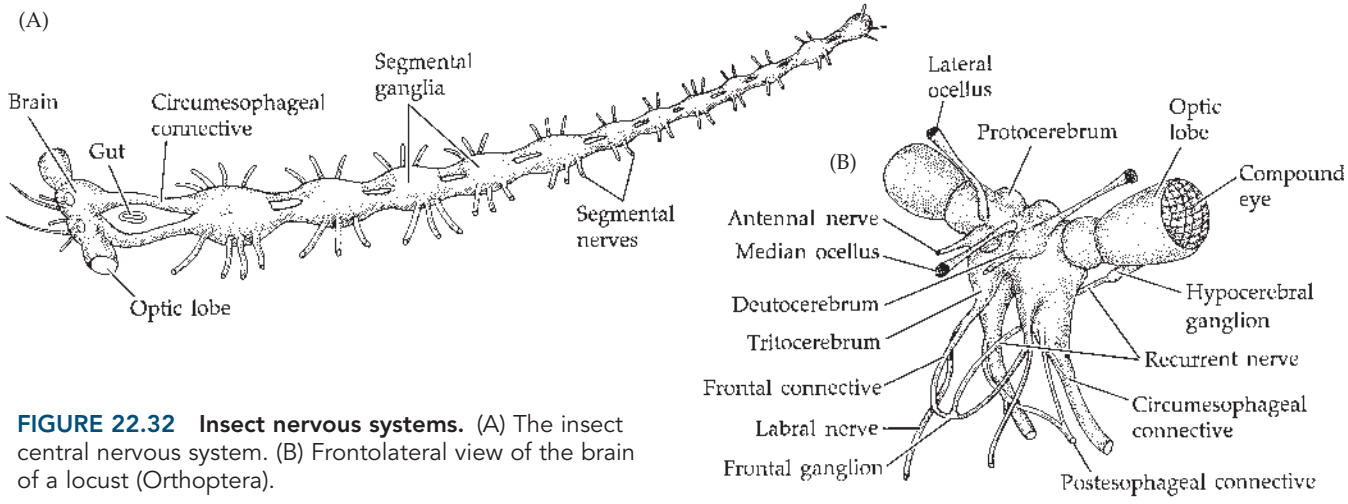

FIGURE 22.32 Insect nervous systems. (A) The insect central nervous system. (B) Frontolateral view of the brain of a locust (Orthoptera).

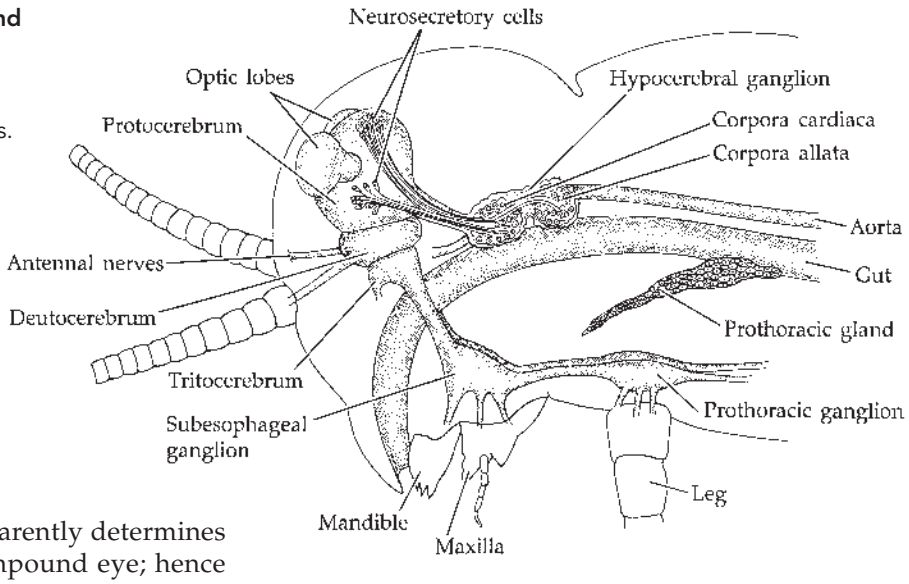

FIGURE 22.33 Endocrine organs and central nervous system in the head and thorax of a generalized insect. These organs all play roles in the control of molting and metamorphosis.

The number of ommatidia apparently determines the overall visual acuity of a compound eye; hence large eyes are typically found on active, predatory insects such as dragonflies and damselflies (order Odonata), which may have over 10,000 ommatidia in each eye. On the other hand, workers of some ant species have but a single ommatidium per eye (ants live in a world of chemical communication)! Similarly, larger facets capture more light and are typical of nocturnal insects. In all cases, a single ommatidium consists of two functional elements: an outer light-gathering part composed of a lens and a crystalline cone, and an inner sensory part composed of a rhabdome and sensory cells (Figure 22.34C).

In some insects the outer surface of the cornea (lens) is covered with minute conical tubercles about 0.2 μm tall and arranged in a hexagonal pattern. It is thought that these projections decrease reflection from the surface of the lens, thus increasing the proportion of light transmitted through the facet. Insect eyes in which the crystalline cone is present are called **eucone eyes** (Figure 22.34B). Immediately behind the crystalline cone (in eucone eyes) are the elongate sensory neurons, or retinular cells. Primitively, each ommatidium probably contained eight retinular cells arising from three successive divisions of a single cell. This number is found in some insects today, but in most it is reduced to six or seven, with the other one or two persisting as short basal cells in the proximal region of each ommatidium. Arising from each retinular cell is a neuronal axon that passes out through the basement membrane at the back of the eye into the optic lobe. There is no true optic nerve in insects; the eyes connect

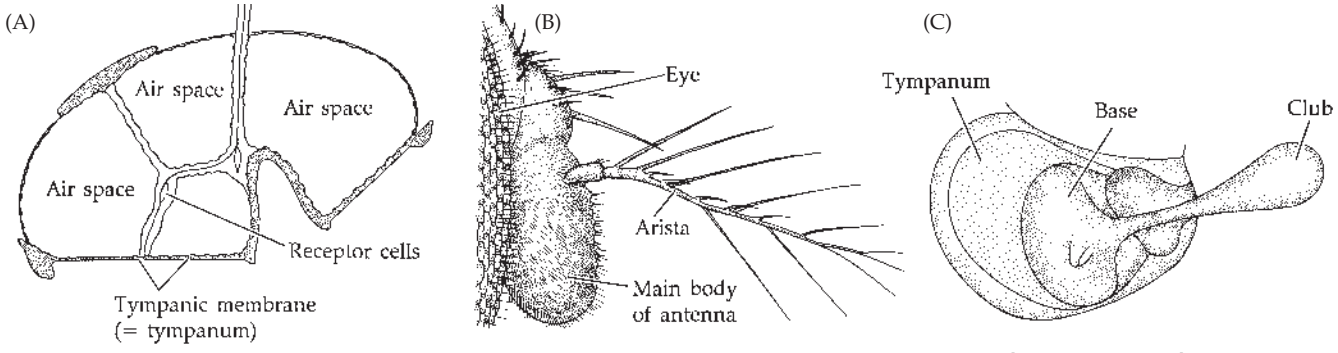
directly with the optic lobe of the brain. The rhabdomeres consist of tightly packed microvilli that are about 50 nm in diameter and hexagonal in cross section. The retinular cells are surrounded by 12 to 18 secondary pigment cells, which isolate each ommatidium from its neighbors.

The general body surface of hexapods, like that of other arthropods, bears a great variety of microscopic sensory setae, known collectively as **sensilla** (sing., sensillum). The incredible diversity of these cuticular surface structures has only begun to be explored, primarily by scanning electron microscopy. Sensilla are most heavily concentrated on the antennae, mouthparts, and legs. Most appear to be tactile or chemosensory. Club-shaped or peg-shaped chemosensory setae, usually called **peg organs** and resembling the aesthetascs of crustaceans, are particularly common on the antennae of hexapods (Figure 22.35).

Insects have internal proprioceptors called **chordotonal organs**. These structures stretch across joints and monitor the movement and position of various body parts. Phonoreceptors also occur in most insect orders. These structures may be simple modified body or appendage setae, or antennae, or complex structures called **tympanic organs** (Figure 22.36). Tympanic organs generally develop from the fusion of parts of a tracheal dilation and the body wall, which form a thin tympanic membrane (= tympanum). Receptor cells in an



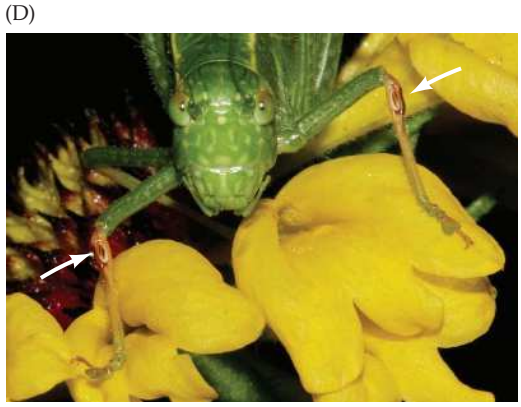


FIGURE 22.36 Insect "ears": insect auditory organs (phonoreceptors) differ widely in their anatomy and location. (A) The "ear" of noctuid moths (Lepidoptera) is a pressure receiver used to detect the ultrasonic cries of hunting bats. It is similar to most insect "ears" in comprising a tympanic membrane backed by a tracheal air space. Two receptor cells attach to the tympanum. (B) In *Drosophila* (Diptera), a feathery seta called an arista arises on the third antennal segment. The arista detects air movements, thus responding to sound through interaction with vibrating air particles. It is used to detect the calling song of the species. (C) In the "ear" of a water boatman (Hemiptera), the tympanum is covered by the base of a club-shaped cuticular body that protrudes outside the body. The club performs rocking movements that allow some frequency analysis of the songs of other water boatmen. (D) Tympani (arrows) on the tibiae of katydid forelegs. (C after J. Prager. 1976. *J Comp Physiol* 110: 33–50. https://link.springer.com/article/10.1007/BF00656780)

underlying air sac, or attached directly to the tympanic membrane, respond to vibrations in much the same fashion as they do in the cochlea of the human inner ear. Many insects can discriminate among different sound frequencies, but others may be tone-deaf. Tympanic organs may occur on the abdomen, the thorax, or the forelegs. Several insects that are prey to bats have the ability to hear the high frequencies of bat echolocation devices, and they have evolved flight behaviors to avoid these flying mammals. For example, some moths, when they hear a bat's echolocation (generally above the range of human ears), will fold their wings and suddenly drop groundward as an evasive maneuver. Praying mantises, whose sonar detection device is buried in a groove on the ventral side of the abdomen, throw out the raptorial forelimbs and elevate the abdomen. These movements cause the insect to "stall" and go into a steep roll, which it pulls out of at the last minute with a "power dive" that effectively avoids bat predators.

Sound communication in insects, like light communication in fireflies (and some ostracods), is a species-specific means of mate communication. Several insect groups (e.g., some orthopterans, coleopterans, dipterans, and hemipterans) possess sound-producing structures. Male flies of the genus *Drosophila* create species-specific mating songs by rapidly vibrating the wings or abdomen. These "love songs" attract conspecific females for copulation. It has been demonstrated that the rhythm of the male's song is encoded in genes inherited from his mother, on the X chromosome, whereas the song's "pulse interval" is controlled by genes on autosomal chromosomes.

Cicadas may possess the most complex sound-producing organs in the animal kingdom (Figure 22.37). The ventral metathoracic region of male cicadas bears two large plates, or opercula, that cover a complex system of vibratory membranes and resonating chambers. One membrane, the tymbal, is set vibrating by special muscles, and other membranes in the resonating chambers amplify the tymbal's vibrations. The sound leaves the cicada's body through the metathoracic spiracle.

Numerous families of beetles and bugs utilize water surfaces as a substratum both for locomotion and for communication by waves or ripples. Such insects produce a signal with simultaneous vertical oscillations of one or more pairs of legs and sometimes also with distinct vertical body motions. The wave patterns produced are species-specific. Potential prey trapped on a surface film may also be recognized in this fashion, just as spiders recognize prey by web vibrations. Limited data suggest that the receptor organs for ripple communication are either specialized sensilla on the legs or special proprioceptors between joints of the legs or antennae, perhaps similar to the tarsal organs of scorpions.

A number of insects are bioluminescent, the most familiar being beetles of the family Lampyridae, known as lightning bugs or fireflies. In the tropics, where they are especially abundant, fireflies are sometimes kept in containers and used as natural flashlights, and women may wrap them in gauze bags worn as glowing hair ornaments. The light of luminescent insects ranges from green through red and orange, depending on the species and the precise chemical nature of the luciferin-luciferase system involved. Light-producing organs are typically composed of clusters of light-producing cells, or **photocytes**, backed by a layer of reflecting cells and covered with a thin, transparent epidermis. The photocytes are richly supplied with tracheae, oxygen being necessary for the chemical reaction. Each species of firefly, and of most other glowing insects, has a distinct flash pattern, or code, to facilitate mate recognition and communication.

One of the most sophisticated communication behaviors among insects may be the famous honeybee "waggle dance." Each day forager bees leave their colony to locate new food sources (e.g., fresh flower blooms). They fly meandering in search forays until a good source is located. Then they return to the hive along a straight flight path (a "bee line"), possibly using memorized ground structure for guidance; while doing so, they are thought to imprint a navigational "map" from the colony to the food source. Most behaviorists believe that this information is communicated to hive mates in a complex tail-wagging dance that allows other bees from the hive to fly directly to the new feeding ground. The forager bee also carries food odors

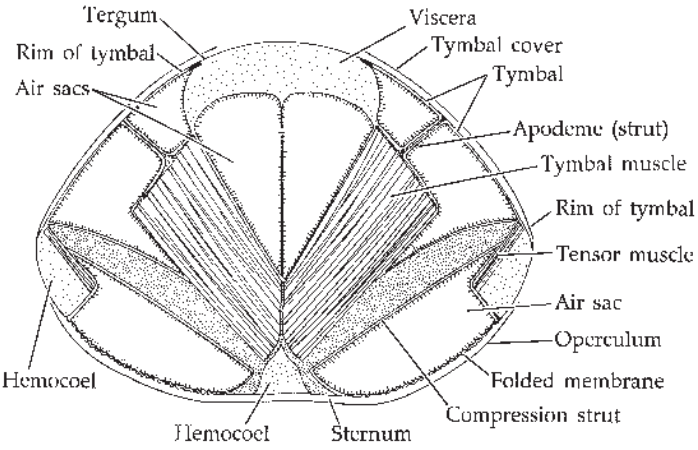

FIGURE 22.37 Sound production structure in cicadas (Hemiptera) from the first abdominal segment (section). Sound is produced by buckling of the tymbal, a thin disc of cuticle. The tymbal muscle is connected to the tymbal by a strut. Contraction of this muscle causes the tymbal to buckle inward, thereby producing a click that is amplified by resonance in the underlying air sacs. On relaxation, the elasticity of the muscle causes the tymbal to buckle out again. On the underside of this abdominal segment, a folded membrane can be stretched to tune the air sacs to the resonant frequency of the tymbal.

(nectar samples), pollen, and various other odors clinging to the hairs on her body. She can also mark the food source with a pheromone produced in a special gland, called the **Nasanov gland**. All of these clues help her hive mates find the new food source. Karl von Frisch was the first person to document all these attributes of bee foraging early in the twentieth century.

A large body of research on bee navigation has accumulated since the pioneering "dancing bee studies" of von Frisch. We now know that honeybees (and solitary bees) have outstanding vision. Much of the bee's daily activity, including navigation and flower recognition, relies strongly on ultraviolet vision. Bees appear to utilize a hierarchical series of flight orientation mechanisms; when the primary mechanism is blocked, a bee can switch to a secondary system. The primary navigation system utilizes the pattern of polarized ultraviolet sunlight in the sky. This pattern depends on the location of the sun as determined by two coordinates, the azimuth and the elevation. Bees and many other animals that orient to the sun have a built-in ability to compensate for both hourly changes (elevation) and seasonal changes (azimuth) in the sun's position with time. On cloudy days, when the sun's light is largely depolarized, bees cannot rely on their ultraviolet celestial navigation mechanism and thus may switch to their second-order navigational system: navigation by landmarks (foliage, rocks, and so on) that were imprinted during the most recent flight to the food source. Limited evidence suggests that some form of tertiary backup system may also exist.

Thus, if the honeybee dance model is correct,[7] honeybees must simultaneously process information concerning time, the direction of flight relative to the sun's azimuth, the movement of the sun, the distance flown, and local landmarks (not to mention complications due to other factors, such as crosswinds) and in doing so reconstruct a straight-line heading to inform their hive mates. If recent evidence is correct, bees (like homing pigeons) may also detect Earth's magnetic fields with iron compounds (magnetite) located in their abdomens. Bands of cells in each abdominal segment of the honeybee contain iron-rich granules, and nerve branches from each segmental ganglion appear to innervate these tissues.[8]

In some insects the ocelli are the principal navigation receptors. Some locusts and dragonflies and at least one ant species utilize the ocelli to read compass information from the blue sky. As in bees, the pattern of polarized light in the sky seems to be the main compass cue. In some species, both ocelli and compound eyes may function in this fashion. Many (probably most) insects also see ultraviolet light.

Perhaps the most famous insect navigators are North America's monarch butterflies (*Danaus plexippus*). Each autumn, monarchs migrate up to 4,000 km from breeding grounds in the eastern United States and Canada to overwintering sites in the mountains of Michoacán, in central Mexico (one of two major migratory populations in North America, both of which are threatened by habitat loss). They make this remarkable journey by orienting with a sun compass, using the sun's changing azimuth (and knowledge of the relative time of day) to direct their movements. On cloudy days, when a precise solar azimuth is unobtainable, monarchs still manage to orient towards the south-southwest, suggesting that they also have a backup mechanism of orientation, such as a geomagnetic compass. Monarchs are one of a small group of animal species for which a sun compass orientation mechanism has been shown to exist. Not all monarchs migrate, and many resident year-round breeding populations are established throughout the Americas. Less well understood are the migrations of dragonflies, some of which exceed that of monarchs in distance traveled.

Many insects release noxious quinone compounds to repel attacks. Perhaps best known in this regard are certain Tenebrionidae, many of which stand on their heads to do so. But the champions of this chemical warfare strategy are definitely the bombardier beetles, members of the carabid subfamilies Brachininae and Paussinae, which expel quinone compounds at temperatures reaching 100°C (Figure 22.7C).

Reproduction and Development

Reproduction Hexapods are dioecious, and most are oviparous. A few insects are ovoviviparous, and many can reproduce parthenogenetically. Most insects rely on direct copulation and insemination. Reproductively mature insects are termed adults or **imagos**. Female imagos have one pair of ovaries, formed of clusters of tubular ovarioles (Figure 22.38A). The oviducts unite as a common duct before entering a genital chamber. Seminal receptacles (spermathecae) and accessory glands also empty into the genital chamber. The genital chamber opens, via a short **copulatory bursa** (= vagina), on the sternum of the eighth, or occasionally the seventh or ninth, abdominal segment. The male reproductive system is similar, with a pair of testes, each formed by a number of sperm tubes (Figure 22.38B). Paired sperm ducts dilate into seminal vesicles (where sperm are stored) and then unite as a single ejaculatory duct. Near this duct, accessory glands discharge seminal fluids into the reproductive tract. The lower end of the ejaculatory

[7] The honeybee dance hypothesis is not without its detractors, and some workers doubt its existence altogether; see the General References section for this chapter for a glimpse at the history of the honeybee dance controversy.

[8] Many animals possess magnetotactic capabilities, including some molluscs, hornets, salmon, tuna, turtles, salamanders, homing pigeons, cetaceans, and humans. Magnetotactic bacteria also exist, which swim to the north in the Northern Hemisphere, to the south in the Southern Hemisphere, and in both directions at the geomagnetic equator. In all these cases, iron oxide crystals in the form of magnetite have been shown to underlie the primary detection devices. However, in honeybees, the iron-containing structures are trophocytes that contain paramagnetic magnetite. These magnetotactic trophocytes surround each abdominal segment and are innervated by the central nervous system.

duct is housed within a penis, which extends posteroventrally from the ninth abdominal sternite.

Courtship behaviors in insects are extremely diverse and often quite elaborate, and each species has its own recognition methods. Courtship may consist of simple chemical or visual attraction, but more typically it involves pheromone release, followed by a variety of displays, tactile stimulation, songs, flashing lights, or other rituals that may last for hours. The subject of insect courtship is a large and fascinating study of its own. Although the field of pheromone biology is still in its infancy, sexual attractant or aggregation pheromones have been identified from about 500 different insect species (about half of which are synthesized and sold commercially for pest control purposes).

Most insects transfer sperm directly as the male inserts either his **aedeagus** (Figure 22.38B,D) or a gonopod into the genital chamber of the female. Special abdominal claspers, or other articulated cuticular structures on the male, often augment his copulatory grip. Such morphological modifications are species specific and thus serve as valuable recognition characters, for both insect mates and insect taxonomists. Copulation often takes place in midflight. In some of the primitive wingless insects, and in the Odonata, sperm transfer is indirect. In these cases, a male may deposit his sperm on specialized regions of his body to be picked up by the female; or he may simply leave the sperm on the ground, where they are found and taken up by females. In bedbugs (order Hemiptera, family Cimicidae) males use the swollen penis to pierce a special region of the female's body wall; sperm are then deposited directly into an internal organ (**the organ of Berlese**). From there they migrate to the ovaries, where fertilization takes place as eggs are released.

Sperm may be suspended in an accessory gland secretion, or, more commonly, the secretion hardens around the sperm to produce a spermatophore. Females of many insect species store large quantities of sperm within the spermathecae. In some cases sperm from a single mating is sufficient to fertilize a female's eggs for her entire reproductive lifetime, which may last a few days to several years.

Insect eggs are protected by a thick membrane (the chorion) produced within the ovary. Fertilization occurs as the eggs pass through the oviduct to be deposited. Accessory glands contribute adhesives or secretions that harden over the zygotes. In many species, cuticular extensions around the gonopore of the female form an **ovipositor** (Figure 22.38C), with which she places the eggs in a brooding site that will afford suitable conditions for the young once they hatch (such as in a shallow underground chamber, in a plant stem, or within the body of a host insect). Although 50–100 eggs are usually laid at a time, as few as one and as many as several thousand are deposited by some species. The volume of eggs scales up to eight

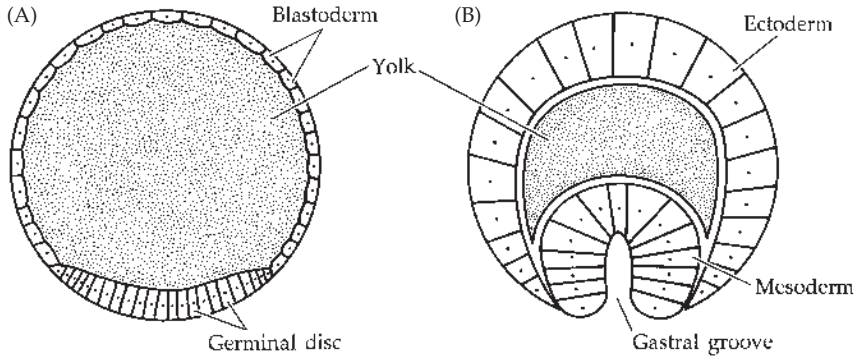

FIGURE 22.39 Early stages of insect development. (A) The blastoderm (blastula) of a generalized insect, subsequent to cytokinesis (cross section). Note the thickened germinal disc. (B) An early gastrula of a honeybee (cross section). Note the gastral groove and the proliferation of mesoderm.

orders of magnitude across insect groups, the smallest being those of the parasitoid wasp *Platygaster vernalis* (volume = 7×10^{-7} mm^3) and the largest those of the earth-boring beetle *Bolboleaus hiaticollis* (volume = 5×10^2 mm^3). Some insects, such as cockroaches, enclose several eggs at a time in a protective egg case.

Parthenogenesis is common in a variety of insect groups. It is used as an alternative form of reproduction seasonally by a number of insect taxa, particularly those living in unstable environments. In the Hymenoptera (bees, wasps, ants), it is also used as a mechanism for sex determination. In these cases, diploid fertilized eggs become females, and haploid unfertilized eggs develop into males. Infections by the bacterium *Wolbachia*, a frequent parasite of arthropod reproductive systems, are known to affect reproduction in many insect species. In some cases, infections result in infertility, whereas in others they transform males into functional females. But in some wasp species, *Wolbachia* infections eliminate males altogether by disrupting the first cell division of the egg, resulting in diploid eggs that can develop only as females—thus creating parthenogenetic strains of normally sexual wasps. Such asexual strains of wasps will revert back to dioecy if the *Wolbachia* dies out.[9]

Embryology As discussed in Chapter 20, the large centrolecithal eggs of arthropods are often very yolky, a condition resulting in modifications of the cleavage pattern. Most hexapods undergo meroblastic cleavage by way of intralecithal nuclear divisions, followed by migration of the daughter nuclei to the peripheral cytoplasm (= periplasm). Cytokinesis does not occur during these early nuclear divisions (up to 13 cycles), which thus generate a syncytium, or plasmodial phase of embryogenesis. The nuclei continue to divide until the periplasm is dense with nuclei, whereupon a syncytial blastoderm exists. Eventually, cell membranes begin to form, partitioning uninucleate cells from one another. At this point the embryo is a periblastula, comprising a yolky sphere containing a few scattered nuclei and covered by a thin cellular layer (Figure 22.39).

Along one side of the blastula a patch of columnar cells forms a germinal disc, sharply marked off from the thin cuboidal cells of the remaining blastoderm (Figure 22.39A). From specific regions of this disc, presumptive endodermal and mesodermal cells begin to proliferate as germinal centers. These cells migrate inward during gastrulation to lie beneath their parental cells, which now form the ectoderm. The mesoderm proliferates inward as a longitudinal gastral groove (Figure 22.39B). The cells of the developing gut usually surround and gradually begin absorbing the central yolky mass of the embryo, and paired coelomic spaces appear in the mesoderm.

As segments begin to demarcate and proliferate, each receives one pair of mesodermal pouches and eventually develops appendage buds. As the mesoderm contributes to various organs and tissues, the paired coelomic spaces merge with the small blastocoel to produce the hemocoelic space. The mouth and anus arise by ingrowths of the ectoderm that form the proctodeal foregut and hindgut, which eventually establish contact with the developing endodermal midgut.

Polyembryony occurs in a number of insect taxa, particularly parasitic Hymenoptera. In this form of development the early embryo splits to give rise to more than one developing embryo. Thus, from two to thousands of larvae may result from a single fertilized egg, which is often deposited in the body of another (host) insect.

Postembryonic development Within Hexapoda there are three main types of development: **ametabolous** (= direct, amorphic, or ametamorphic development), **hemimetabolous**, and **holometabolous** (indirect or complete metamorphosis). Figure 22.40 depicts these development types. Species in the most primitive wingless hexapod orders (entognathans, archaeognathans, and zygentomans) undergo ametabolous development. The young hatch out as juveniles closely resembling the adult, imago condition, but the overall body size increases with each successive molt. Winged insects undergo either hemimetabolous development

[9] *Wolbachia pipientis* are maternally transmitted, gram-negative, obligate intracellular bacteria found in filarial nematodes, crustaceans, arachnids, and at least 20% of all insect species. Many *Wolbachia* increase their prevalence in populations by manipulating host reproductive systems.

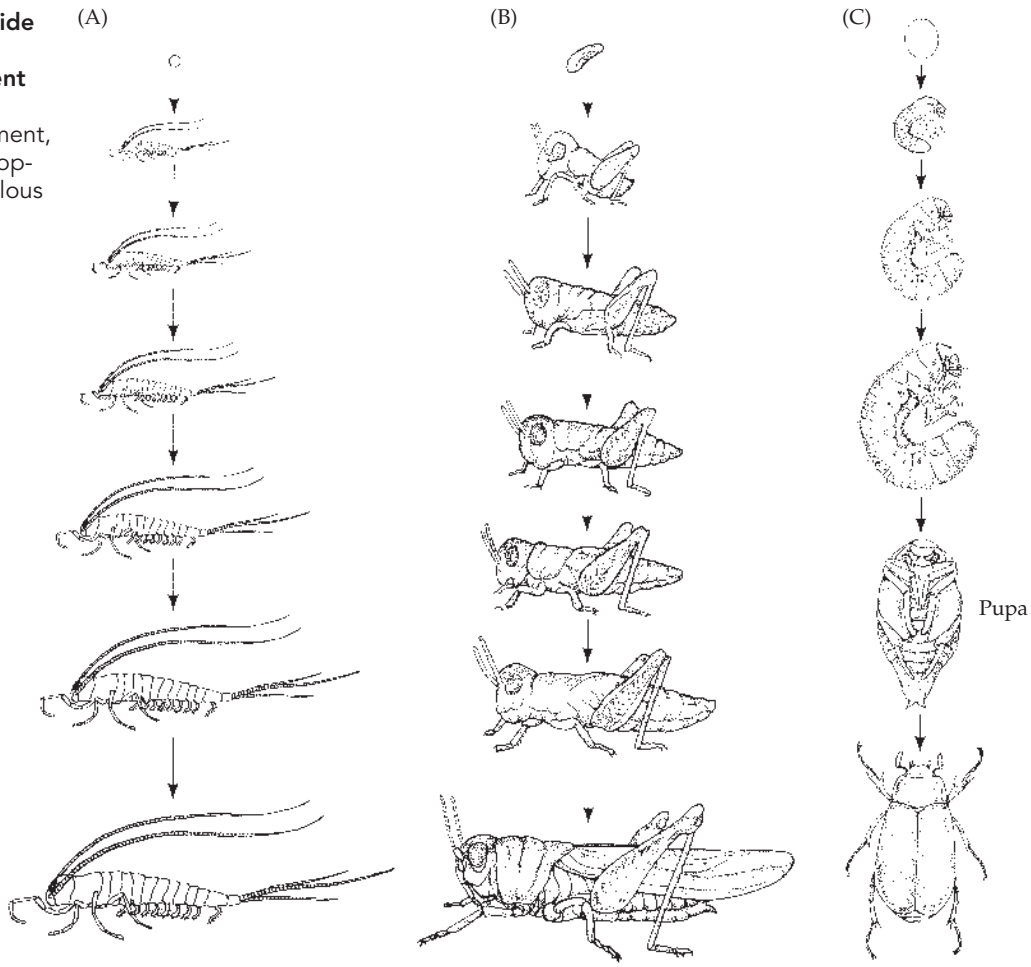

FIGURE 22.40 Side-by-side comparison of the three main types of development found in hexapods. (A) Ametabolous development, (B) hemimetabolous development, and (C) holometabolous development.

(Figures 22.40B and 22.41) or holometabolous development (Figures 22.40C and 22.42).

In hemimetabolous development, principal changes during growth are primarily in body size and proportions and in the development of wings and sexual structures. The juveniles of hemimetabolous insects are often called **nymphs** (terrestrial juveniles) or **naiads** (aquatic juveniles). Naiads occur in Plecoptera (stoneflies), Odonata (dragonflies and damselflies), and Ephemeroptera (mayflies), and they differ from other hemimetabolous groups in that these juveniles are quite different from the adult in body type and habitat. Nymphs and adults often live in the same general habitat; naiads and their respective adults do not. Nymphs and naiads possess compound eyes, antennae, and feeding and walking appendages similar to those of the adults. However, functional wings and sexual structures are always lacking, although juveniles have wing rudiments called wing pads or wing buds, and the wings themselves become exposed for the first time during the preadult molt.

Holometabolous insects hatch as vermiform larvae that bear no resemblance whatsoever to the adult forms. These larvae are so different from adults that they are often given separate vernacular names; for example, butterfly larvae are called caterpillars, fly larvae maggots, and beetle larvae grubs. Holometabolous larvae lack compound eyes (and often antennae), and their natural history differs markedly from that of adults. Their mouthparts may be wholly unlike those of adults, and external wing buds are never present. Often the greater part of a holometabolous insect's lifetime is spent in a series of larval instars. Larvae typically consume vast quantities of food and attain a larger size than adults. Termination of the larval stage is accompanied by **pupation**, during which (in a single molt) the pupal stage is entered (Figures 22.42 and 22.43). **Pupae** do not feed or move about very much. They often reside in protective niches in the ground, within plant tissues, or housed in a **cocoon**. Energy reserves stored during the long larval life are utilized by the pupa to undergo wholesale body transformation. Many larval tissues are broken down and reorganized to attain the adult form; external wings and sexual organs are formed. The remarkable transformation from larval stage to adult stage in holometabolous insects is one of the most impressive achievements of animal evolution (Figure 22.42). The opening photo of this chapter features the moth, *Rothschildia cincta*, taken soon after it eclosed from its silken cocoon, upon which

FIGURE 22.41 Illustrations and photo of the life stages of milkweed bugs (Hemiptera), illustrating the main life stages of hemimetabolous development. Note the wing pads in instars 3–5. (After S. Reynolds.2013. In R. F. Chapman et al. [Eds.], *The Insects*, 5th Ed., pp. 398–459. Cambridge University Press, Cambridge.)

it rests after undergoing one of the most amazing transformations known.[10]

The role of ecdysone in initiating molting is described in Chapter 20. This hormone works in conjunction with a second endocrine product in controlling the sequence of events in insect metamorphosis. This second product, juvenile hormone, is manufactured and released by the corpora allata associated with the brain (Figure 22.33). When ecdysone initiates a molt in an early larval instar, the accompanying concentration of juvenile hormone in the hemolymph is high. A high concentration of juvenile hormone ensures a larva-to-larva molt. After the last larval instar is reached, the corpora allata ceases to secrete juvenile hormone. Low concentrations of juvenile hormone result in a larva-to-pupa molt. Finally, when the pupa is ready to molt,

[10]Dancers in some Native American tribes in northwestern Mexico and the southwestern United States create ankle rattles by adding small rocks inside dry *Rothschildia cincta* cocoons, which they string together and around their legs.

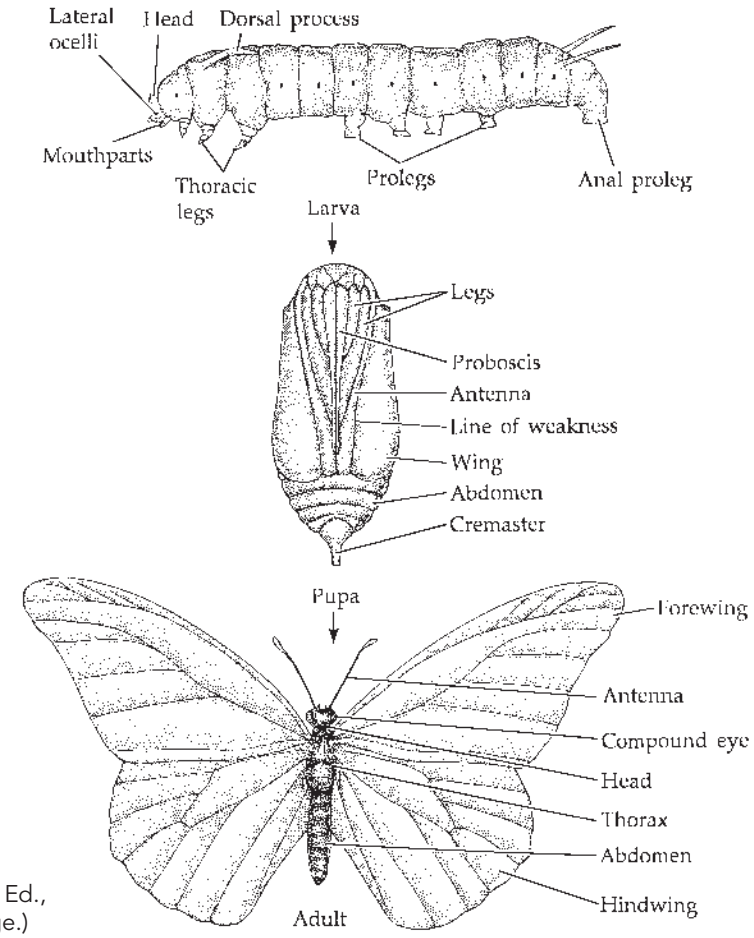

FIGURE 22.42 Life stages of a butterfly (Lepidoptera), illustrating the main life stages of holometabolous development. (After S. Reynolds. 2013. In R. F. Chapman et al. [Eds.], *The Insects*, 5th Ed., pp. 398–459. Cambridge University Press, Cambridge.)

juvenile hormone is absent from the hemolymph altogether; this deficiency leads to a pupa-to-adult molt. There is recent evidence that Hox genes (e.g., *Scr*) can control the number of larval molts, suggesting that such genes could underlie the evolution of life history traits in insects.

Hexapod Evolution

Hexapods (and arachnids and myriapods) were among the earliest animals to colonize and exploit terrestrial and freshwater ecosystems. The fossil record is good, with about 1,263 recognized families (by comparison, there are 825 recognized fossil families of tetrapod vertebrates). The oldest known fossil hexapods are from the Early Devonian (Pragian) Rhynie chert, which has led to the hypothesis that hexapods originated in the late Silurian with the earliest terrestrial ecosystems. The remarkable diversification of insects is undoubtedly related to the evolution of wings, and insects are the only group of invertebrates with the ability to fly. Whole genome duplications have also occurred in at least 14 hexapod orders (e.g., Lepidoptera, Odonata, Trichoptera), and these have likely contributed to insect radiations. Fossil winged insects exist from the Late Mississippian (~324Ma), which suggests a Carboniferous origin of insect flight. However, the description of *Rhyniognatha* (~412 Ma) from a mandible, potentially indicative of a winged insect, suggests a late Silurian to Early Devonian origin of winged insects. Divergence time estimates based on a molecular phylogenetic analysis of many nuclear, protein-coding genes (Misof et al. 2014) corroborate an origin of winged insect lineages during this time period, which implies that the ability to fly emerged soon after the establishment of complex terrestrial ecosystems. Since then, insects have shaped Earth's terrestrial ecosystems, coevolving with another hyperdiverse terrestrial group, the flowering plants, ultimately qualifying the Cenozoic to be called "the age of insects."

By the Carboniferous, various modern insect orders were flourishing, although many were quite unlike today's fauna. Some Carboniferous hexapods are notable for their gigantic size, such as silverfish (Zygentoma) that reached 6 cm in length and dragonflies (Odonata) with wingspans of about 70 cm. In addition to the living orders of insects, at least ten other orders arose and radiated in late Paleozoic and early Mesozoic times, then went extinct.

The Permian saw an explosive radiation of holometabolous insects, although many groups went extinct in the great end-Permian extinction event (Chapter 1). In fact, relatively few groups of Paleozoic insects survived into the Mesozoic, and many recent families first appeared in the Jurassic. By the Cretaceous, most modern families were extant, insect sociality had evolved, and many insect families had begun their intimate relationships with angiosperms. Tertiary insects were essentially modern and included many genera indistinguishable from the Recent (Holocene) fauna.

Our current view of the evolutionary relationships of hexapod orders is presented in Figure 22.44. This

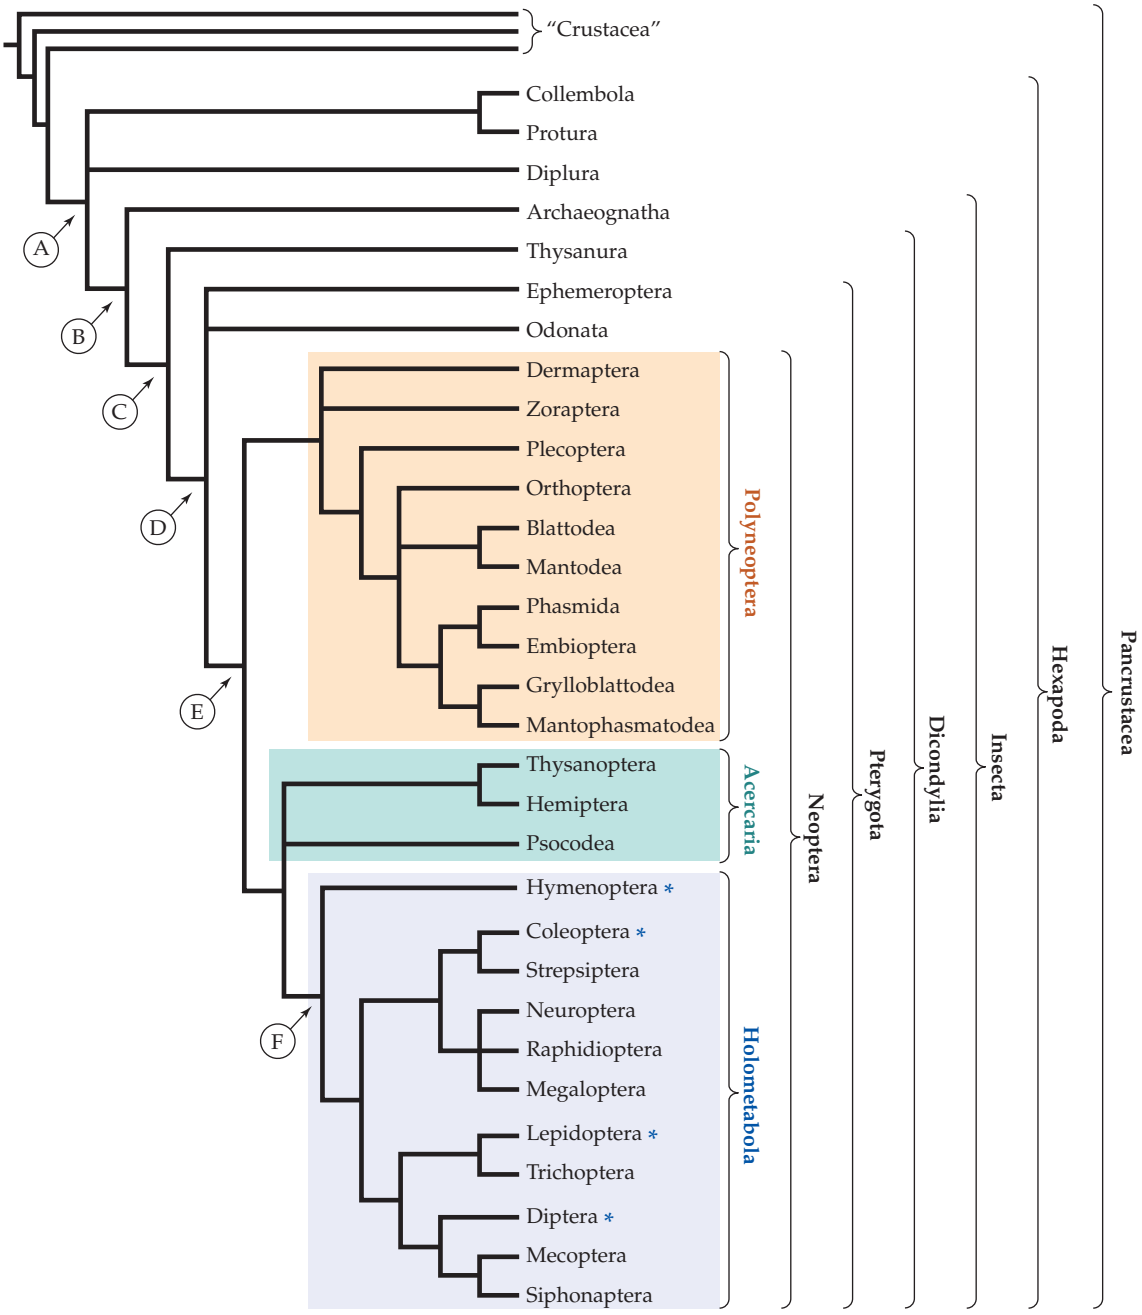

FIGURE 22.44 Phylogeny of the 31 orders of Hexapoda. Major clades are indicated to the right of the tree. The most recent common ancestor of extant taxa with traits that led to the success of the Hexapoda are denoted with circled letters to the left of the tree. These key innovations include (A) arthropod body subdivided into three tagmata: the head, 3-segmented thorax with one pair of uniramous legs on each segment, and an 11-segmented abdomen (synapomorphies of Hexapoda); (B) the evolution of external mouthparts (an apomorphy of the class Insecta); (C) the evolution of dicondylic mandibles (an apomorphy of the Dicondylia); (D) the evolution of wings (an apomorphy of Pterygota); (E) the evolution of wing folding (an apomorphy of Neoptera); (F) the evolution of holometabolous development, or complete metamorphosis (an apomorphy of the Holometabola). The most diverse insect orders, commonly known as the "big four," are denoted with asterisks. Crustacea, a paraphyletic group due to its exclusion of the Hexapoda, is shown at the base of the tree.

tree is based on Misof et al. (2014), presenting a molecular phylogenetic analysis of 1,478 single-copy nuclear, protein-coding genes (see Chapter 2 for detailed tree with divergence time estimates). This continues to be the most data-rich analysis of the hexapods conducted to date. The results of this analysis support many of the long-held views of hexapod evolution but also provide novel support for some parts of the tree that had been difficult to resolve based on smaller molecular sets and by analyses of morphological characters alone. As noted in Chapter 20, recent phylogenomic analyses suggest the Hexapoda and remipede crustaceans are sister groups.

The hexapods are divided between three entognathous orders and the Insecta. The three entognathous

orders (the Collembola, Protura, and Diplura) all have internalized mouthparts. Most current workers regard the Collembola + Protura to be a monophyletic group (called the Ellipura), and this relationship is strongly supported by the most recent analyses. However, whether the Diplura are more closely related to the Collembola + Protura or to the Insecta (a view persuasively argued by Kukalová-Peck) remains hotly debated, with recent analyses favoring the latter (e.g., Schwentner et al., 2017). Thus, the entognathous hexapods may or may not form a monophyletic group. Among the potential synapomorphies that may unite all three orders is entognathy itself (the overgrowth of the mouthparts by oral folds from the lateral cranial wall). In addition, the Malpighian tubules and compound eyes are reduced—compound eyes are degenerate in Collembola and absent in the extant Diplura and Protura. However, these reductions could be convergences resulting from small body size. Our evolutionary tree thus depicts an unresolved trichotomy at the base of the Hexapoda, and we treat the entognathous hexapods as a potentially paraphyletic group in our classification.

The monophyly of the Insecta (Archaeognatha, Zygentoma, and Pterygota) (Figure 22.44, node B) is undisputed. The principal synapomorphies of this group include the structure of the antenna, with its lack of muscles beyond the first segment (scape); the presence of a group of special chordotonal organs (vibration sensors) in the second antennal segment (pedicel) called the Johnston's organ; a well-developed posterior tentorium (forming a transverse bar); subdivision of the tarsus into tarsomeres; females with ovipositor formed by gonapophyses (limb-base endites) on segments 8 and 9; and long, annulated, posterior terminal filaments (cerci).

The Insecta have traditionally been divided into the wingless insects (Archaeognatha and Zygentoma) and the winged insects (Pterygota). However, on the basis of molecular studies and the presence of a dicondylic mandible, the Zygentoma (silverfish) are now thought to be the sister group of the Pterygota. They are classified together in a lineage known as the Dicondylia (see Figure 22.44, node C).

The Pterygota are, of course, distinguished by the presence of wings on the mesothorax and metathorax of adults. There is wide agreement that wings evolved only once in Hexapoda along the branch leading to the Pterygota (Figure 22.44, node D). However, the Pterygota comprise two groups, Palaeoptera and Neoptera, with fundamentally different wing types. The Palaeoptera ("ancient wings") include the Odonata (dragonflies and damselflies) and Ephemeroptera (mayflies), which are characterized by many-veined, netlike wings that cannot be folded over the back. It is still unclear whether or not the two palaeopterous orders, Ephemeroptera and Odonata, form a monophyletic group, and they are therefore depicted in a trichotomy with Neoptera in our summary tree (Figure 22.44, node D). The Neoptera ("modern wings") have reduced wing venation, but more importantly, they can rotate their wing joint and fold back their wings when they are not flying (Figure 22.44, node E). This is one of the most important evolutionary innovations in hexapods. Wing folding allows insects to protect their fragile wings, especially from abrasion, thereby allowing them to live in tight spaces such as crevices under bark, under rocks, and in burrows, nests, and tunnels.

The Neoptera is divided into three broad groups: Polyneoptera (10 orders); Acercaria, or Paraneoptera (3 orders); and the Holometabola, or Endopterygota (11 orders). Polyneopterans are a morphologically diverse group of insects with biting-chewing mouthparts and hemimetabolous development. The phylogenetic relationships among the orders within Polyneoptera, and the monophyly of the group itself have long been controversial. However, recent phylogenomic work recovered strong support that the polyneopteran orders form a monophyletic group.

The Acercaria includes the Thysanoptera, Hemiptera, and the Psocodea. Supported by many derived characters, the monophyly of this group is likely (but controversial), since Misof et al. (2014) found evidence that the Psocodea may be the sister group to Holometabola. Although this relationship appears to be well supported by their analyses (see Figure 2.6) with high bootstrap support values, this measure of support is of controversial utility for such large molecular data sets.

The monophyly of the Holometabola is well established. The 11 orders placed together in the Holometabola are united on the basis of holometabolous development (Figure 22.44, node F). The eminent success of the holometabolous lifestyle is demonstrated by the fact that holometabolous species outnumber hemimetabolous species ten to one. The most species-rich insect orders (Hymenoptera, Coleoptera, Lepidoptera, and Diptera), commonly known as the "big four," all undergo complete (holometabolous) metamorphosis. There is a popular theory among evolutionary biologists that views indirect development, including holometabolous development in insects, as selectively advantageous because it results in the ecological segregation of adults from young, thus avoiding intraspecific competition and allowing each stage to develop its own suite of specific survival strategies. We have seen that such transformations in development are common in marine and some freshwater invertebrates, but only the insects have managed to exploit this strategy so successfully on land.

Chapter Summary

This chapter described the vast world of Hexapoda—the insects (Ectognatha) and three small orders of hexapods with internal mouthparts (Collembola, Protura, and Diplura). With nearly a million described hexapod species, and 10 to 100 times that number of undescribed species, we have only scratched the surface of hexapod diversity and biology. All hexapods have a distinct body plan comprising a head, a 3-segmented thorax, an abdomen of 11 (or fewer in groups with a reduced abdomen) segments, three pairs of thoracic legs, a single pair of antennae, three sets of "jaws" (mandibles, maxillae, and labium), an aerial gas exchange system composed of tracheae and spiracles, Malpighian tubules formed as proctodeal (ectodermal) evaginations, and, in the subclass Pterygota, wings. No other group of arthropods has a thorax fixed at 3 segments, each with a pair of walking legs, nor do any other invertebrates have wings. Hexapods are an ancient group, their origin likely being in the Lower Ordovician. Insects are not only extremely diverse, but also incredibly abundant in the terrestrial world. Insects coevolved with flowering plants, and many wild species of plants rely on them for pollination (as do about 80% of the world's crop species). Of the 31 recognized orders of Hexapoda, several stand out as megadiverse and are known among entomologists as "the big four": Coleoptera (beetles) with 387,100 described species, Diptera (flies) with 159,295 species, Lepidoptera (butterflies and moths) with 157,402 species, and Hymenoptera (bees and wasps) with 115,000 species. Within Hexapoda there are three main types of development: ametabolous (direct, or amorphic development), hemimetabolous, and holometabolous (indirect, or complete development, with distinct larval stages that undergo pupation to adulthood). Hexapods arose from a crustacean ancestor (thus making the Crustacea paraphyletic if the hexapods are excluded), and the two subclasses together comprise the Pancrustacea; Pancrustacea and Myriapoda together comprise the clade Mandibulata.

CHAPTER 23

Phylum Arthropoda

Subphylum Myriapoda: Centipedes, Millipedes, and Their Kin

The arthropod subphylum Myriapoda includes four groups traditionally ranked as classes: Chilopoda (centipedes), Diplopoda (millipedes), Pauropoda (pauropods), and Symphyla (symphylans). All modern myriapods are terrestrial, but the lineage probably began its evolution in the aquatic realm. Although molecular clock phylogenies suggest a late Cambrian (500 Ma) monophyletic origin for the Myriapoda, the first fossil record of millipedes is from the Late Ordovician or early Silurian, and these are thought to represent marine species. The oldest reliable terrestrial myriapod fossils date only from the late Silurian (~425 Ma). Figure 23.1 illustrates a variety of myriapod types. More than 16,000 living species have been described so far.

Centipedes and millipedes are familiar arthropods, easily distinguished from all other terrestrial invertebrates by a body divided into just two tagmata, the head and the long, homonomous, and many-segmented trunk bearing many pairs of jointed legs. As in the Hexapoda, the head is equipped with one pair of antennae. The mouthparts are represented by the mandibles and the first maxillae; a second pair of maxillae is present in the centipedes and symphylans, but in millipedes and pauropods the corresponding segment bears no appendages.

Millipedes are slow-moving detritus feeders that generally spend their time burrowing through soil and litter, consuming plant remains and converting vegetable matter into humus. In tropical environments where earthworms are often scarce, millipedes may be the major soil-forming animals. Uniquely among the arthropods, most of their trunk segmental units bear two pairs of legs each and are commonly described as **diplosegments** (Figure 23.2F). When threatened, many millipedes roll up into a flat coil, and some can roll up

into perfect balls (like many isopods). Millipedes typically have many trunk segments, but some have only 9 to 12. Despite their vernacular name (from *milli*, "thousand," *pedes*, "feet"), which has equivalents in many languages, only one species has been found with a thousand legs, the newly discovered *Eumillipes persephone* (a subterranean species from Western Australia) that has 330 segments and 653 pairs of legs.

Millipedes are incapable of strong biting and at first sight seem only to rely on their calcified cuticle and their rolling ability for defense, but the majority possess repugnatorial glands with lateral openings (**ozopores**) that secrete volatile toxic liquids (Figure 23.2F). Their chemical weaponry is surprisingly diverse: it includes the benzoquinones, hydroquinones, phenol, and acetates of long-chain carboxylic acids produced

FIGURE 23.1 Representative myriapods. (A) The European centipede *Himantarium gabrielis*, whose leg count may reach 179 pairs. (B) The scutigeromorph centipede *Dendrothereua homa* from Yucatan, Mexico. (C) The African scolopendromorph centipede *Alipes grandidieri*. The tibia and tarsal articles of the terminal legs are conspicuously flattened and leaflike; stridulation is produced by friction between the articles. by juloids; and the benzoic acid, benzaldehyde, and hydrogen cyanide produced by polydesmoids. A few tropical species have toxins powerful enough to cause blisters on human skin. Pill millipedes, such as the common European species of *Glomeris*, lack lateral ozopores, but from along their dorsal midline they squeeze out drops of fluid containing quinazolinones, which belong to the same class of substances as the synthetic drug Quaalude (methaqualone), a powerful sedative. One common household species in North America and Europe (introduced long ago from Asia), the polydesmidan *Oxidus gracilis*, releases strong-smelling defensive chemicals when injured. Members of the subclass Penicillata, which are small, soft bodied, and without repugnatorial glands, have evolved a mechanical defense strategy of throwing stiff bristles from their posterior end at ants and other predators. Given their range of defensive tactics, it is not surprising that many millipedes have aposematic (warning) coloration, usually bright reds, yellows, and oranges, and that some soil-dwelling vertebrates (lizards and worm snakes) have evolved look-alike coloration (Batesian mimicry).

Millipedes in the family Xystodesmidae (order Polydesmida) produce hydrogen cyanide as a defensive chemical, and they use aposematic coloration to warn predators of their toxicity. Coloration patterns in these species include bright yellows, oranges, reds, and violet. One nocturnal genus in this family, *Motyxia*, known only from California, does not display conspicuous coloration. Remarkably, however, they produce a green bioluminescent glow at a dominant wavelength of 495 nm by way of a biochemical source of light produced in the exoskeleton. The source is a photoprotein with a chromophore containing a porphyrin as its functional group. This is the only known instance of light production via a photoprotein on land, all other examples being marine. The emitted light could be a sexual signal to attract mates, or an aposematic warning glow to announce the presence of a cyanide-based chemical defense.

In contrast to millipedes, most centipedes are fast-running predators, have one pair of legs per segment, and have poison claws at the tip of their first pair of legs, which are thus turned into a peculiar kind of maxillipeds called **forcipules** or **prehensors**. When threatened, centipedes usually strike out with the poison claws, with which they can inflict a painful bite. A few *Scolopendra* species have warning coloration—black and red banding. Lithobiomorph centipedes bear large numbers of unicellular repugnatorial glands on the last four pairs of legs, which they kick in the direction of an enemy—a behavior that throws out sticky droplets of noxious secretions. Despite their vernacular name (from *centi*, "hundred," *pedes*, "feet"), these creatures rarely have as many as 100 legs, and only in the order Geophilomorpha is this attained; the highest number of leg pairs recorded thus far (in *Gonibregmatus plurimipes*) is 191.

CLASSIFICATION OF THE SUBPHYLUM MYRIAPODA

CLASS CHILOPODA (CENTIPEDES)
- SUBCLASS NOTOSTIGMOPHORA
  - ORDER SCUTIGEROMORPHA
- SUBCLASS PLEUROSTIGMOPHORA
  - ORDER CRATEROSTIGMOMORPHA
  - ORDER GEOPHILOMORPHA
  - ORDER LITHOBIOMORPHA
  - ORDER SCOLOPENDROMORPHA

CLASS DIPLOPODA (MILLIPEDES)
- SUBCLASS PENICILLATA
  - ORDER POLYXENIDA
- SUBCLASS CHILOGNATHA
  - INFRACLASS PENTAZONIA
    - ORDER GLOMERIDESMIDA
    - ORDER GLOMERIDA
    - ORDER SPHAEROTHERIIDA
  - INFRACLASS HELMINTHOMORPHA
    - SUPERORDER COLOBOGNATHA
      - ORDER PLATYDESMIDA
      - ORDER POLYZONIIDA
      - ORDER SIPHONOCRYPTIDA
      - ORDER SIPHONOPHORIDA
    - SUPERORDER EUGNATHA
      - ORDER JULIDA
      - ORDER SPIROBOLIDA
      - ORDER SPIROSTREPTIDA
      - ORDER CALLIPODIDA
      - ORDER CHORDEUMATIDA
      - ORDER STEMMIULIDA
      - ORDER SIPHONIULIDA
      - ORDER POLYDESMIDA

CLASS PAUROPODA (PAUROPODS)

CLASS SYMPHYLA (SYMPHYLANS)

Myriapod Classification

Subphylum Myriapoda

Terrestrial mandibulate and tracheate arthropods provided with 1 pair of antennae; mandibles with

articulating endite; first maxillae free or fused together; second maxillae partly or wholly fused, or absent; postcephalic trunk of numerous, mostly similar segments (or diplosegments); appendages of head and trunk uniramous; most lineages with lateral compound eyes or groups of closely packed ocelli; exoskeleton without well-developed wax layer (except in some desert species); without endodermally derived digestive ceca; ectodermally derived (proctodeal) Malpighian tubules assist in excretion; often with organs of Tömösváry; copulation often indirect; development direct, but often with postembryonic increase in the number of segments and appendages. About 16,350 described, living species.

Class Chilopoda

With numerous freely articulating trunk segments, each with 1 pair of legs, the first pair modified as large poison claws held under the head like mouthparts; antennae simple, of fixed (14 in the Geophilomorpha, 17 in most Scolopendromorpha) or variable (in excess of 100 in some cave-dwelling Lithobiomorpha) number of articles; both pairs of maxillae may be medially coalesced; cuticle uncalcified; gonopore on last true body segment; spiracles lateral, except in Scutigeromorpha; with 15 to 191 leg-bearing body segments (number always odd in the adults); legs long, extending laterally such that the body is carried close to the ground; last pair of legs often sexually dimorphic, extending backward and not used for locomotion.

Centipedes of the subclass Notostigmophora have middorsal spiracles and very short tracheae that end on the dorsal vessel; hemolymph containing hemocyanin; a dome-shaped head, with compound eyes; and 15 pairs of long, thin legs. The subclass Pleurostigmophora includes centipedes with lateral spiracles, a flattened head, and a variable number of legs. The largest centipedes belong to the order Scolopendromorpha (having either 21 or 23 pairs of legs, with 39 or 43 only in one species, *Scolopendropsis duplicata*), although the highest leg count occurs in the long, thin geophilomorphs (27 to 191 pairs of legs). The globally distributed order Scolopendromorpha contains the species most people readily recognize as centipedes. North America, north of Mexico, is the only major inhabited region that has no native species of scutigeromorph centipedes, although the long-legged, swift-moving European species *Scutigera coleoptrata* has become widely introduced and is often encountered in houses. Approximately 3,300 living species of centipedes have been described.

Class Diplopoda

Trunk comprising 9 to 330 segmental units; most of these (diplosegments) with 2 pairs of legs, spiracles, ganglia, and heart ostia; each diplosegment with 1 tergite, 2 pleura, and 1 to 3 sternites; first trunk segment legless, modified as collum; diplosegments 2–4 (and also 5 in the order Spirobolida) with 1 pair of legs each; total number of leg pairs in adults ranging from 11 up to 653; antennae simple, generally 7-jointed; first maxillae fused into a gnathochilarium; second maxillae absent; gonopores opening on third trunk segment, on or near coxae of second pair of legs; cuticle usually calcified; many species capable of rolling into a tight coil; spiracles located ventrally, typically in front of leg coxae, and never valvular (i.e., they cannot be closed); legs ventrally positioned and generally short, such that the body is carried close to the ground. On some or most trunk segments many millipedes have lateral repugnatorial glands that secrete noxious chemicals that can irritate the skin and eyes. In addition to their defensive role against predator attacks, the secretions of julids have been shown to have antimicrobial and antioxidative effects. A few millipedes spray their secretions up to 40 cm. About 12,000 species of millipedes have been described.

The segmental nature of the trunk rings was recently challenged by insights obtained from gene expression studies demonstrating that dorsal and ventral halves of the body are decoupled in their early development. The body itself is usually elongate. Most common forms are either subcylindrical and wormlike, short legged, and capable of rolling into a tight spiral when disturbed, or broadly flattened and equipped with lateral wing- or keel-like cuticular extensions of the body wall, called **paranota**, that may cover the legs. Filamentous outgrowths (spinnerets) bearing the openings of silk-producing glands are sometimes present at the caudal end of the body. Female gonopores open on eversible vulvae, sometimes transformed into ovipositors or into sclerotized appendages (**cyphopods**). Male gonopores occur on the leg bases or on paired (rarely unpaired) penes. Sperm transfer is either direct or mediated by specialized copulatory legs called **gonopods**. Millipede gonopods are present only in males, though not in all groups. Helminthomorphan millipedes have one or two pairs of gonopods closely behind the body ring that bears the gonopores, whereas in pentazonian millipedes there are no gonopods but the last pair of legs (the **telopods**) are modified in males as pincers used to grasp the female during mating. Spiracles are situated close to the leg bases. In the subclass Penicillata, the exoskeleton is soft; in the Chilognatha, the cuticle is calcified, hard, and rigid.

The main subgroups of the Diplopoda are defined by the following characters:

- **Penicillata** Cuticle soft, not calcified; 9–11 diplosegments covered by tufts of bristles; males without copulatory appendages
- **Chilognatha** Cuticle calcified; wide tracheal pouches; sperm actively transferred by male into the female genital opening

for more ebook, testbank, solution manuals requests: email 9601267342@qq.com

- **Pentazonia** Ventral plates (stigmatic plates, traditionally called sternites) of diplosegments divided along the midline; tracheae anastomosing; terminal leg pair of male (telopods) pincer shaped; intestine N shaped, that is, bent twice. Glomeridesmids are flattened millipedes with 21–22 diplosegments; they cannot roll into a ball. Glomerids and sphaerotheriids are short, round, 12- or 13-segmented millipedes that can roll into a perfect ball.
- **Helminthomorpha** More than 21 body rings; stigmatic plates undivided; lateral ozopores (often limited to some diplosegments and sometimes lost); unbranched tracheae arising in a cluster from the tracheal pouch
- **Colobognatha** Gnathochilarium without palps; adults protect egg clutch by curling around them; first postembryonic stage with four pairs of legs; ninth and tenth leg pair of adult males transformed into sexual appendages (gonopods)
- **Eugnatha** Mandible with two articulated basal articles; pleurites fused to tergites; eighth (sometimes also ninth) leg pair of adult males transformed into sexual appendages (gonopods). This is by far the largest group of millipedes, including common cylindrical species (e.g., orders Julida, Spirobolida, and Spirostreptida), as well as the Polydesmida, whose segments are often provided with lateral keels, or paranota, that give them a flattened zipperlike aspect.

Class Pauropoda

Minuscule (0.3–2 mm) whitish-brownish myriapods; eyeless; with 4- or 6-segmented biramous antennae with 3 flagella and a unique candelabra-shaped or globular sense organ; trunk of 11 segments, tergites weakly sclerotized except in a few families; 8–11 pairs of legs (none on the first trunk segment); tergites of trunk segments usually covering more than 1 segment each; first maxillae fused into a gnathochilarium; second maxillae absent; most species without tracheal or circulatory systems; gonopores on third trunk segment. Although found in all parts of the world, pauropods are not commonly noticed; they occur mainly in moist soils and woodland litter. About 850 species have been described.

Class Symphyla

Small (1–9 mm, but up to 30 mm in *Hanseniella magna*); eyeless; trunk with 14 segments, last fused to telson; first 12 trunk segments each with a pair of legs (the first pair occasionally vestigial); penultimate segment with spinnerets and a pair of long sensory hairs; dorsal surface with 15–24 tergal plates; soft uncalcified cuticle; antennae long, threadlike, of up to 50 segments; first maxillae medially coalesced; second maxillae completely fused to form a complex labium; 1 pair of spiracles opening on the head; tracheae supply first 3 trunk segments only; gonopores open on third trunk segment. Symphylans, generally uncommon, occur in soil and rotting vegetation. About 200 species have been described.

The Myriapod Body Plan

Myriapods differ from hexapods and most crustaceans in their retention of a largely homonomous trunk with paired segmental appendages. The head appendages and legs are similar to those of hexapods. Metamerism is also evident internally in structures such as the segmental heart ostia, tracheae, and ganglia. The key features that distinguish the Myriapoda are listed in Box 23A.

Centipedes (chilopods) bear one pair of walking legs per segment (Figure 23.2A–D). Most species are a few centimeters in length, although the smallest are just 3–4 mm long and some tropical giants attain lengths of nearly 30 cm.

In the millipedes (diplopods) the head is followed by a limbless segment called the **collum**, a heavily sclerotized collar between the head and trunk (Figure 23.2E). Each of the next three segmental units bears a single pair of legs. The trunk is articulated into diplosegments, each bearing a double complement of metameric organs (Figure 23.2F). Millipedes range in length from about 0.5 to 30 cm. The cuticle of millipedes is particularly robust, being well sclerotized and usually calcified.

BOX 23A Characteristics of the Subphylum Myriapoda

1. Body of two tagmata: head and multisegmented trunk
2. All appendages multiarticulate and uniramous
3. Head appendages, from anterior to posterior: antennae, mandibles, first maxillae, and second maxillae; second maxillae fused into a single flaplike structure called a "labium" or absent; first and second maxillae often bearing palps
4. With an aerial gas exchange system composed of tracheae and spiracles (possibly evolved multiple times and convergent with those in Hexapoda)
5. With one or two pairs of ectodermally derived (proctodeal) Malpighian tubules (convergent with those in Hexapoda)
6. Most with lateral compound eyes or with groups of closely packed ocelli
7. Gut simple, without digestive ceca
8. Gonochoristic; with direct development

(I) Ventral view of the terminal segments of a male geophilomorph centipede (*Strigamia*).(G–I from J. G. E. Lewis. 1981. *The Biology of Centipedes*. Cambridge University Press, New York.)

Pauropods are minute, soft-bodied, eyeless, soil-inhabiting myriapods (Figure 23.1F). They are less than 2 mm in length and have 12 trunk segments. As in millipedes, some segmental pairing occurs, and usually only six tergites are visible dorsally.

Symphylans (Figure 23.1G) are also minute, eyeless myriapods, only one species exceeding 1 cm in length. The trunk has 12 (rarely 11) pairs of legs. Some tergites are divided, and 15–24 tergites are usually visible dorsally. The thirteenth body segment bears spinnerets, a pair of long sensory hairs, and a tiny postsegmental telson. Like pauropods, symphylans inhabit loose soil and humus.

Head and Mouth Appendages

In myriapods, the eyes and protocerebrum are located in a preantennal position. The antennary segment bears the antennae and houses the deutocerebrum. The next segment (the premandibular segment) houses the tritocerebrum but lacks appendages. The three following segments carry, in turn, the mandibles and the first and second pairs of maxillae. The second maxillae are fused as a "labium" in symphylans but have been lost altogether in millipedes and pauropods. In millipedes and pauropods the first maxillae fuse to form a flaplike gnathochilarium. The ganglia of the mandibular and maxillary segments are generally fused to form the subesophageal ganglion. The antennae of millipedes are primarily composed of seven distinct antennomeres and a short, retractile tip bearing four apical sensory cones. As in the other mandibulates, the mouth region of Myriapoda is bordered by a labrum anteriorly and by a hypopharynx posteriorly. The latter arises as a flaplike (or tonguelike) outgrowth of the body wall through which the salivary glands open.

Locomotion

Myriapods rely on their well-sclerotized exoskeleton for body support. In centipedes, the legs extend laterally, keeping the body close to the ground to maintain stability while at the same time providing for long strides and generally rapid locomotion. In millipedes, the legs arise ventrally and are typically short, again keeping the body close to the ground while providing for powerful, though slow, locomotion.

The basic design of arthropod limbs was described in Chapter 20. The power exerted by a limb is greatest at low speeds and least at high speeds. At lower speeds the legs are in contact with the ground for longer periods of time, and in the case of myriapods more legs are contacting the ground at any given moment. In burrowing forms, such as many millipedes, the legs are short, and the gait is slow and powerful as the animals bulldoze their way through soil or rotting wood. In centipedes, which mostly run at high speeds, less than half the limbs may touch the ground at any given moment, and for shorter periods of time (Figure 23.3). Longer limbs increase the speed of a running gait, and limbs long in length and stride are typical features of the fastest-running centipedes and symphylans. The legs of most myriapods move in clear metachronal waves from posterior to anterior (Figure 23.3A–C).

Locomotor repertoires typically evolve in concert with the overall habits of animals, particularly feeding behaviors. Most centipedes are surface-dwelling predators that must move quickly to capture their prey. *Scutigera* is a centipede that qualifies as a world-class runner, reaching speeds up to 42 cm/sec when in pursuit of prey. On the other hand, most millipedes are detritivores that burrow through soil, leaf litter, or rotten timber in search of food.

One group of centipedes lacks the high-speed modifications of their relatives. Large geophilomorphs such as the European *Himantarium* burrow, aided by dilation of the body and use of the trunk musculature in a fashion similar to that of earthworms. This peristalsis-like motion is rare in arthropods because of their rigid exoskeleton. However, geophilomorphs have enlarged areas of flexible cuticle on the sides of the body between the tergites and sternites; these enlarged areas (pleura) allow them to significantly alter their body diameter. Other centipedes have smaller, flexible pleural areas that allow some degree of lateral undulatory motion.

Thanks to a well-developed musculature and to the soft integument, pauropods are able to both elongate the body and shorten it by a high degree of contraction, allowing them to creep in narrow irregular spaces; adult pauropods also run swiftly in short rushes.

Feeding and Digestion

Most centipedes are active, aggressive predators on smaller invertebrates, particularly worms, snails, and other arthropods. Their first trunk appendages (**prehensors** or **forcipules**), located ventral to the mouth field (Figure 23.2D), are raptorial limbs used to stab prey and inject poison. The poison is produced in large venom glands, generally located in the basal articles

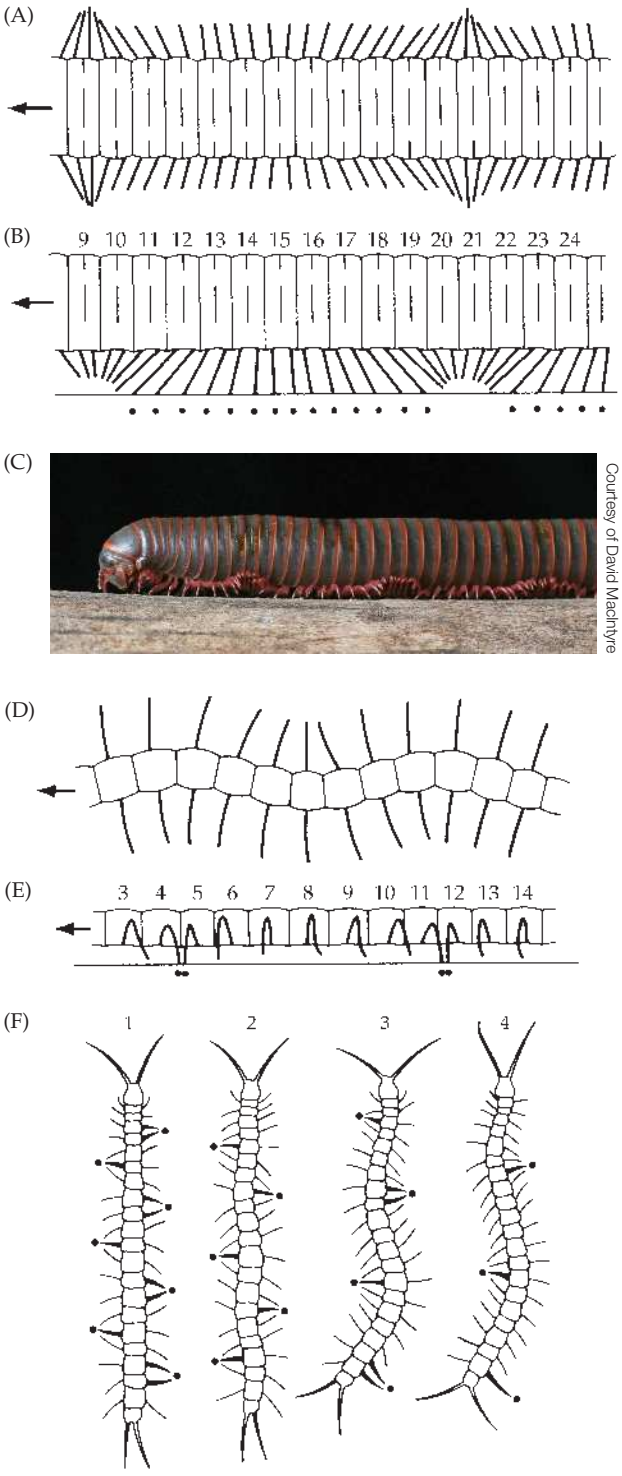

FIGURE 23.3 Locomotion in millipedes and centipedes. (A,B) Schematic of a typical millipede (such as *Spirostreptus* or *Gymnostreptus*) in motion. The dorsal view (A) shows left and right leg sets exactly in phase with each other. The lateral view (B) of the same animal shows that the majority of the limb tips are on the ground at once, an arrangement yielding a slow but powerful gait. (C) A millipede (*Narceus americanus*) in motion. Also see chapter opener photo of *N. americanus* (the giant North American millipede). (D,E) Schematic of a typical centipede (such as *Scolopendra* or *Cryptops*) in motion. The dorsal view (D) shows the limb pairs in opposite phase and the undulations of the body that accentuate stride length. The lateral view (E) of the same animal illustrates that fewer than one-third of the limb tips are on the ground at any one time, an arrangement yielding the short, swift strokes typical of a rapid but weak gait. Arrows indicate the animal's direction of travel; dots are points of leg-tip contact with the substratum. (F) Locomotion in a scolopendrid centipede at various speeds. Parts 1–4 show the body waves and leg actions at increasing speeds. Limbs shown with heavy lines are in their power strokes, with the tips against the substratum (dots); limbs depicted by thin lines are in various stages of their recovery strokes. Notice that at maximum speed the animal is still supported by a tripod stance. (F after S. M. Manton. 1965. *Zool J Linn Soc* 46: 252–483.)

of the forcipules. The poison is so effective that large centipedes, such as the tropical *Scolopendra*, can subdue small vertebrates. Chemically, centipede toxins are extremely diverse, especially in the Scolopendromorpha. As many as 39 toxins have been found in the venom of the Florida blue centipede *Scolopendra viridis*. The bite of even the most dangerous centipede is normally not fatal to people, but the venom can cause a reaction similar to that accompanying a serious wasp or scorpion sting.

The feeding strategy of millipedes is quite different. Most millipedes have a preference for dead and decaying plant material, although some species (e.g., *Blaniulus guttulatus*) have been reported to cause damage to cultivated plants. Millipedes play an important role in the recycling of leaf litter in many parts of the world. Most bite off a large piece of plant tissue with their powerful mandibles, mix it with saliva as they chew it, and then swallow it. Some, such as siphonophorids, are believed to feed on the juices of living plants and fungi. A few millipedes (some callipodidans and a few chordeumatidans) have evolved predaceous lifestyles.

The feeding biology of pauropods is not well understood, but most appear to feed on fungi and decaying plant and animal matter. *Millotauropus*, however, feeds on springtails and their eggs.

Symphylans are primarily herbivores, although a few have adopted a carnivorous, scavenging lifestyle. Many symphylans consume live plants. One species, *Scutigerella immaculata*, is a serious pest in plant nurseries and flower gardens, where it has been reported at abundances exceeding 90 million per acre.

Like the guts of all arthropods, the long, usually straight myriapod gut is divisible into an ectodermal foregut, endodermal midgut, and ectodermal hindgut (Figure 23.4). There are no digestive ceca branching off the gut. Salivary glands are associated with the mouth appendages. The mouth leads inward to a long esophagus, which is sometimes expanded posteriorly as a storage area, or crop and gizzard (as in most centipedes). The gizzard often contains cuticular spines

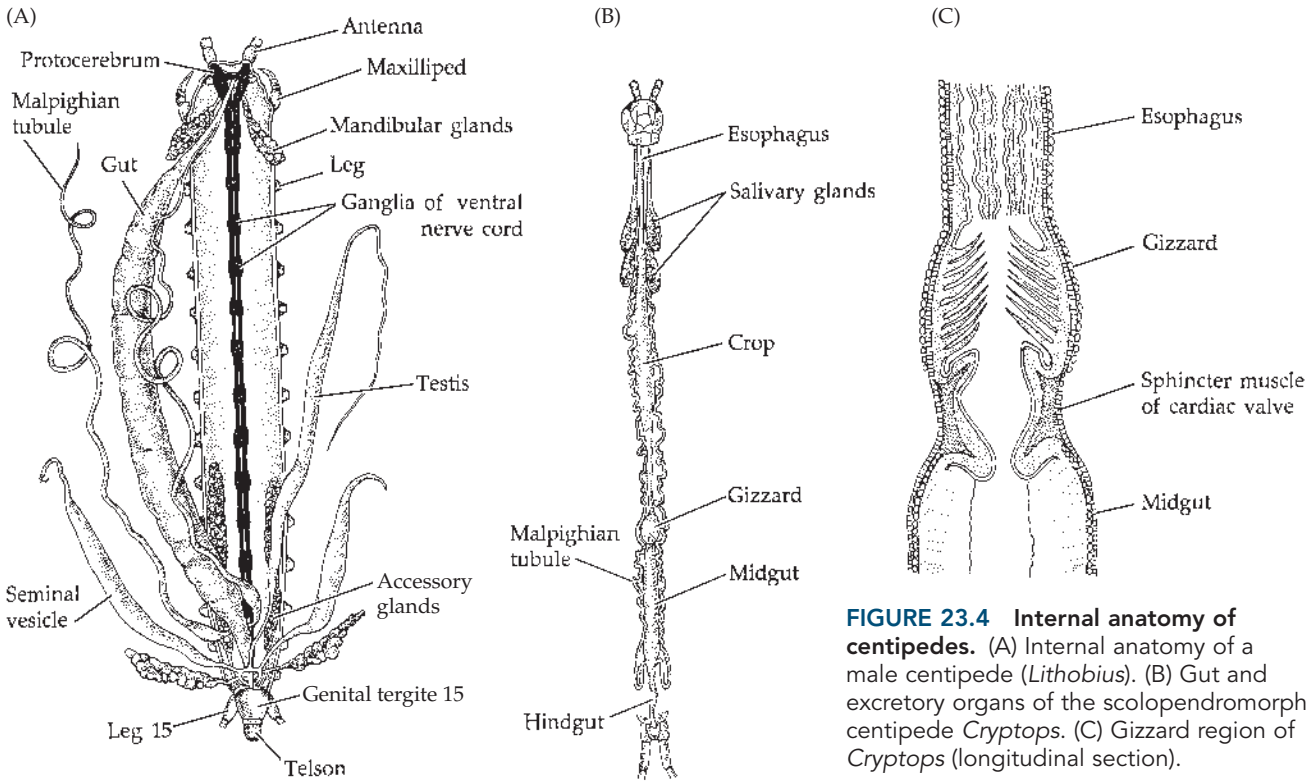

FIGURE 23.4 Internal anatomy of centipedes. (A) Internal anatomy of a male centipede (*Lithobius*). (B) Gut and excretory organs of the scolopendromorph centipede *Cryptops*. (C) Gizzard region of *Cryptops* (longitudinal section).

that help strain large particles from the food entering the midgut, where absorption occurs (Figure 23.4C). As in other arthropods, the gut of myriapods produces a peritrophic membrane—a sheet of thin, porous, chitinous material that lines and protects the midgut and that may pull free to envelop and coat food particles as they pass through the gut.

Circulation and Gas Exchange

The myriapod circulatory system includes a dorsal tubular heart that pumps the hemocoelic fluid (blood) toward the head. The heart narrows anteriorly to a vessel-like aorta, from which blood flows posteriorly through large hemocoelic chambers before returning to the pericardial sinus and then back to the heart via paired lateral ostia. Circulation is slow, and system pressure is relatively low. In millipedes, the heart bears two pairs of ostia in each diplosegment; one pair of ostia occurs in each segment in centipedes. The copper-containing respiratory pigment hemocyanin has been found in the blood of scutigeromorph centipedes and a few millipedes and symphylans, but not in pauropods, which are arguably too small to get benefit from the presence of a respiratory pigment.

Most myriapods rely on a tracheal system for gas exchange (Figure 23.5). As explained in Chapter 20, tracheae are extensive tubular invaginations of the body wall opening through the cuticle by pores called spiracles. The tracheae originating at one spiracle often anastomose with others to form branching networks penetrating most of the body. Spiracles are placed segmentally, although not necessarily on all segments: in the lithobiomorphs and in most scolopendromorphs, spiracle-bearing segments alternate with segments without spiracles. In the scutigeromorph centipedes, the respiratory openings are dorsal and lead to thick bundles of very short tracheae that terminate at the heart. Millipedes usually bear two pairs of spiracles per diplosegment, just anterior to the leg coxae. In the symphylans a single pair of spiracles opens on the sides of the head, and the tracheae supply only the first three trunk segments. Except for a few species retaining primitive characters, pauropods lack a tracheal system.

Each spiracle is usually recessed in an atrium, the walls of which are lined with setae or spines (trichomes) that prevent dust, debris, and parasites from entering the tracheal tubes. The spiracles are often surrounded by a sclerotized rim or lip, the **peritrema**, which also aids in excluding foreign particles. A muscular valve or other closing device is present in many centipedes and under control of internal partial pressures of O_2 and CO_2. As in insects, ventilation of the tracheal system is accomplished by simple diffusion gradients, as well as by pressure changes induced by the animal's movements. The blood of myriapods appears to play a limited role in oxygen transport (except in the very active scutigeromorphs).

The innermost parts of the tracheal system are the tracheoles, which are thin-walled, fluid-filled channels that end as a single cell, the tracheole end cell (= tracheolar cell). Unlike the cuticular wall of the tracheae, the wall of

the tracheoles is not shed during ecdysis. The tracheoles are so minute (0.2–1.0 mm) that ventilation is impossible and gas transport here relies on aqueous diffusion.

Excretion and Osmoregulation

When myriapods invaded land, the problem of water conservation necessitated the evolution of entirely new structures to remove metabolic wastes—Malpighian tubules (Figure 23.4). These excretory organs function much as those of insects (Chapter 22), and the Malpighian tubules of myriapods and hexapods represent a striking case of convergent evolution. Myriapods usually possess only one pair of Malpighian tubules, but there are three tubules in Craterostigmomorpha and four in Scutigeromorpha. In those species that are largely confined to moist habitats and nocturnal activity patterns, a significant portion of the excretory wastes may be ammonia rather than uric acid.

The myriapod cuticle is sclerotized and calcified to various degrees, adding a measure of waterproofing, but aside from a few species, such as the spirostreptid *Orthoporus ornatus* of American deserts, it lacks the waxy layer seen in insects. For this reason, myriapods rely to a considerable extent on behavioral strategies to avoid desiccation. Many live in humid or wet environments or are active only during cool periods. Other myriapods stay hidden in cool or moist microhabitats, such as under rocks, during hot hours of the day or dry periods.

A few geophilomorph centipedes live in intertidal habitats, under rocks or in algal mats. A few millipedes have semiaquatic habits, for example, the littoral julidan *Thalassisobates littoralis* that lives among the stranded decaying matters on the shores of the Mediterranean Sea. However, this species does not spend much time underwater, unlike some subterranean species from caves in southern Europe or the Amazonian *Myrmecodesmus adisi*, whose juveniles spend up to 11 months underwater. A few geophilomorph centipedes, also from periodically inundated Amazonian forests, tolerate month-long submersion. When underwater, these myriapods apparently rely on plastron respiration; in other words, they use water-dissolved oxygen that reaches their tracheae via minute air bubbles trapped into the spiracles or retained by a specialized integument. Although the tracheal system of myriapods (except for the unique sort present in scutigeromorph centipedes) greatly resembles that of insects, there is evidence that it evolved independently.

Nervous System and Sense Organs

The myriapod nervous system conforms to the basic arthropod plan described in Chapter 20. Very little secondary fusion of ganglia occurs, and the ventral nerve cord retains much of its primitive double nature, with a pair of fused ganglia in each segment. Millipedes possess two pairs of fused ganglia in each diplosegment.

As in other arthropods, the cerebral ganglion of myriapods comprises three distinct regions: the preantennal protocerebrum (associated with the eyes, if these are present), the deutocerebrum (associated with the antennae), and the tritocerebrum (Figure 23.6). A

for more ebook, testbank, solution manuals requests, email: 9601267342@qq.com

subesophageal ganglion controls the mouthparts, salivary glands, and some local musculature.

Myriapods typically possess eyes, although these are lacking in all pauropods, symphylans, and geophilomorphs and in many scolopendromorphs among the centipedes, as well as in siphoniulids, siphonophoridans, and polydesmidans among the millipedes. Many troglobitic (cave-dwelling) species belonging to other groups, especially to the lithobiomorph centipedes, are also blind. Centipedes can possess a few or many independent eyes (Figure 23.7). In the scutigeromorph centipedes, up to

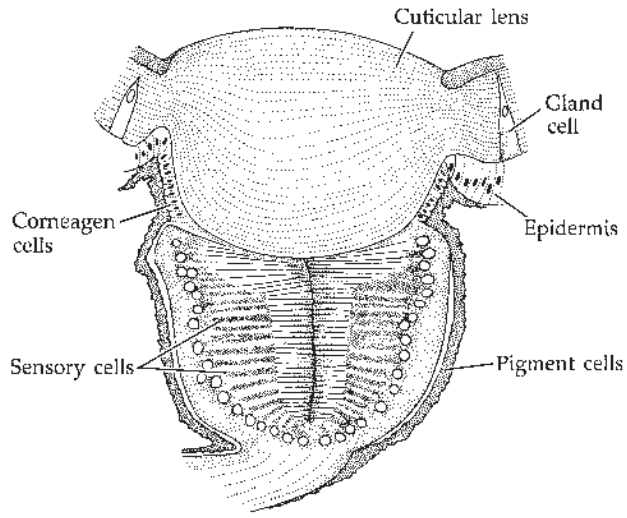

FIGURE 23.7 An eye of a centipede (section).

200 of these eyes cluster to form a compound eye. However, the eyes of living centipedes appear to function only in the detection of light and dark, and not in image formation. Many millipedes have a compound eye of up to about 90 ommatidia on each side of the head. Some millipedes also possess integumental photoreceptors, and many eyeless species exhibit negative phototaxis.

Centipedes and millipedes are noted for their highly sensitive antennae, which are richly supplied with tactile and chemosensory setae. In many species, an **organ of Tömösváry** (Figure 23.8) is located at the base of each antenna. Each part of this paired organ consists of a disc with a central pore where the ends of sensory neurons converge. The exact role of this organ has yet to be clearly established, and speculation has run the gamut from chemosensation to pressure or humidity sensation or the detection of sound or vibration.

Reproduction and Development

Myriapods are gonochoristic and oviparous, although parthenogenesis occurs in several families of millipedes and in some centipedes, pauropods, and symphylans. Many myriapods, like most arachnids, rely on indirect copulation and insemination. Packets of sperm (spermatophores) are deposited in the environment, or they are held by the male and picked up by the female. All myriapods have direct development, with the young hatching (except in pauropods) as "miniature adults," although often with fewer body segments.

Chilopoda Female centipedes possess a single elongate ovary located above the gut, whereas males have from 1 to 26 testes similarly placed (Figure 23.9). The oviduct joins with the openings from several accessory glands and a pair of seminal receptacles just internal to the gonopore, which is situated on the genital segment (the legless segment in front of the telson). The gonopore of females is usually flanked by a pair of small grasping appendages, or gonopods, that manipulate the males' sperm packets. In males the testes join the ducts of several accessory glands and a pair of seminal vesicles near the gonopore, which opens on the ventral surface of the genital segment. The male gonopore also lies between a pair of small gonopods.

Sperm are packed into spermatophores, which are transferred to the female. In some cases (e.g., scutigeromorphs), males deposit spermatophores directly on the ground and the females simply pick them up. In most species, however, males deposit a spermatophore on a silken **nuptial net**, which is spun from modified genital glands (Figure 23.10). Mating pairs of centipedes typically perform courtship behavior, stroking each other with their antennae and often moving the large (up to several millimeters) spermatophore into the nuptial net. Eventually the female picks up the spermatophore with her gonopods and inserts it into her gonopore.

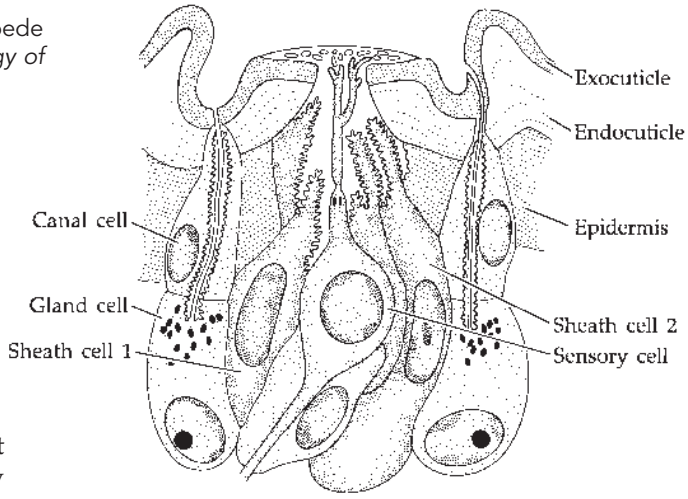

FIGURE 23.8 The organ of Tömösváry. From the centipede *Lithobius forficatus*. (After J. G. E. Lewis. 1981. *The Biology of Centipedes*. Cambridge University Press, New York.)

Fertilization occurs as the eggs pass through the gonoduct. Females often coat the fertilized eggs with moisture and fungicides before depositing them in the ground or in rotting vegetation.

In Craterostigmomorpha, Scolopendromorpha, and Geophilomorpha, the female remains coiled around her brood until hatching, ventrally in the case of craterostigmomorphs and scolopendromorphs (Figure 23.10D), and dorsally in most geophilomorphs. Parental caretaking is almost unknown in the other myriapod classes, except for a few polyzoniidan and platydesmidan millipedes that also exhibit brood care. In a few platydesmidan millipedes, embryo brooding is provided by the male.

Scutigeromorphs, lithobiomorphs, and craterostigmomorphs hatch with 4, 7, and 12 pairs of legs, respectively, and obtain the final number of 15 leg pairs following one (craterostigmomorphs) or a few molts but continue molting until they reach maturity and beyond (hemianamorphosis). Scolopendromorphs and geophilomorphs, however, develop by epimorphosis. That is, they reach the final number of body segments during the embryonic development; no segment or leg pair is added during the postembryonic life.

Diplopoda Millipedes possess a single pair of elongate gonads in both sexes. Unlike those of centipedes, millipede gonads lie between the gut and the ventral nerve cord. The gonopores open on the third (genital) trunk segment. In females each oviduct opens separately into a genital atrium near the coxae of the second pair of legs. A groove in the vulva leads into one or more seminal receptacles. In many millipede groups (but not in polydesmidans), males possess a pair of penes, or **gonapophyses**, also on the coxae of the second pair of legs.

The mandibles are used to transfer sperm in the "pill millipedes," but more commonly one or two pairs of legs are modified as copulatory appendages, or gonopods. Usually, gonopods replace the anterior pair or both pairs of legs of the seventh trunk segment; only in the Colobognatha do the gonopods replace the posterior leg pair of trunk segment 7 and the anterior leg pair of trunk segment 8. Males bend the anterior body

segments back under the trunk until the penes and gonopods make contact, whereupon the latter pick up a spermatophore in preparation for mating.

In most millipedes, mating occurs by indirect copulation, in which the male and female genital openings never actually make contact, although the male and female may embrace with their legs and mandibles and may coil their trunks together. Sometimes a pair remains in such an embrace for up to two days. Pheromones are known to play an important role in many species. Antennal tapping, head drumming, and stridulation may be included in the mating repertoire (Figure 23.11). Males of the family Sphaerotheriidae produce sounds during courtship by rubbing the telopods against the back edge of the body. The *Sphaerotherium* (Sphaeotheriida) male usually stridulates when in contact with a female to initiate mating, probably to prevent the female from rolling into a ball or to stimulate her to unroll if she has already done so.

Males often have an array of secondary sexual characteristics, including strong modifications of the first pair of legs. In species of the genus *Chordeuma* (Chordeumatida) in Europe, dorsal glands on trunk ring XVI of the male produce a secretion upon which females feed prior to mating.

Fertilization takes place as the eggs are laid. In pentazonian millipedes, the last pair of male legs is modified into strong claspers, used to hold the female in place. In these millipedes, males mold soil into a small cup into which they ejaculate sperm. The sperm-filled cup is then passed to the female, who is firmly held by the male's large claspers. Eggs are usually laid in the soil, although some species also produce silk bags to house the eggs. Some species fashion a nest of soil and humus reinforced

FIGURE 23.11 Rusty millipede (*Trigoniulus corallinus*), Hawaii. The large, shield-like plate behind the head of this millipede is the first trunk ring, the collum, a segment without appendages. The next four diplosegments (2–5) have a single pair of legs, whereas ring 6 has two pairs of legs. Notice, too, that ring 7 of the male (on top) appears to lack legs. In fact this ring's diminutive appendages are hidden and specialized for sperm transfer to the female if she accepts him as a mate. All remaining rings from diplosegment 8 to the last diplosegment of the body have two pairs of walking legs. The close contact between male (above) and female might suggest mating, but during sperm transfer the partners actually take a different position. This photograph likely shows a preliminary act (i.e., mechanical stimulation by the male) and mating will follow if the female accepts the male.

with parental feces, or the entire nest may be composed of fecal material. One to 300 eggs are laid at a time.

Most newborn millipedes have only three pairs of legs; new segments and leg pairs are added at each molt, according to one of three possible developmental schedules. In Pentazonia (as in the pill millipede *Glomeris*: Glomerida) the final number of segments and leg pairs is obtained after some molts, but the millipede must undergo further molts without segmental increase before achieving adult size and sexual maturity (hemianamorphosis). In polydesmidans and other helminthomorphs, the achievement of the final number of segments and leg pairs coincides with obtaining the adult condition and no further molt occurs (teloanamorphosis). In the remaining helminthomorphs, new segments and leg pairs are added at every molt, and the animal continues molting even after reaching sexual maturity (euanamorphosis).

The males of some European julids may undergo periodomorphosis: specific environmental conditions may induce sexually mature males to molt to intercalary males with regressed gonopods, thereby suspending reproductive activity. This is resumed after one or more additional molts, with newly differentiated gonopods.

Pauropoda In female pauropods a single ovary lies beneath the gut, but in the males the testes are located above the gut. As in millipedes, the gonopore of the female (a median, unpaired opening) and the gonopores of the male (two paired openings) are on the third trunk segment. Females take up a spermatophore, often after the male has suspended it from one or a few silk threads spanning two stones or leaves. Fertilization is internal. The yolky eggs are laid in decaying wood. Postembryonic development begins with a motionless "pupoid stage" with minute oral and anal openings and inarticulated traces of the antennae and of the first two pairs of legs. The next molt produces the first active juvenile, with three pairs of legs. The development then proceeds by anamorphosis through four juvenile stages and one adult stage.

Symphyla Symphylans display one of the more unusual methods of fertilization in the animal kingdom. Paired gonads discharge through gonopores on the third trunk segment in both sexes. Males deposit spermatophores in the environment. At least some symphylans construct stalklike structures, topped with spermatophores. When a female encounters one of these sperm packages, she bites off the spermatophores and stores the sperm in her preoral cavity. When her own eggs are ripe, the female removes them from her gonopore with her mouthparts and cements them to moss or some other substrata. Fertilization occurs during this process as she coats each egg with the stored sperm. Young symphylans hatch with only about half the adult number of trunk segments and appendages.

During postembryonic development, first-order and second-order molts regularly alternate until maturity is reached. A new two-segment unit is added after each first-order molt, but only one more pair of legs is differentiated, the other pair differentiating after the subsequent second-order molt, at which time no new segments are added. Mature symphylans continue to molt throughout life (up to 40 times in *Scutigerella immaculata*), without further addition of segments or legs.

Embryonic Development

The yolky eggs of myriapods rely almost entirely on meroblastic cleavage. Most myriapods undergo early cleavage by intralecithal nuclear divisions, followed by a migration of the daughter nuclei to the peripheral cytoplasm (= periplasm). Here they continue to divide until the periplasm is dense with nuclei, whereupon cell membranes begin to form, partitioning uninucleate cells from one another. At this point the embryo is a periblastula, comprising a yolky sphere that has a few scattered nuclei and is covered by a thin cellular layer, or blastoderm.

Along one side of the blastula a patch of columnar cells forms a germinal disc, sharply marked off from the thin cuboidal cells of the remaining blastoderm. From specific regions of this disc, presumptive endodermal and mesodermal cells begin to proliferate as germinal centers. These cells migrate inward during gastrulation to lie beneath their parental cells, which now form the ectoderm. The mesoderm proliferates inward as a longitudinal gastral groove; the cells of the developing gut usually surround and gradually begin absorbing the large central yolky mass of the embryo.

Segments begin to demarcate and proliferate and eventually develop appendage buds. The mouth and anus arise by ingrowths of the ectoderm that form the fore- and hindguts, which eventually establish contact with the developing endodermal midgut.

Variations on this basic scheme occur in groups with secondary yolk reduction, such as in pauropods and symphylans. In these groups a largely holoblastic cleavage takes place, and a coeloblastula actually forms. In most centipedes, a type of cleavage occurs that is somewhat intermediate between total and superficial cleavage. After a few intralecithal nuclear divisions, the yolk breaks up into blocks called yolk pyramids. Gradually the yolk pyramids disappear, and development shifts to the superficial type.

Myriapod Phylogeny

Myriapoda and Hexapoda had long been considered sister groups, together forming a clade called Atelocerata, in turn regarded as sister group to the Crustacea within Mandibulata. The sister-group relationship between myriapods and hexapods was based upon

for more ebook, testbank, solution manuals requests: email:3601267340@qq.com

several seemingly strong synapomorphies, including proctodeal Malpighian tubules, lack of the second pair of antennae, uniramous legs, and tracheal respiratory systems. However, there is now strong evidence that hexapods arose from within Crustacea, and thus the putative synapomorphies linking Hexapoda to Myriapoda must have evolved through convergent or parallel evolution. Some molecular phylogenies suggested that Myriapoda is sister group to Chelicerata (within a clade called Myriochelata or Paradoxopoda), but most recent studies agree that Myriapoda is a sister group to the Pancrustacea (Hexapoda plus a paraphyletic Crustacea).

The monophyly of the four myriapod classes is supported by the following traits:

- **Chilopoda** Appendages of first trunk segment housing a poison gland; 15 pairs (secondarily more) of walking legs; alternation of long and short tergites, with reversal on segments 7–8, and spiracles associated with the segments bearing long tergites
- **Diplopoda** Trunk formed by diplosegments; antenna with eight articles, the distal article bearing apical sensory cones; spermatozoon without flagellum
- **Pauropoda** Antennae branching, with a special sensory organ (globulus); paired pseudoculi on lateral sides of head capsule
- **Symphyla** Single pair of tracheal stigmata on sides of head capsule; eyes absent; paired lateral pockets in mouth cavity of female functioning as spermathecae; 12 pairs of trunk legs; unpaired genital opening; paired terminal spinnerets

Chilopoda is probably sister group to the remaining myriapod classes, which are collectively classified as the Progoneata, meaning that their genital opening is anterior (in the region of the third body segment) rather than posterior as in the centipedes (Opisthogoneata). Within the Progoneata, Pauropoda and Diplopoda probably form a clade (Dignatha) defined by the lack of limbs on the postmaxillary segment, spiracles opening at the bases of the walking legs, a motionless pupoid stage after hatching, and the first free-living juvenile having three pairs of legs.

Myriapods with calcified exoskeletons are reasonably well preserved in the fossil records, the oldest specimens being from the middle Silurian (425 Ma), although older trace fossils from the Late Ordovician (some 450 Ma) have also been attributed to them. Both modern clades of chilognathan millipedes (Pentazonia and Helminthomorpha) are documented since the Pennsylvanian, in the Carboniferous. Extinct myriapod taxa are the Arthropleurida (which includes the giant *Arthropleura*, up to 2.6 m long), Eoarthropleurida, and Microdecemplicida, all Paleozoic. From middle Silurian to late Carboniferous are documented the Archypolypoda, a group of millipedes with the trunk composed of alternating smaller and larger units with one leg pair each. Myriapods with uncalcified cuticle such as centipedes and penicillate millipedes are fairly common in amber and are extensively documented since the Cretaceous, but the oldest centipedes—*Crussolum crusserratum*, a notostigmophoran, and *Devonobius delta*, a pleurostigmophoran of debated affinities—are known from the Silurian–Devonian and Middle Devonian (380 Ma), respectively.

Chapter Summary

This chapter introduced you to one of the four subphyla of Arthropoda, the Myriapoda—centipedes, millipedes, and two very small groups called Pauropoda and Symphyla. All of the 16,000 known species of living myriapods are terrestrial, but the lineage probably had its origin in the aquatic realm. Myriapods are familiar arthropods, easily distinguished from most other terrestrial invertebrates by a body divided into just two tagmata: the head and the long, homonomous, and many-segmented trunk bearing many pairs of jointed legs. As in the subphylum Hexapoda, myriapods have an aerial gas exchange system composed of tracheae and spiracles (convergent with those in Hexapoda). Also as in the Hexapoda, the head is equipped with a single pair of antennae. The mouthparts are represented by the mandibles and the first maxillae; a second pair of maxillae is present in the centipedes and symphylans, but in millipedes and pauropods the corresponding segment bears no appendages. Millipedes are slow-moving detritus feeders that generally spend their time burrowing through soil and litter. Uniquely among the arthropods, most millipede trunk segmental units bear two pairs of legs each and are described as diplosegments. In contrast to millipedes, most centipedes are fast-running predators, with one pair of legs per segment and with poison claws at the tips of the first pair of trunk legs (thus turned into peculiar maxillipeds called forcipules or prehensors). When threatened, centipedes usually strike out with the poison claws, with which they can inflict a painful bite. Important future research on the Myriapoda will include a better understanding of centipede venoms and millipede defensive secretions as well as the genomic and physiological adaptations they acquired in adapting to terrestrial environments.

CHAPTER 24

Phylum Arthropoda
Subphylum Chelicerata

The arthropod subphylum Chelicerata includes Xiphosura (horseshoe crabs), Arachnida (spiders, scorpions, mites, ticks, daddy longlegs, and several less familiar groups), and Pycnogonida (sea spiders); the first two taxa together have been traditionally referred to as Euchelicerata, but recent phylogenomic work has questioned this separation, as it finds that horseshoe crabs often nest within Arachnida (a classificatory change that we do not make in this edition as we await further studies and possible confirmation). In addition to the 113,000 or so described living species, there is an impressive array of fossil forms (about 2,000 species), such as the Paleozoic giant water scorpions (Eurypterida; nearly 250 described species), some of which were nearly 3 m long, that lived from the Ordovician to the Permian. Chelicerata had their origin in ancient Cambrian seas. Pycnogonida and Xiphosura remain entirely marine, but Arachnida invaded land long ago and today are mostly terrestrial, with notable exceptions among the mites. If the new position of horseshoe crabs is correct, this implies a recolonization of the sea. When compared with other Metazoa, Chelicerata are second only to the insects in species diversity, having adapted to virtually every imaginable situation and lifestyle on land, with the mites having an enormous diversity of life cycles.

In addition to the basic characteristics common to all arthropods, chelicerates are distinguished by several unique features (Box 24A). The body is typically divided into two main regions—the prosoma and opisthosoma (Figures 24.1–24.3), although this is different in mites and ticks.[1]

This chapter has been revised by Gonzalo Giribet and Gustavo Hormiga.

[1]These two body regions are sometimes also referred to as the cephalothorax and abdomen, but they are not homologous with those regions in other arthropods.

** Molecular phylogenetic support for a monophyletic Scalidophora is ambivalent
*** Paraphyletic (excludes Hexapoda)

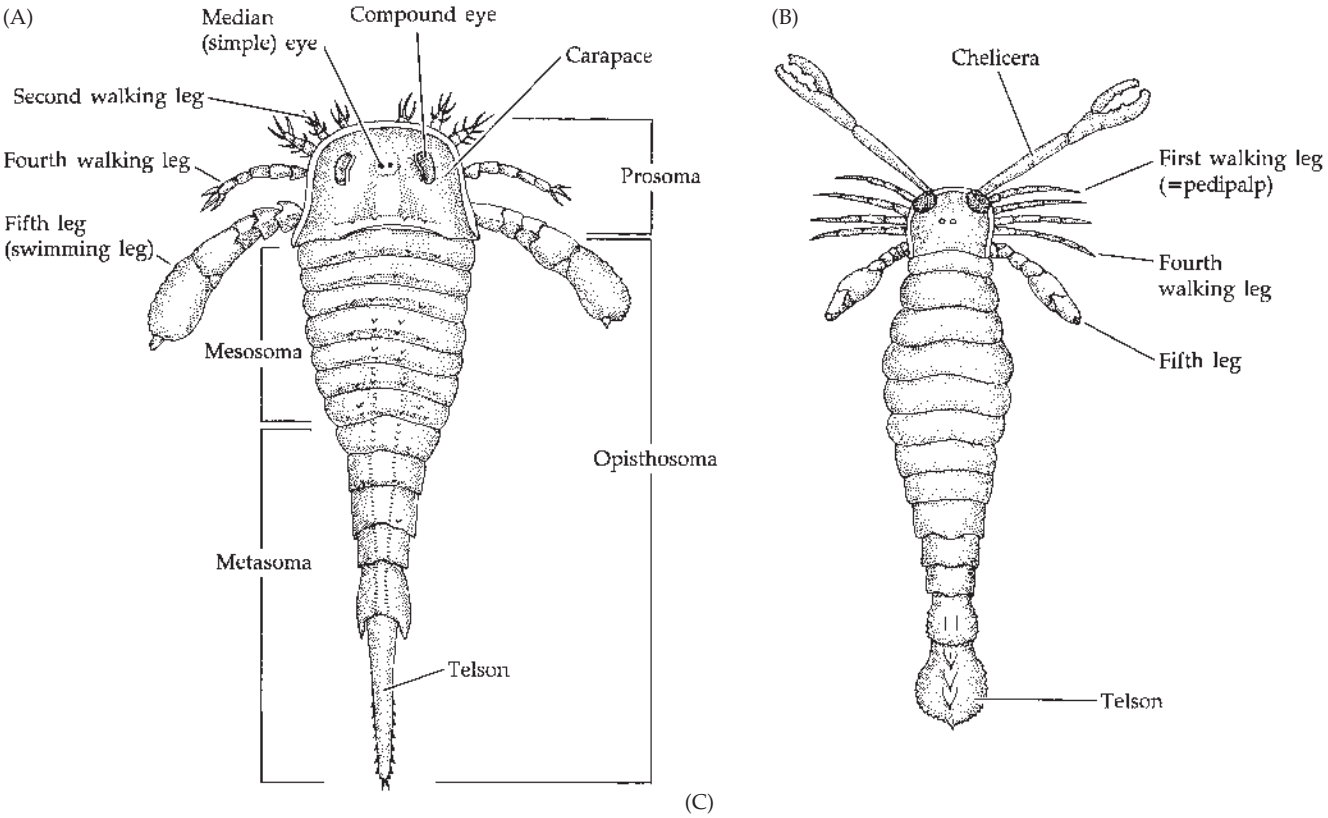

FIGURE 24.1 Water scorpions (subclass Merostomata, order Eurypterida), an extinct group of chelicerates. (A) *Eurypterus* (dorsal view). (B) *Pterygotus bohemicus*, which reached lengths of nearly 3 meters. (C) *Eurypterus remipes*, a species from the Silurian Period of the Paleozoic. Eurypterids flourished in Paleozoic seas; some probably invaded fresh water and perhaps even land.

Millard H. Sharp/Science Source

BOX 24A Characteristics of the Subphylum Chelicerata

1. Body of two tagmata—prosoma and opisthosoma. Prosoma composed of 7 somites, often covered by carapace-like dorsal shield. Opisthosoma composed of up to 12 somites and a postsegmental telson; subdivided into two parts in some groups.
2. Appendages of prosoma are chelicerae/chelifores, pedipalps/palps, and typically four pairs of walking legs; antennae absent. All appendages multiarticulate.
3. Gas exchange by book gills, book lungs, or tracheae; or through cuticle and gut.
4. Excretion typically by coxal glands and/or Malpighian tubules. Chelicerate Malpighian tubules are probably not homologous with those of insects, terrestrial isopods, or tardigrades.
5. With simple median and lateral (compound in xiphosurans) eyes
6. Gut with two to six pairs of digestive ceca.
7. Most are gonochoristic.

In contrast to most other arthropods, it is not possible to delineate a discrete "head" in chelicerates. There are no antennae, but generally six of the seven prosomal segments bear appendages. The first pair of appendages, corresponding to the second prosomal segment, is the chelicerae (called chelifores in pycnogonids), followed by the pedipalps, and then four pairs of walking legs. In the pycnogonids there may exist an additional pair of appendages, the ovigers, between the pedipalps and first walking legs, and the number of walking legs can be greater than four pairs. The chelicerae and pedipalps are specialized for an enormous variety of roles in the various chelicerate groups, including prey capture, sensation, locomotion, and copulation; some of the walking legs also may assume some of these functions, especially tactile (e.g., the first or second legs of some arachnid orders) or copulatory (e.g., the third leg of the male ricinuleids). The opisthosoma usually bears a terminal postsegmental telson. In Xiphosura, and in some arachnid orders, the opisthosoma may be subdivided into two regions, a mesosoma and a metasoma (Figure 24.1). A detailed discussion of chelicerate anatomy is provided in The Euchelicerate Body Plan section.

Chelicerata is a large and diverse taxon comprising three rather different groups: Xiphosura, which includes the horseshoe crabs; Arachnida, including the terrestrial spiders, scorpions, and mites, among others; and Pycnogonida, the sea spiders. To assist readers in gaining a grasp of this large and diverse subphylum, we treat the Euchelicerata and Pycnogonida separately in this chapter.

(C) A mange mite, *Sarcoptes scabiei* (Acariformes, Sarcoptiformes). (D) An adult chigger mite, *Trombicula* (Acariformes, Trombidiformes). Note the sejugal furrow between the second and third legs. (E) One of the feather mites, *Analges* (Acariformes, Sarcoptiformes). (F) A tick, *Dermacentor* (Parasitiformes, Ixodida). (G) *Tydeus starri* (Acariformes, Trombidiformes), with a deep sejugal furrow.

CLASSIFICATION OF CHELICERATA

CLASS PYCNOGONIDA The sea spiders, 1,368 extant species.

FAMILY AUSTRODECIDAE (e.g., *Austrodecus*)

FAMILY RHYNCHOTHORACIDAE (*Rhynchothorax*)

FAMILY PYCNOGONIDAE (*Pentapycnon, Pycnogonum*)

FAMILY COLOSSENDEIDAE (e.g., *Colossendeis, Decolopoda, Dodecolopoda, Pentacolossendeis, Hedgpethia*)

FAMILY ENDEIDAE (*Endeis*)

FAMILY PHOXICHILIDIIDAE (e.g., *Anoplodactylus, Phoxichilidium*)

FAMILY PALLENOPSIDAE (*Bathypallenopsis, Pallenopsis*)

FAMILY AMMOTHEIDAE (e.g., *Achelia, Ammothella, Nymphopsis, Tanystylum*)

FAMILY "ASCORHYNCHIDAE" (e.g., *Ascorhynchus, Nymphonella*)

FAMILY "CALLIPALLENIDAE" (e.g., *Austropallene, Callipallene, Pseudopallene*)

FAMILY NYMPHONIDAE (e.g., *Nymphon, Pentanymphon, Sexanymphon*)

Members of the acarine orders. (H) An opilioacarid mite, *Neoacarus* sp. (Opilioacariformes) from South Africa. (I) Phoretic mites on the harvestman *Rhampsinitus transvaalicus*. (J) Phoretic mites on the harvestman *Sadocus polyacanthus*. (K) A Chyzeriidae mite (Acariformes, Trombidiformes). (L) Injured boa constrictor from Tobago with large tick infestation; look closely and you'll see numerous recently attached ticks, in addition to the engorged ones. (A after T. H. Savory. 1964. *Arachnida*. Academic Press, New York; B,D after P. A. Meglitsch. 1972. *Invertebrate Zoology*. Oxford University Press, London.)

CLASS EUCHELICERATA The eucheliceratas.

SUBCLASS MEROSTOMATA

ORDER XIPHOSURA Horseshoe crabs. (*Limulus*, *Carcinoscorpius*, *Tachypleus*)

SUBCLASS ARACHNIDA Spiders, scorpions, mites, ticks, and their kin; 16 extant orders.

ORDER AMBLYPYGI Whip spiders, tailless whip scorpions. (e.g., *Acanthophrynus*, *Damon*, *Heterophrynus*, *Stegophrynus*, *Tarantula*)

ORDER ARANEAE True spiders.

SUBORDER MESOTHELAE Segmented spiders; 1 family, Liphistiidae. (e.g., *Heptathela*, *Liphistius*)

SUBORDER OPISTHOTHELAE
Unsegmented spiders.

INFRAORDER MYGALOMORPHAE
Tarantula-like spiders; orthognathous chelicerae. About 27 families, including the following:

FAMILY CTENIZIDAE Trapdoor spiders. (e.g., *Cteniza*, *Cyrtocarenum*)

FAMILY EUCTENIZIDAE (e.g., *Eucteniza*, *Aptostichus*)

FAMILY ATYPIDAE Purse-web spiders. (e.g., *Atypus, Sphodros*)

FAMILY THERAPHOSIDAE Tarantulas and bird spiders. (e.g., *Acanthoscurria*, *Aphonopelma, Theraphosa*)

FAMILY DIPLURIDAE Diplurid funnel-web spiders. (e.g., *Diplura, Linothele*)

FAMILY ATRACIDAE Australian funnel-web spiders. (e.g., *Atrax*, *Hadronyche*)

INFRAORDER ARANEOMORPHAE
Araneomorph spiders; labidognathous chelicerae. About 75 families, including the following:

FAMILY HYPOCHILIDAE Lampshade weavers. (e.g., *Hypochilus, Ectatosticta*)

FAMILY GRADUNGULIDAE Long-claw spiders. (e.g., *Gradungula, Progradungula, Hickmania*)

FAMILY AUSTROCHILIDAE Missing-link spiders. (e.g., *Austrochilus, Thaida*)

FAMILY FILISTATIDAE Crevice weavers. (e.g., *Filistata, Kukulcania*)

FAMILY OONOPIDAE Goblin spiders. (e.g., *Costarina, Oonops, Opopaea, Orchestina*)

FAMILY DYSDERIDAE Woodlouse hunters. (e.g., *Dysdera*, *Harpactocrates, Rhode*)

FAMILY PHOLCIDAE Cellar spiders, daddy longleg spiders. (e.g., *Modisimus*, *Pholcus*, *Spermophora*)

FAMILY SCYTODIDAE Spitting spiders. (e.g., *Scytodes*)

FAMILY SICARIIDAE Brown recluse spiders. (e.g., *Loxosceles*, *Sicarius*)

FAMILY ARCHAEIDAE Assassin spiders. (e.g., *Austrarchaea, Eriauchenus*)

FAMILY ERESIDAE Velvet spiders. (e.g., *Eresus, Stegodyphus*)

FAMILY THERIDIIDAE Cobweb and widow spiders. (e.g., *Anelosimus*, *Argyrodes*, *Episinus*, *Latrodectus*, *Parasteatoda*, *Steatoda*)

FAMILY ULOBORIDAE Cribellate orb-weavers. (e.g., *Hyptiotes*, *Miagrammopes*, *Uloborus*)

FAMILY DEINOPIDAE Ogre-faced spiders. (e.g., *Deinopis, Menneus*)

FAMILY ARANEIDAE Ecribellate orb-weavers. (e.g., *Araneus*, *Argiope*, *Cyrtophora*, *Gasteracantha*, *Mastophora*, *Nephila*, *Neoscona*, *Zygiella*)

FAMILY TETRAGNATHIDAE Long-jawed orb-weavers. (e.g., *Dolichognatha*, *Leucauge*, *Meta*, *Pachygnatha, Tetragnatha*)

FAMILY MIMETIDAE Pirate spiders. (e.g., *Australomimetus*, *Ero, Mimetus*)

FAMILY LINYPHIIDAE Sheet-web spinners, dwarf spiders. (e.g., *Agyneta*, *Dubiaranea, Erigone*, *Haplinis*, *Oedothorax*, *Linyphia, Neriene*)

FAMILY ANAPIDAE Ground orb-weavers. (e.g., *Acrobleps, Anapis, Comaroma, Micropholcomma*)

FAMILY CLUBIONIDAE Sack-spiders. (e.g., *Clubiona, Elaver*)

FAMILY AGELENIDAE Funnel-weavers. (e.g., *Agelena, Coelotes, Tegenaria*)

FAMILY LYCOSIDAE Wolf spiders. (e.g., *Lycosa, Pardosa, Pirata, Schizocosa*)

FAMILY CTENIDAE Wandering spiders. (e.g., *Acanthoctenus*, *Anahita, Ctenus, Phoneutria*)

FAMILY TRECHALEIDAE Longlegged water spiders. (e.g., *Barrisca, Cupiennius, Trechalea*)

FAMILY PISAURIDAE Nursery-web spiders. (e.g., *Architis, Dolomedes, Pisaura*)

FAMILY OXYOPIDAE Lynx spiders. (e.g., *Oxyopes, Peucetia*)

FAMILY THOMISIDAE Crab spiders. (e.g., *Diaea, Misumena, Thomisus, Xysticus*)

FAMILY SPARASSIDAE Huntsman spiders. (e.g., *Delena, Heteropoda, Micrommata, Olios, Pandercetes*)

FAMILY GNAPHOSIDAE Ground spiders. (e.g., *Drassodes, Eilica, Gnaphosa, Micaria, Zelotes*)

FAMILY SALTICIDAE Jumping spiders. (e.g., *Habronattus, Lyssomanes, Maratus, Phidippus, Portia, Salticus, Spartaeus*)

ORDER OPILIONES Harvestmen, daddy longlegs.

SUBORDER CYPHOPHTHALMI Mite harvestmen; 6 families. (e.g., *Cyphophthalmus, Siro, Pettalus, Neogovea, Stylocellus, Troglosiro*)

SUBORDER EUPNOI Daddy longlegs; 7 families. (e.g., *Caddo, Leiobunum, Neopilio, Phalangium*)

SUBORDER DYSPNOI Daddy longlegs, hard-bodied daddy longlegs; 8 extant families. (e.g., *Acropsopilio, Ischyropsalis, Nemastoma, Ortholasma, Sabacon, Trogulus*)

SUBORDER LANIATORES Armored harvestmen; 29 families. (e.g., *Algidia, Fumontana, Sitalcina, Sandokan, Stygnomma, Zalmoxis, Vonones*)

ORDER PALPIGRADI Palpigrades, micro-whip scorpions; 2 families with 6 extant genera. (e.g., *Allokoenenia, Eukoenenia, Koenenia, Leptokoenenia, Prokoenenia*)

ORDER PSEUDOSCORPIONES Pseudoscorpions, false scorpions; 25 families. (e.g., *Chelifer, Chitrella, Chthonius, Dinocheirus, Garypus, Menthus, Pseudogarypus*)

ORDER RICINULEI Ricinuleids or hooded-tick spiders; 3 genera: *Cryptocellus, Pseudocellus, Ricinoides*

for more ebook/ testbank/ solution manuals requests: email 2601267346@qq.com

ORDER SCHIZOMIDA Schizomids; 2 families. (e.g., *Agastoschizomus, Megaschizomus, Nyctalops, Protoschizomus, Schizomus*)

ORDER SCORPIONES Scorpions; 20 families.

PARVORDER BUTHIDA

SUPERFAMILY BUTHOIDEA (e.g., *Androctonus, Buthus, Centruroides, Tityus*)

SUPERFAMILY CHAERILOIDEA (e.g., *Chaerilus*)

SUPERFAMILY PSEUDOCHACTOIDEA (e.g., *Troglokhammouanus*)

PARVORDER IURIDA

SUPERFAMILY IUROIDEA (e.g., *Iurus*)

SUPERFAMILY BOTHRIUROIDEA (e.g., *Bothriurus*)

SUPERFAMILY SUPERSTITIONOIDEA (e.g., *Superstitionia*)

SUPERFAMILY CHACTOIDEA (e.g., *Euscorpius*)

SUPERFAMILY SCORPIONOIDEA (e.g., *Diplocentrus*, *Urodacus*)

SUPERFAMILY VAEJOVOIDEA (e.g., *Vaejovis*)

INCERTAE SEDIS (e.g., *Belisarius*, *Hadrurus*, *Uroctonus*)

ORDER SOLIFUGAE Sun spiders, wind spiders, camel spiders; 13 families. (e.g., *Biton*, *Branchia*, *Dinorhax*, *Galeodes*, *Solpuga*)

ORDER UROPYGI Whip scorpions or vinegaroons; 1 family with 16 genera. (e.g., *Albaliella*, *Chajnus*, *Mastigoproctus*)

SUPERORDER PARASITIFORMES Mites and ticks.

ORDER HOLOTHYRIDA About 25 species, mainly feeding on the fluids of dead arthropods. (e.g., *Allothyrus, Neothyrus*)

ORDER IXODIDA Hard ticks and soft ticks. (e.g., *Amblyomma, Dermacentor, Ixodes, Rhipicephalus, Argas, Nuttalliella*)

ORDER MESOSTIGMATA Free-living predatory mites. (e.g., *Uropoda, Lasioseius*)

SUPERORDER OPILIOACARIFORMES

ORDER OPILOACARIDA Primitive mites. (e.g., *Opilioacarus, Neocarus*)

SUPERORDER ACARIFORMES Mites, dust mites, and "chiggers."

ORDER TROMBIDIFORMES A large, diverse order of mites, comprising more than 25,000 described species in 151 families. (e.g., *Trombidium, Scirus, Demodex, Tydeus*)

SUBORDER PROSTIGMATA (e.g., *Halotydeus, Penthaleus*)

SUBORDER SPHAEROLICHIDA

ORDER SARCOPTIFORMES Large order of mites, comprising around 230 families and 15,000 described species.

SUBORDER ORIBATIDA "Chewing" mites, moss mites, or beetle mites. (e.g., *Archegozetes, Conoppia*)

SUBORDER ASTIGMATA "Biting mites," dust mites, many parasites of vertebrates. (e.g., *Acarus, Dermatophagoides*)

Synopses of Living Chelicerate Groups

Class Eucheliceratа

Body composed of 2 tagmata: prosoma and opisthosoma. Prosoma composed of 7 segments, often covered by a carapace-like dorsal shield; with simple median eyes and compound or simple lateral eyes. Opisthosoma of up to 12 segments (subdivided into 2 parts in some groups) and a postsegmental telson. Prosomal appendages are chelicerae, pedipalps, and 4 pairs of walking legs; antennae absent; all appendages uniramous and multiarticulated.

Subclass Merostomata

Prosoma covered by a large, hardened, carapace-like shield; pedipalps similar to walking legs; opisthosoma undivided or divided into mesosoma and metasoma; with flaplike appendages as book gills; telson long and spiked. The merostomates diversified during the great Cambrian invertebrate radiation. Fossil eurypterids and xiphosurans are known from the Ordovician, and they flourished in the Silurian and Devonian. Alas, only 4 species of merostomates have survived to modern times, all xiphosurans—the horseshoe crabs.

Order Xiphosura Certain extinct forms and the living horseshoe crabs (Figure 24.2). Opisthosoma unsegmented and undivided, but with 6 pairs of flaplike appendages, the first pair fused medially as a genital operculum over the gonopores, the last 5 pairs modified as book gills. Pedipalps and walking legs chelate; last (fourth) pair of legs splayed distally for support on soft sediments (*Carcinoscorpius, Limulus, Tachypleus*).

Extant members of the order Xiphosura (the horseshoe crabs) are regarded as "living fossils" and are, of course, far better known than their extinct relatives. Especially well studied is *Limulus polyphemus* (Figure

The class Pycnogonida (sea spiders) is treated separately at the end of this chapter.

24.2C), the common horseshoe crab of the Atlantic and Gulf coasts of North America and a favorite laboratory animal of physiologists. Living xiphosurans inhabit shallow marine waters, generally on clean sandy bottoms, where they crawl about or burrow just beneath the surface, preying on other animals or scavenging. The chelicerae are smaller than the other appendages, being composed of only three articles. Each walking leg is formed of seven articles (coxa, trochanter, femur, patella, tibia, tarsus, pretarsus), the last two of which form the chelae (Figure 24.2B). The coxal endites of the pedipalps and first three walking legs are modified as gnathobases for mastication. Arising from the coxae of the fourth walking legs are tiny appendage-like processes called flabella. In addition, just posterior and medial to the last walking legs is a pair of reduced appendages called chilaria. Their function is unknown, and there is some controversy about their evolutionary significance—some specialists believe that they may reflect an additional opisthosomal segment.

The four living species of Xiphosura belong to three geographically distinct genera in the family Limulidae. *Limulus* (*L. polyphemus*) is restricted to eastern North America, ranging from Nova Scotia to the Yucatán region of Mexico; *Tachypleus* (*T. gigas* and *T. tridendatus*) occurs in Southeast Asia; *Carcinoscorpius* (*C. rotundicauda*) has been collected only from Malaysia, Thailand, and the Philippines and is capable of migrating upriver into fresh water. Another 100 or so extinct species have been described, the oldest being a species of *Lunataspis* from deposits in Manitoba (Canada) that are 445 million years old.

Subclass Arachnida

Prosoma wholly or partly covered by a carapace-like shield; opisthosoma segmented or unsegmented, divided (in scorpions) or undivided; opisthosomal appendages absent or modified as spinnerets (spiders) or pectines (scorpions); penes absent (except in most Opiliones and some mites); gas exchange by tracheae, book lungs, or both but also through the cuticle; nearly all terrestrial; over 110,000 species, in 16 orders.

"Acari" The term "Acari" has been traditionally used for several lineages of mites, ticks, and chiggers (Figure 24.3) that are now thought to be nonmonophyletic and that are currently classified in at least six orders in two main clades of uncertain phylogenetic position within the arachnid tree of life. The first clade is Parasitiformes (encompassing the orders Holothyrida, Ixodida, Mesostigmata) and Opilioacariformes (order Opilioacarida). The second clade is Acariformes (encompassing the orders Trombidiformes and Sarcoptiformes). These two lineages include a huge morphological disparity and a large diversity of ecological and reproductive strategies. For convenience, the six acarine orders (in three superorders) are discussed together below.

In mites (Acariformes) the prosoma and opisthosoma are fused, and a region of flexible cuticle (the **cirumcapitular furrow**) separates the chelicerae and pedipalps from the rest of the body. This anterior body region is called the **capitulum** or gnathosoma, and the remainder of the body is called the **idiosoma**, which is in turn divided into **podosoma** and **opisthosoma**. Another nomenclature divides the body into proterosoma and hysterosoma: the proterosoma includes the gnathosoma and the first two pedigerous segments, and the hysterosoma includes the last two pedigerous segments and the opisthosoma. The old junction between prosoma and opisthosoma is usually visible as the **disjugal furrow**, but more often these are indistinguishably fused. Further, in Acariformes a secondary sejugal furrow sometimes exists between the second and third walking legs, the chelicerae are pincer-like or styliform, the pedipalpal coxae are uniquely fused with head elements, the opisthosoma is unsegmented except in a few primitive forms, gas exchange is cutaneous or by tracheae, the eyes are present or absent, and males of some species have a penis.

Mites and ticks comprise the largest group of arachnids. There are approximately 54,600 described species, and some experts suggest that there may be as many as one million or more yet to be described! Because of the size and diversity of these orders, we give a somewhat extended account. Even so, it is not possible to do justice here to the vast range of forms and lifestyles represented by the mites and ticks.

Mites and ticks occur worldwide. Most are terrestrial, many are parasitic, and some have invaded aquatic environments, both freshwater and marine. Their tremendous evolutionary success, especially of the Acariformes, is reflected in their species diversity and in their extremely varied lifestyles. This success is probably due, at least in part, to a compact body and reduced size. By coupling small size with the inherent arthropod quality of segment and appendage specialization, mites have exploited myriad microhabitats unavailable to larger animals. If the group is polyphyletic, then several ancestral arachnid lineages evolved convergently to capitalize on miniaturization.

Recent classification schemes divide the members of the old "Acari" into two or three groups. One of these is a group of omnivorous and predatory forms named Opilioacariformes with the single order Opilioacarida (Figure 24.3H), which constitutes the sister group of Parasitiformes (some authors group both into Parasitiformes). Opilioacarida are characterized by the retention of opisthosomal segmentation (at least ventrally) and the presence of a transverse groove (the disjugal furrow) separating the prosoma from the opisthosoma. These mites are found on tropical forest floors and in arid temperate habitats.

for more ebook/ testbank/ solution manuals requests: email 2012673467@qq.com

The remainder of the thousands of mites and ticks are placed in Parasitiformes and Acariformes, the latter housing most of the species. The body of parasitiform mites is undivided dorsally, there being no clear transverse groove (Figure 24.3A). Parasitiformes includes free-living and symbiotic forms in all parts of the world. The free-living species inhabit various terrestrial habitats, including leaf litter, decaying wood and other organic debris, mosses, insect and small mammal nests, and soil. Most of these mites are predators on small invertebrates. Many species are full-time or part-time symbionts with other animals, either as immatures or as adults. Their hosts are frequently other arthropods, such as centipedes, millipedes, ants, and especially beetles. In some cases the relationship is truly parasitic, in others it is phoretic (Figure 24.3I,J,L), and in many instances the nature of the association is unknown.

The most familiar members of the Parasitiformes are the ticks (families Argasidae and Ixodidae; Figure 24.3F,L). Ticks are blood-sucking ectoparasites on vertebrates (one species, *Aponomma ecinctum*, lives on beetles). They are the largest-bodied members of the entire order, and some swell to 2 to 3 cm in length during a blood meal. The chelicerae are smooth and adapted for slicing skin, and together with the pedipalp coxae they form a structure called the capitulum. The ixodids are called the hard ticks because of a sclerotized shield covering the entire dorsum. They parasitize reptiles, birds, and mammals. They generally remain attached to their hosts for days or even weeks, feeding on blood. Some are vectors of important diseases, including *Dermacentor andersoni* (the vector of Rocky Mountain spotted fever) and *Rhipicephalus annulatus* (the vector of Texas cattle fever). Lyme disease (first described in Old Lyme, Connecticut, in 1975) is a bacterial disease that is harbored in deer and certain rodents and is transmitted by several tick species in North America, including the deer tick *Ixodes scapularis* and the western black-legged tick *Ixodes pacificus*.

Soft ticks (Argasidae) lack the heavily sclerotized dorsal shield of hard ticks. They are usually rather transient parasites on avian and mammalian hosts (particularly bats), typically feeding for less than an hour at a time. When not attached to a host, these ticks remain hidden in cracks and crevices or buried in soil. Disease-carrying soft ticks include *Argas persicus* (the vector of fowl spirochetosis) and *Ornithodoros moubata* (the vector of African relapsing fever, or "tick fever").

The vast and diverse Acariformes, once considered to be polyphyletic, are now recognized as a well-supported clade. These mites usually have bodies divided into two regions, but not as the normal prosoma and opisthosoma, which are fused. Rather, the disjugal furrow is lost, and a secondarily evolved sejugal furrow partly or wholly traverses the dorsum between the origins of the second and third pairs of walking legs (Figures 24.3D,G). In some acariform mites this division is secondarily lost.

Free-living acariform mites are found in virtually every conceivable situation: in soil, leaf litter, decaying organic matter, mosses, lichens, fungi, under bark, on freshwater algae, in sands, on seaweed, and at all altitudes and at most ocean depths. "Chiggers" is a name given to the larvae of acariform mites of several genera, notably *Trombicula*. They include both herbivores (some fungivores) and predators, and their feeding methods are diverse. Many ingest solid as well as liquid food, and a few aquatic forms actually suspension feed. One species, *Halacarellus auzendei*, is known from hydrothermal vent environments. Certain groups are serious pests that destroy stored grain crops and other food products. On the other hand, some predatory acariform mites have been used for biological pest control of other arthropods—even other mites! Bites from mites in the wild can be an annoyance to humans.

Most of the symbiotic acariform mites are parasites on vertebrate and invertebrate hosts. Various species parasitize marine and freshwater crustaceans, freshwater insects, marine molluscs, terrestrial arthropods, the pulmonary chambers of terrestrial snails and slugs, the outer surfaces of all groups of terrestrial vertebrates, and the nasal passages of amphibians, birds, and mammals. In addition to direct parasitism, many mites are phoretic, using their hosts for dispersal. There are also many plant-eating mites that are considered parasitic.

A great many acariform mites cause economic or medical problems by direct predation and parasitism, by acting as disease vectors, or by feeding on stored food products. The family Penthaleidae includes the red-legged earth mite (*Halotydeus destructor*) and the winter grain mite (*Penthaleus major*), both of which are serious pests of many important crops. Members of the superfamily Eriophyoidea are vermiform mites adapted to feeding on various plants. This group includes the gall and leaf-curl mites, as well as a number of others that serve as vectors for certain disease-causing viruses (e.g., wheat and rye mosaic viruses). Another family of mites (Demodicidae) includes parasites of hair follicles and sebaceous glands of mammals. Two species, *Demodex folliculorum* and *D. brevis*, occur specifically in the hair follicles and sebaceous glands, respectively, of the human forehead. Another, *D. canis*, causes mange in dogs. Some other problems caused by acariform mites include subcutaneous tumorlike growths in humans, various sorts of skin irritations, mange in many domestic animals, reduced wool production in sheep, and feather loss in birds.

With a mixture of reluctance and relief, we leave the mites; interested readers should consult the references at the end of this book for sources of additional information.

Order Amblypygi Whip spiders (Figure 24.4A,B). Prosoma undivided, covered by a carapace-like shield and connected to opisthosoma by narrow pedicel; opisthosoma segmented but undivided; with two pairs of book lungs; telson absent; chelicerae biarticulated, modified as spiderlike fangs; pedipalps raptorial; first pair of legs are greatly elongate as antenniform sensory appendages. With 8 eyes, except in some cave-dwelling species. Molting occurs throughout life as the animals keep growing in size.

The 160 or so extant species of amblypygids (there are 9 described fossil species) are commonly known as whip spiders or tailless whip scorpions, reflecting their similarities to both spiders and uropygids (whip scorpions).

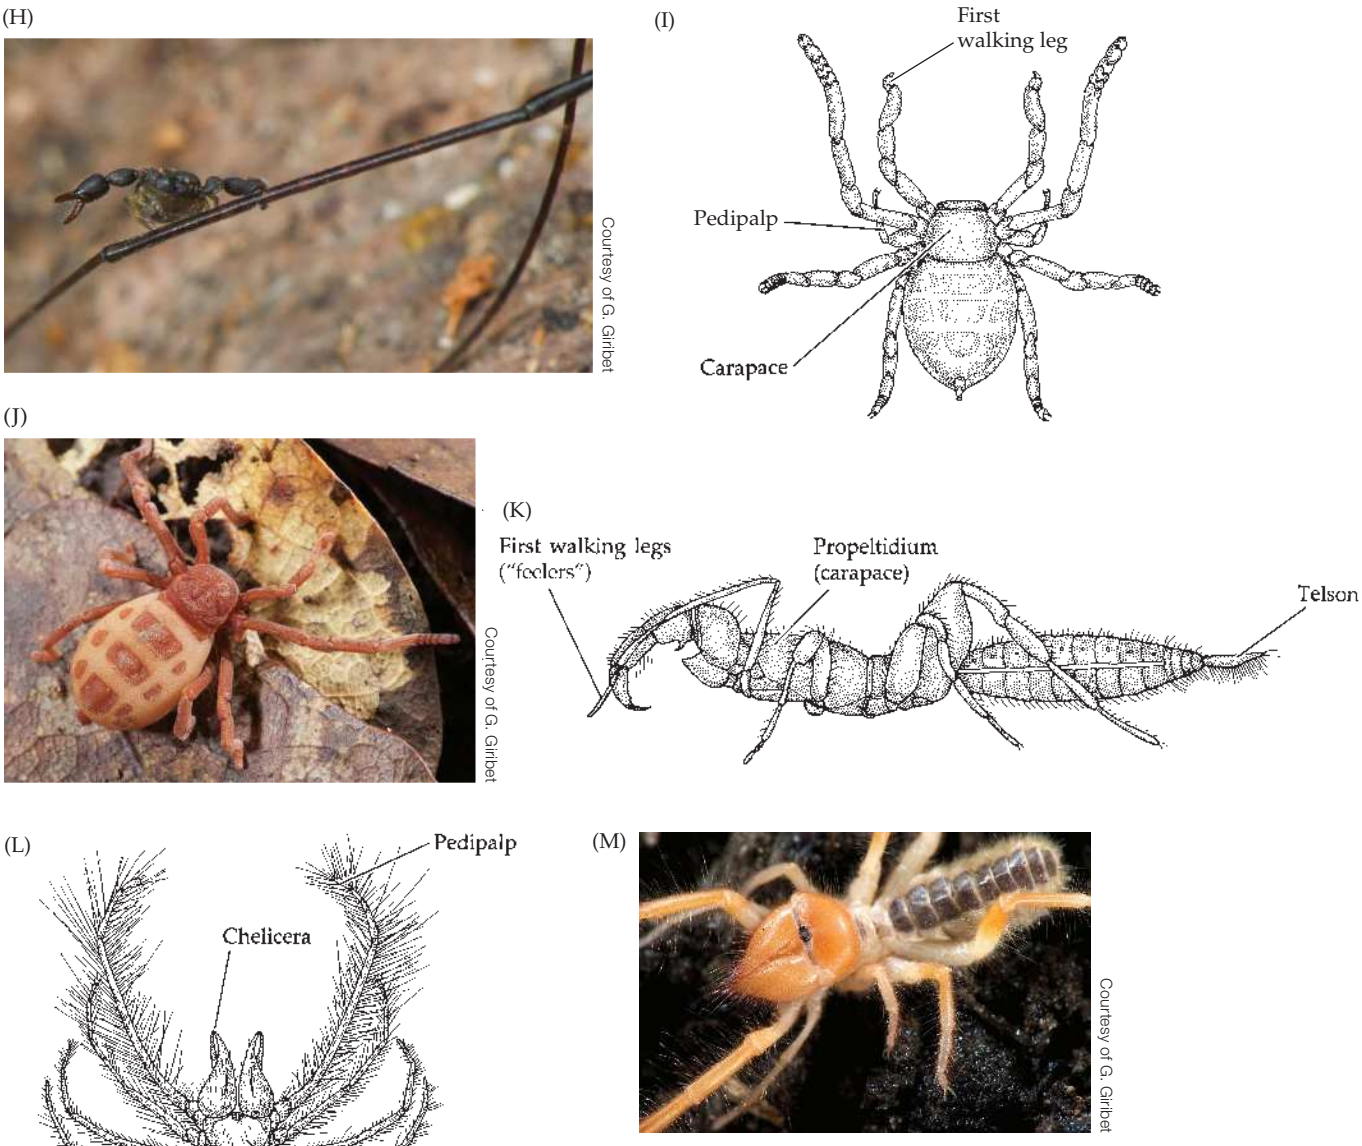

FIGURE 24.4 Some examples of arachnids other than spiders and scorpions. (A,B) Whip spiders (order Amblypygida). (A) *Heterophrynus batesii* (from the Amazon region). (B) *Stegophrynus dammermani*. (C,D) Daddy longlegs, or harvestmen (order Opiliones). (C) A daddy longlegs. (D) An armored harvestman (Laniatores), *Phareicranaus manauara*. (E) *Koenenia* (Palpigradi). (F–H) Pseudoscorpions (order Pseudoscorpiones). (F) *Chelifer cancroides*, a frequent hitchhiker on houseflies. (G) An unidentified female pseudoscorpion from New Zealand carrying its eggs. (H) A pseudoscorpion grabbing onto a harvestman's leg as a form of phoresy. (I,J) Ricinuleids (order Ricinulei). (I) *Ricinoides crassipalpe*, dorsal view. (J) A nymph of *Ricinoides atewa*. (K) A schizomid (order Schizomida), *Schizomus crassicaudatus*. (L,M) Sun spiders (order Solifugae). (L) *Galeodes arabs*. (M) *Eremobates*.

FIGURE 24.4 (*continued*) Some examples of arachnids other than spiders and scorpions. (N,O) Whip scorpions (order Uropygi). (N) *Mastigoproctus*. (O) *Thelyphonellus amazonicus*. (P) The cave palpigrade *Eukoenenia spelaea*. (Q) An unidentified schizomid from Panama. (B,F,L after T. H. Savory. 1964. *Arachnida*. Academic Press, New York.)

Externally they resemble whip scorpions, they have some internal characters related to spiders, but they lack spinnerets and poison glands. Amblypygids are widely distributed in warm humid areas, where they are found under bark or logs or in leaf litter and in similar protected habitats; several species are cave dwellers. Some species are able to stay underwater hours at a time or live in beaches; others live in extremely dry environments, including deserts. One western African small blind species inhabits termite nests.

Most species are less than 5 cm in length, but the first pair of legs may be as long as 25 cm! These limbs are used as touch receptors and chemoreceptors (like antennae in nonchelicerate arthropods) and are important in prey location because these animals hunt at night. Amblypygids walk sideways with these long "feelers" extended, sensing for potential prey. Once located, the prey is grasped by the enlarged spiny pedipalps and torn open by the chelicerae. The body fluids are then sucked from the victim and ingested. Many species of amblypygid have complex mating behaviors.

Order Araneae Spiders (Figure 24.5). Spiders, of course, are the most familiar of all chelicerates, and they are one of the most abundant groups of land animals. In fact, they might be the most commonly encountered macroscopic terrestrial invertebrates (along with isopods, ants, and flies) in the world! They have successfully exploited nearly every terrestrial environment, and many freshwater and intertidal habitats as well. Spiders display a truly staggering array of lifestyles—yet they all utilize a fairly uniform body plan, and the vast majority are generalist predators. Prosoma undivided, covered by a carapace-like shield and attached to opisthosoma by narrow pedicel; opisthosoma undivided and unsegmented except in liphistiids and some mygalomorph families, which have discrete tergites (i.e., "segmented abdomens"); chelicerae modified as fangs, served by venom glands located in the prosoma (absent in the families Uloboridae and in the Anapidae genus *Holarchaea*); pedipalps modified in the adult males as copulatory organs; opisthosoma bears book lungs and/or tracheae, silk-producing glands, and spinnerets, the last being highly modified appendages that serve to spin the silk produced by the silk glands; most with 8 eyes. Most araneomorphs cease to molt

(*Continued on next page*)

once adulthood is achieved, but mygalomorphs molt through their life time.

The body is divided into a fused prosoma and a fleshy, less sclerotized, opisthosoma. The first opisthosomal segment forms a narrow pedicel, which joins the two body regions. Each chelicera has two segments; the basal segment is short and conical (the paturon), and the distal segment is a hard, curved fang, usually bearing a pore from the duct of the poison gland (Figures 24.5D,E and 24.16A). A medial flap (the labium)

FIGURE 24.5 (*continued*) Spiders. (J) An orb-weaving spider from Madagascar, *Caerostris* sp. (Araneidae). (K) *Theraphosa blondi* (Theraphosidae), the Goliath tarantula, from the Brazil Amazon region; this is the largest extant spider. (L) *Cupiennius coccineus* (Trechaleidae), from the rain forests of Costa Rica, a favorite study subject of neurobiologists. (M) A female of the Tasmanian cave spider *Hickmania troglodytes*, from Australia (Gradungulidae). (N) Liphistiid spider "trap door" from Thailand (closed and open). Note the silk trip lines radiating from the entrance. (O) *Myrmecotypus* sp. (Corinnidae), from the rain forests of Brazil, a spider that mimics ants; ant mimicry has evolved multiple times among spiders. (B,C,G,H after R. Foelix. 2011. *Biology of Spiders*. Oxford University Press, Oxford.)

projects ventrally over the mouth. Each pedipalp is composed of six segments, and in most spiders the proximal segments are enlarged as lobes called endites, which bear gnathobases that flank the mouth and are used to handle and grind food (sometimes endites are also referred to as maxillae, although endites are not homologous with the maxillae of crustaceans and insects). Beyond the gnathobases, the pedipalps extend forward as tactile organs in females and juveniles, but they are highly modified as sperm transfer organs in

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

mature males. In a few species of spiders (e.g., tarantulas) the pedipalps function as walking "legs." The ventral surface of the prosoma bears a cuticular plate, or sternum, around which arise the four pairs of walking legs, each composed of eight articles.

The opisthosoma bears openings for gas exchange, the gonads and associated structures, the spinnerets, and the anus. On the ventral surface posterior to the pedicel is a transverse **epigastric furrow** in which the gonopores are located. In most females, a slightly elevated plate, the **epigynum**, lies in front of the epigastric furrow and bears the openings to the seminal receptacles. Lateral to the furrow are spiracles that open to the book lungs, or anterior tracheae. The hind part of the opisthosoma bears the anus and the spinnerets (the latter are situated near the middle of the opisthosoma in the Mesothelae). The ability of spiders to produce silk and fashion it into a great variety of functional devices has been a major factor in their evolutionary success, as we will see below.

There are more than 50,000 described spider species, classified into about 129 extant families. The largest spiders by leg span are the giant huntsman spiders (Sparassidae), some of which reach 30 cm (12 in.) in diameter. The largest spider by weight is probably the goliath birdeater tarantula (*Theraphosa blondi*), which can weigh over 170 g (6.0 oz). The smallest adult spiders are found in the micro-orb-weaver genus *Patu* (Symphytognathidae), the males measuring under 0.4 mm. The order Araneae is divided into two suborders. The suborder Mesothelae includes the "segmented" spiders (family Liphistiidae, about 145 species), which are characterized by persisting segmentation of the opisthosoma (Figure 24.5F), with conspicuous tergites, and midabdominal location of the spinnerets. Most are 1–3 cm long and build burrows with a trapdoor over the entrance; some have silk trip lines that converge radially onto the entrance (Figure 24.5N). All are predators, feeding on animals that pass within striking distance of the burrow opening.

The other suborder, Opisthothelae (with more than 49,000 species), comprises two large groups: the infraorder Mygalomorphae (tarantula-like spiders) and the infraorder Araneomorphae ("typical" spiders). Almost all members of both infraorders have an unsegmented opisthosoma and posteriorly located spinnerets, but they can be differentiated by the nature of the chelicerae (Figures 24.5G,H). Mygalomorph spiders have chelicerae that articulate in a manner that enables movement of the appendages parallel to the body axis (**orthognathous**), whereas araneomorph spiders have chelicerae that move at right angles to the body axis (**labidognathous**). An intermediate condition, known as **plagiognath** chelicerae, can be found in liphistiids, some mygalomorphs (e.g., Hexathelidae), and some araneomorphs (e.g., Hypochilidae).

Order Opiliones Daddy longlegs, or harvestmen, including mite harvestmen (Figure 24.4C,D). Divided into 4 extant suborders (Cyphophthalmi, and the three Phalangida suborders: Eupnoi, Dyspnoi, and Laniatores) and an extinct one (Tetrophthalmi). With an important fossil record, including multiple Paleozoic species. Prosoma entire or divided (as it also is in schizomids, palpigrades, and solifuges), sometimes into a proterosoma and two free segments. The prosoma joins broadly to the often segmented opisthosoma, but prosoma and opisthosoma can fuse dorsally in what is known as a scutum completum. Chelicerae small, of 3 articles, pincerlike; pedipalps long and leglike or well developed into a prehensile appendage, especially in Laniatores. Blind or with 1 pair of median eyes; whether the eyes of some Cyphophthalmi have their origin in median or lateral eyes remains debated. One pair of tracheae on opisthosoma; male with spermatopositor organ (in Cyphophthalmi) or penis (in Phalangida); female with an ovipositor organ.

The order Opiliones is a large and diverse group of about 6,500 species of uncertain relationships to other arachnid orders. Opiliones are known from nearly all climatic regions of the world, including subarctic areas, but are most abundant in tropical and temperate regions of the Southern Hemisphere. Most species have small bodies, less than 2 cm in length, but many Phalangida have very long legs (up to 10 cm).

Opiliones prefer damp, shaded areas and are commonly found in leaf litter, on trees and logs in dense forests, and in caves. They feed on various small invertebrates and also scavenge on dead animal and plant matter, mostly at night. Food is grasped by the pedipalps and passed to the chelicerae for chewing. These animals are among the few arachnids capable of ingesting solid particles instead of the usual liquefied food. Opiliones possess a pair of defensive repugnatorial glands, which produce noxious secretions containing quinones and phenols. As discussed later, most arachnids mate by indirectly passing sperm from the male to the female. Phalangida (and some mites) are the only arachnids in which males use a penis for direct copulation, while in Cyphophthalmi the male uses a "penislike" spermatopositor organ to place a spermatophore near the female gonostome—the ventral opening where the spermatopositor, penis, or ovipositor organs protrude in Opiliones. Many Opiliones display parental care, including of the rarer exclusive paternal form, also known from pycnogonids.

Order Palpigradi Palpigrades or micro-whip scorpions (Figure 24.4E). Minute arachnids with the prosoma divided into proterosoma, covered by the carapace-like propeltidium, followed by 2 free segments and joined to opisthosoma by a narrow pedicel; opisthosoma segmented and divided into broad mesosoma and short narrow metasoma, the latter bearing a long multiarticulated telson; eyes absent.

Palpigrades are delicate animals that walk by sensing the substrate with what seems a nervous behavior of the first pair of walking legs and using their unmodified palps for walking (unlike all other arachnids). While moving, most palpigrades keep the first pair of legs held upwards, moving them laterally. It is possible that the uplifted flagellum is associated with perception of the environment. These small, often highly translucent arachnids range in size from 0.65 mm in *Eukoenenia grassii* to 2.8 mm in the "giant" *E. draco* from caves on the island of Mallorca, Spain. These tiny arachnids have undergone a great deal of evolutionary reduction in association with their small size and cryptic habits. They are colorless, have very thin cuticles, and lack circulatory and gas exchange organs. Most are found under rocks or in caves, in very humid environments, and a few species live on sandy beaches. One species has recently been reported to feed on heterotrophic Cyanobacteria. The mode of sperm transfer in these arachnids remains unknown.

These rare animals have been recorded from widely separated parts of the world, and their biology and biogeography remain poorly known. The phylogeny of palpigrades has been recently investigated. The living members of the order are currently divided into two families: Eukoeneniidae, with four genera and more than 100 species, and Prokoeneniidae, with two genera and seven species. However, the position of Palpigradi among the arachnid orders remains elusive.

Order Pseudoscorpiones False scorpions (Figure 24.4F–H). Prosoma covered by a dorsal carapace-like shield, but clearly segmented ventrally. Opisthosoma undivided but with 11–12 segments and broadly joined to prosoma. Chelicerae chelate bearing silk glands; pedipalps large and scorpion-like, with venom glands in most species (in the clade Iocheirata); eyes present or absent.

There are about 3,700 described species of false scorpions, with the body lengths of adults generally ranging from 0.7 to 5 mm, but the largest species, *Garypus titanius* from Ascension Island, reaches 12 mm in length. The group is cosmopolitan and found in a great variety of habitats—under stones, in litter, in soil, under bark, and in animal nests. The genus *Garypus* is found on sandy and cobble marine beaches, and one pseudoscorpion species, *Chelifer cancroides*, typically cohabits with humans and is found in homes worldwide.

These strange little creatures resemble scorpions—to which they are probably related—in general appearance, but they lack the elongation of the opisthosoma and telson and do not have a stinging apparatus. However, most species possess poison glands in the pedipalps with which they immobilize their prey, usually other tiny arthropods (e.g., mites). Once captured, the victim is torn open by the chelicerae and the body fluids are sucked out. Also, like spiders, false scorpions produce silk, but the silk glands open on the chelicerae, with the glands located in the prosoma. This silk is used to build silken chambers for hibernation, molting, and egg laying.

A number of false scorpions use larger arthropods as temporary "hosts" for purposes of dispersal. This phenomenon of "hitchhiking," known as phoresy, typically involves females that grab onto the larger host animal with their pedipalps. The host is often a flying insect or other arthropod (Figure 24.4H). The abovementioned cosmopolitan species, *Chelifer cancroides*, for example, is frequently encountered as a phoretic "guest" on houseflies.

Order Ricinulei Ricinuleids or hooded-tick spiders (Figure 24.4I,J). Prosoma fully covered by a carapace-like shield and broadly joined with opisthosoma. Opisthosoma unsegmented, with paired tracheae; with a prosomal-opisthosomal locking mechanism. Chelicerae pincerlike, covered with a flaplike hinged plate named the **cucullus**; pedipalps small, with coxae fused medially. Eyes absent in extant species, but some have a lighter patch in the side of the prosoma that is thought to be light sensitive; 2 pairs of lateral eyes present in some fossil species. Third leg pair of males modified for sperm transfer. Cuticle very thick and ornamented with numerous sensory structures and sensory setae (Figure 24.4I,J).

There are 98 extant described species of ricinuleids; they are small, the largest species reaching 11 mm long, and live in caves and leaf litter in tropical forest in western Africa (*Ricinoides*) and the Neotropics (*Cryptocellus* and *Pseudocellus*), but fossil species are known from Myanmar Cretaceous amber. All are slow-moving predators on other small invertebrates. Ricinuleids have a hexapod larva and three other developmental stages (protonymph, deutonymph, and tritonymph); they may take 1 to 2 years to reach maturity and live 5 to 10 years. In immatures, the tergites and sternites are more widely spaced, and there are fewer than in the adults, where they almost touch.

Order Schizomida Schizomids (Figure 24.4K,Q). Prosoma divided; first 5 segments (the proterosoma) covered by a short carapace-like shield (the propeltidium), followed by 2 free segments, the mesopeltidium and metapeltidium. Opisthosoma segmented and divided; mesosoma with 1 pair of book lungs; metasoma with short, thin telson. Eyes present or absent.

There are about 300 species of small (less than 1 cm) arachnids in this order. Although some authors classify them as a suborder of Uropygi, they are distinguished from true whip scorpions by the divisions of the prosoma and the shorter telson. Schizomids live in leaf litter, under stones, in caves, and in burrows and are most common in tropical and subtropical areas of Asia, Africa, and the Americas. A few temperate species are known.

for more ebook/ testbank/ solution manuals requests email 9601267344@qq.com

The first walking legs are sensorial and resemble those of the closely related uropygids; together, the two comprise a clade. Like the uropygids, schizomids are predators on small invertebrates, and they also possess opisthosomal repugnatorial glands.

Order Scorpiones True scorpions (Figure 24.6). Body clearly divided into 3 regions: prosoma, mesosoma, and metasoma. Prosomal segments fused and covered by a carapace-like shield. Opisthosoma elongate, segmented, and divided into mesosoma and metasoma of 7 and 5 segments, respectively; telson spinelike, with poison gland. Chelicerae of 3 articles; pedipalps large, chelate, of 6 articles. With a pair of median eyes and sometimes additional pairs of lateral eyes, but some species are blind. First mesosomal segment bears a gonopore covered by genital operculum; second mesosomal segment bears a pair of unique sensory appendages called pectines; third through sixth mesosomal segments each with a pair of book lungs. Metasoma without appendages.

Scorpions are among the oldest terrestrial arthropods, and some consider them the most primitive arachnids, although recent phylogenetic analyses suggest that they are related to the other arachnids with book lungs, or Tetrapulmonata (Araneae, Amblypygi, Uropygi, and Schizomida). Others believe that they evolved from aquatic ancestors, perhaps from the eurypterids or a common ancestor, and invaded land during the Carboniferous Period. All of the roughly 2,000 known species are terrestrial predators. They inhabit a variety of environments, ranging from deserts to tropical rain forests, where some arboreal species occur, and even deep caves. They are notably absent from colder regions of the world. Scorpions include the largest living arachnids, with some reaching lengths of 18 cm.

The chelicerae are short and bear gnathobases for grinding food. The pedipalps are large, with the last two articles forming grasping chelae. The walking legs each comprise eight articles (coxa, trochanter, femur, patella, tibia, metatarsus, tarsus, pretarsus). The ventral surface of the mesosoma bears the genital pore, a

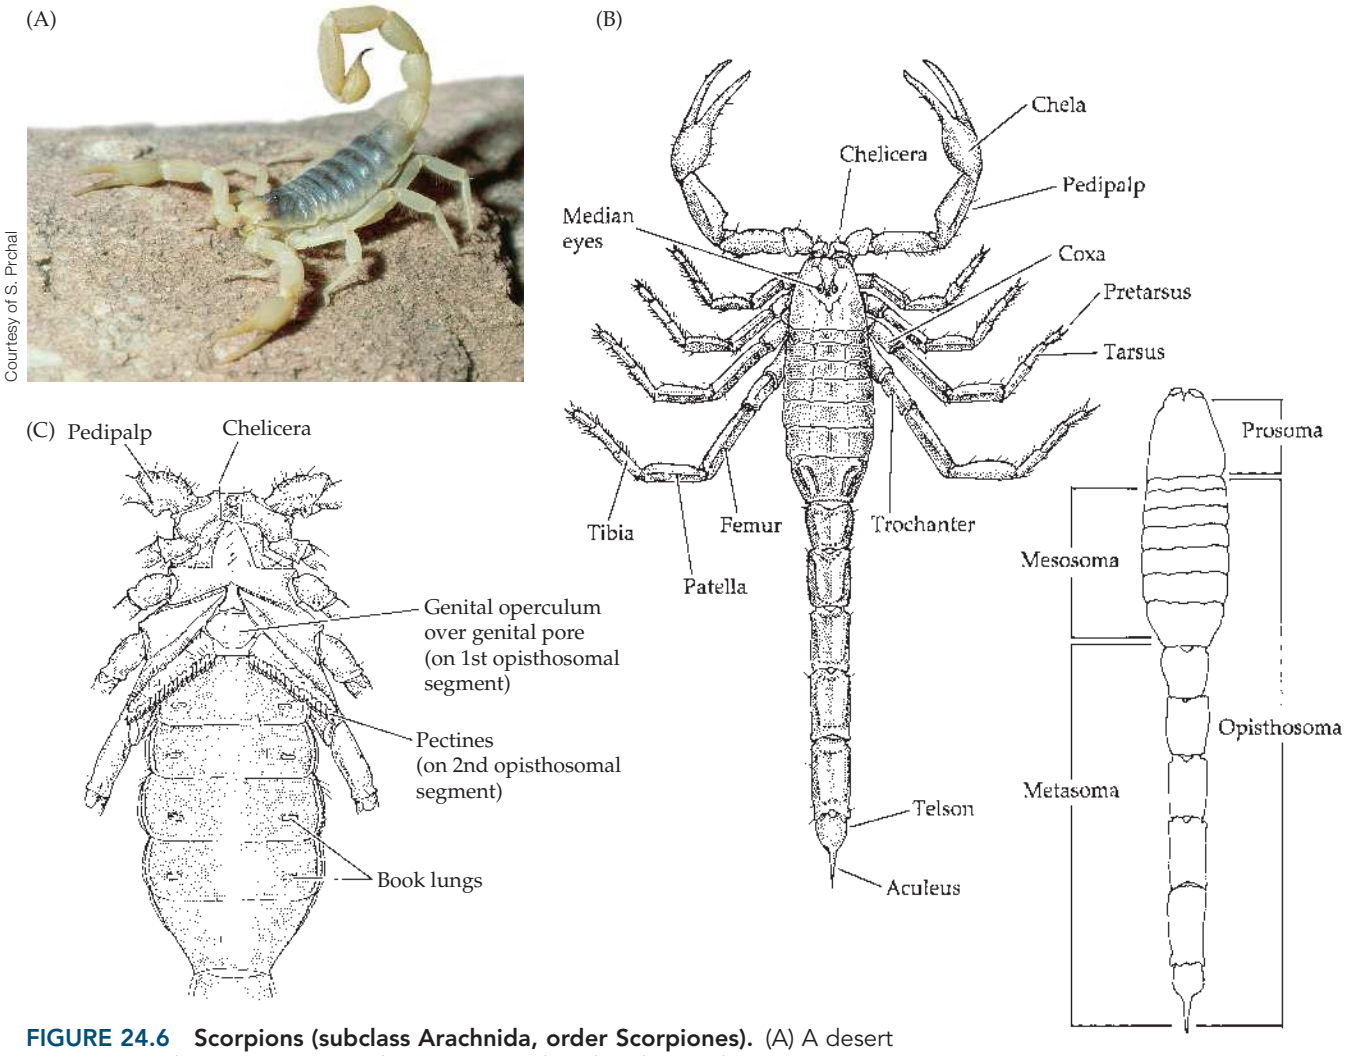

FIGURE 24.6 Scorpions (subclass Arachnida, order Scorpiones). (A) A desert scorpion, *Androctonus*. (B,C) *Buthus martensii* (dorsal and ventral views).

pair of pectines, and four pairs of spiracular openings to the book lungs. The anus is located on the last true segment of the metasoma and is followed by a stinging apparatus derived from the telson and bearing a sharp barb called the aculeus.

Scorpions are admired and feared in many cultures. They are well known for glowing in the dark under UV light; even the cast-off exuvium glows. Scorpions display complex mating behaviors and maternal care.

Order Solifugae Sun spiders, camel spiders, or wind spiders (Figure 24.4L,M). Prosoma divided into a proterosoma covered by a carapace-like shield and 2 free segments; opisthosoma undivided, but with 11 segments, bearing 3 pairs of tracheae; chelicerae huge and held forward, consisting of 2 articles; pedipalps long and leglike; propeltidium with 1 pair of eyes. On the ventral side of the fourth pair of legs, solifuges have up to 10 malleoli or racquet organs, unique sensory organs that occur in these animals.

Most of the 1,105 or so species of solifuges (or solpugids) live in tropical and subtropical desert environments of the Americas, Asia, and Africa. In contrast to many arachnids, they are often daytime hunters, hence the common name "sun spiders." They are also known as "wind spiders" because the males run at high speeds, "like the wind," or "camel spiders" because they are often found in deserts.

Some solifuges are only a few millimeters long, but many reach lengths of up to 7 cm. The feeding habits of many solifuges are unknown. Among those that have been studied, most are omnivorous, but they frequently show a preference for termites or other arthropods. Lacking poison, they rip their live prey apart with their strong chelicerae. They can also end up killing their partners during their aggressive copulation behavior.

Order Uropygi Whip scorpions and vinegaroons (Figure 24.4N,O). Prosoma elongated and covered by a carapace-like shield. Opisthosoma segmented and divided; mesosoma broad with 2 pairs of book lungs; metasoma short with long, whiplike telson; first walking legs elongated and multiarticulated distally. With 1 pair of median and 4 or 5 pairs of lateral eyes.

Whip scorpions are moderately large arachnids reaching lengths of up to 8 cm. There are 124 known species of living Uropygi (or Thelyphonida), most of which occur in Southeast Asia; a few are known from the southern United States, Mexico, and parts of Central and South America; and some species in Africa have probably been introduced. With the exception of a few desert species, whip scorpions live under rocks, in leaf litter, or in burrows in relatively humid tropical and subtropical habitats. The telson is sensitive to light, and most uropygids are negatively phototactic and active only at night.

The elongate first walking legs are held forward as "feelers," aiding the animals in their nocturnal hunting excursions. They feed on various small invertebrates by grasping prey with the pedipalps and grinding it with the chelicerae. The long telson is constantly moving about, probably serving as a sensory structure in case a predator moves in from behind.

Whip scorpions possess a pair of repugnatorial glands that open near the anus. When a uropygid is threatened by a potential predator, it raises the opisthosoma and sprays an acidic liquid from these glands on the would-be attacker. Some forms (e.g., *Mastigoproctus*) produce a secretion high in acetic acid, earning them the common name "vinegaroons." The spray nozzle of vinegaroons is like a turret, such that they can spray in almost any direction, even in front of them. Most live in self-made burrows.

Uropygi are closely related to Schizomida. In fact, some authors use the name Thelyphonida for the whip scorpions and the term Uropygi to refer to Schizomida + Thelyphonida as a clade. This clade is, in turn, closely related to Amblypygi and Araneae, constituting the group Tetrapulmonata, or the lung-bearing arachnids.

The Eucheliceratе Body Plan

Looking over the taxonomic summaries in the Synopses of Living Chelicerate Groups section will give you a good sense of diversity within Eucheliceratа. This section covers the general biology and structure of members of this large class, with an emphasis on the xiphosurans, spiders, and scorpions. We hope to convey an impression not only of diversity but also of unity within this group and to reinforce the concept of the evolutionary plasticity of the arthropod body plan in general.

As noted earlier, the body of chelicerates is typically divided into two main regions, the **prosoma** and the **opisthosoma** (Figures 24.1, 24.2, 24.5, and 24.6); a discrete head is not recognizable. The prosoma includes 7 segments; the opisthosoma includes up to 12 segments and a postsegmental, postanal telson. As in other arthropod groups, these basic body regions have undergone various degrees of specialization and tagmosis. In most eucheliceratеs the entire prosoma is fused and covered by a carapace-like shield. However, in certain groups (e.g., schizomids, palpigrades, solifuges, and some harvestmen) the prosoma is divided into three parts: a **proterosoma**, comprising the first five segments, all fused and covered by a carapace-like shield (often called the propeltidium), and two free segments (often called the **mesopeltidium** and **metapeltidium**). The opisthosoma may be undivided, as it is in most spiders, ricinuleids and harvestmen or divided into an anterior **mesosoma** and posterior **metasoma**, as it is in scorpions and in eurypterids.

The appendages further distinguish the eucheliceratеs from other arthropods. There are no antennae, and the first segment bears the eyes, with all six following segments of the prosoma bearing appendages. The

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

first pair of appendages is embryologically postoral, often pincerlike, **chelicerae**. During embryogeny, the chelicerae migrate to a position lateral to the mouth, or even preoral, as compared with adults of most groups; here they serve as fangs or grasping structures during feeding. The chelicerae can be formed of two or three articles and are followed by a pair of postoral **pedipalps**, which are usually elongate or, more rarely, chelate. The pedipalps are usually sensory in function, but in some groups (e.g., scorpions) they aid in feeding and defense. The remaining four segments of the prosoma typically bear four pairs of walking legs.

The number of segments and appendages on the opisthosoma varies. In general, appendages are absent or very reduced, although in the horseshoe crabs they persist as large platelike limbs, called **book gills**, that function in locomotion and gas exchange. In most chelicerates, the opisthosomal limbs are greatly reduced and persist only as specialized structures, such as the silk-producing spinnerets of spiders or the pectines of scorpions.

In summary, we may define the Eucheliceratа as arthropods in which the body is divided into two regions (or two tagmata): a prosoma and an opisthosoma (with modifications of this body plan in mites, as discussed earlier). Additionally, the first two pairs of appendages are chelicerae (deutocerebral) and pedipalps (tritocerebral), and the remaining four pairs of prosomal appendages are walking legs and innervated by subesophageal ganglia. Evolutionarily, this body plan has been a highly successful one.

As mentioned earlier, the great success of spiders seems to have been due in large part to the evolution of complex behaviors associated with silk and web production, particularly among araneomorph spiders, whose silk fibers are stronger than those of mygalomorphs and liphistiids. Because we are paying special attention to members of the order Araneae in this chapter, and because silk production is so important to nearly all facets of their lives, we present a special section on spider silk and its uses.

Spinnerets, Spider Silk, and Spider Webs

Spider silk is a complex fibrous protein composed mostly of the amino acids glycine, alanine, and serine. Spider silk proteins are known as **spidroins**. The silk is produced in a liquid, water-soluble form that transforms into an insoluble thread after it is extruded from the body. This near instantaneous transformation involves as much as a tenfold increase in the molecular weight of the silk protein, which is enhanced by the formation of intermolecular bonds.

Spider silks are among the toughest energy-absorbing materials known. Some types of silk require up to ten times more energy to fracture than an equivalent volume of the synthetic fiber Kevlar (Kevlar is five times stronger than steel in terms of tensile-strength-to-weight ratio). Some spider silks can stretch as much as rubber. Spider silk is so strong that in some parts of the world (the Solomon Islands, for example) people actually use it as fishing nets by stacking numerous webs on top of one another.

The spider silk-producing organs are located in the opisthosoma and comprise several types of **silk glands**, depending on the taxonomic group. For example, an adult female orb-weaver (e.g., *Araneus*) has seven gland types, each producing silks with different physicochemical properties and functions. The liquid silk produced by these glands (also called "dope") is secreted into ducts that open to the outside through spigots located on the spinnerets (Figure 24.7). As the liquid silk travels along this duct, ionic exchanges occur and water is removed. A muscle-controlled valve toward the distal end of the duct is also involved in the process that causes a phase shift from liquid to a solid fiber. The apparatus spins the silk into threads of different thicknesses and properties. By spinning various kinds of silks in different diameters, spiders produce a variety of threads with unique properties for specific functions and at particular times. The **spinnerets** are highly modified opisthosomal appendages, and they retain some musculature that allows for their movement during spinning (Figure 24.7C). The spinnerets are located in body segments 11 and 12 (opisthosomal segments 4 and 5).

The numbers and kinds of glands and spinnerets vary. Ancestrally, spiders had four pairs of spinnerets (two pairs per segment): anterior lateral, anterior median, posterior lateral, and posterior median. Mesothelae spiders retain the four pairs of spinnerets (although in some species the anterior median pair is reduced to nonfunctional knobs). The recently described uraraneid fossil *Chimerarachne*, from the mid-Cretaceous, has two long pairs of lateral, multiarticulated, spinnerets and two pairs of median spinnerets that are very small in comparison and not articulated. Most extant spiders have three pairs (by the loss or modification of the anterior median spinnerets), although some have only one or two pairs of spinnerets. In many spiders there is a nonfunctional remnant of the anterior median spinnerets known as the **colulus**.

Another spinning organ, the **cribellum** (Figure 24.7D), occurs in several families of araneomorph spiders. Although the cribellum is a synapomorphy of Araneomorphae, it has been independently lost multiple times in this large clade. Like the colulus, the cribellum is a homologue of the anterior median spinnerets. This spinning organ is a platelike structure, anterior to the spinnerets, that bears many small spigots (up to 40,000 in some species). Cribellate silk is emitted in many extremely fine threads and then combed into a delicate mesh (Figure 24.7E) over a pair of axial fibers from the spinnerets by a row of special macrosetae (the calamistrum) on the metatarsus of the fourth legs (Figure 24.7F). In some species the calamistrum consists of two rows of macrosetae. Cribellate orb-weavers (e.g., the Uloboridae) use the resulting mesh, known as a "hackle band," to build the

(G) An SEM (237×) of the spinning apparatus of *A. similis*. The platelike structure anterior to the three pairs of spinnerets is the cribellum. (B after R. S. Wilson. 1969. *Amer Zool* 9: 103–111.)

sticky spiral of their orbs. The cribellum and the calamistrum appear after the third molt, and in males both structures disappear with the final molt, although nonfunctional remnants can be found in the adult males of some species. Similarly, the spigots involved in the spinning of the viscid sticky silk of ecribellate orb-weavers disappear in the final molt of males (there are exceptions, such as the adult males of many erigonine linyphiids, which retain this triplet of spigots).

The varied uses of silk are intimately associated with nearly every aspect of the lifestyle and habits of spiders, as explained more fully in following sections. Different types of silk are used as safety lines and climbing lines (drag lines), to anchor or cement drag lines to the substrate, for the construction of retreats and egg sacs, to wrap prey for brief storage, and to line burrows. In addition, several kinds of silks are used to build foraging webs. Adult males of many araneomorph spiders also use silk to build a sperm web, which is then used to deposit sperm (through the gonopore, in the abdomen) prior to charging their copulatory organs in the pedipalps (a process termed "sperm induction"). Sperm webs are built using special silk glands that open through a set of spigots along the anterior margin of the epigastric furrow (these male spigots are known as "epiandrous fusules"). The number and arrangement of spigots in the spinnerets and of epiandrous fusules varies taxonomically. Many newly hatched spiderlings spin long, thin threads to ride the wind for aerial dispersal ("ballooning").

Although all spiders can produce and use silk, not all of them build webs for prey capture (for example, jumping spiders do not build capture webs but often make silk retreats). In those spiders that use foraging webs, the diversity of web types and architectures is extraordinary, ranging from the highly geometrical, densely woven, micro-orb webs of symphytognathids to the deceivingly simple single line snares of mastophorine araneids whose bodies mimic the pheromones of the preys they feed on. Almost everything in between these extremes of web types seems to exist or be possible, and much of spider web architecture and natural history remains to be discovered and/or described, particularly in the tropical regions. The construction and use of prey-capture webs are discussed in more detail in the Feeding and Digestion section. In general, capture webs serve both to trap and retain prey long enough for it to be subdued and, through vibrations, to signal the spider of its presence. Indeed, most spiders live in a world dominated by vibrations, a world where a potential meal, predator, or mate reveals itself with characteristic resonance patterns. We present here a brief description of the construction of a familiar orb web, as commonly built by members of the families Araneidae and Tetragnathidae.

The spinning of an orb web takes place in three stereotypical phases, which are apparently genetically programmed (Figure 24.8). The first phase is the construction of a supportive Y-shaped framework and a series of radiating threads. The upper branches of the Y are initially laid down as a horizontal thread between two objects in the spider's environment. The spider sits in one spot and secretes the thread into the air; the loose end is then carried by air movements and flutters about until it contacts and sticks to an object. The spider then tacks down its end of the thread, moves to the center of the horizontal line, and drops itself on a vertical thread. The vertical thread is pulled taut and attached, thereby producing the Y-shaped frame. The intersection of the three branches of the Y becomes the hub of the final web, and it is from this point that the radii are extended. Radial threads are then attached to the frame threads. Once this initial phase is complete, the spider quickly lays down a nonsticky temporary spiral thread, starting from the hub, as the second phase of construction (the temporary spiral is left in the finished orb web of some species, such as those in the genera *Nephila* and *Phonognatha*). This spiral thread, along with the initial framework of threads, serves as a working platform during the third and final phase of web building—the production of the sticky spiral or prey trap. In ecribellate orb-weavers this final thread, the sticky spiral, is always coated with a gluey glycoprotein that automatically assumes a beaded distribution after it is deposited (Figure 24.9A). As the sticky spiral is laid down, the temporary spiral is removed or eaten.

Some orb-weavers (e.g., many species of *Argiope* and *Cyclosa*) produce a dense mesh of silk, called a **stabilimentum**, across the hub of their webs (Figure 24.9B). The form and materials used for stabilimenta vary widely taxonomically, and their phylogenetic distribution implies that stabilimenta have evolved independently multiple times. Consequently, the function of the stabilimentum also may vary across groups. Stabilimenta have been hypothesized to serve as a camouflaging device, to aid in thermoregulation, to have a defensive function, to warn large flying animals such

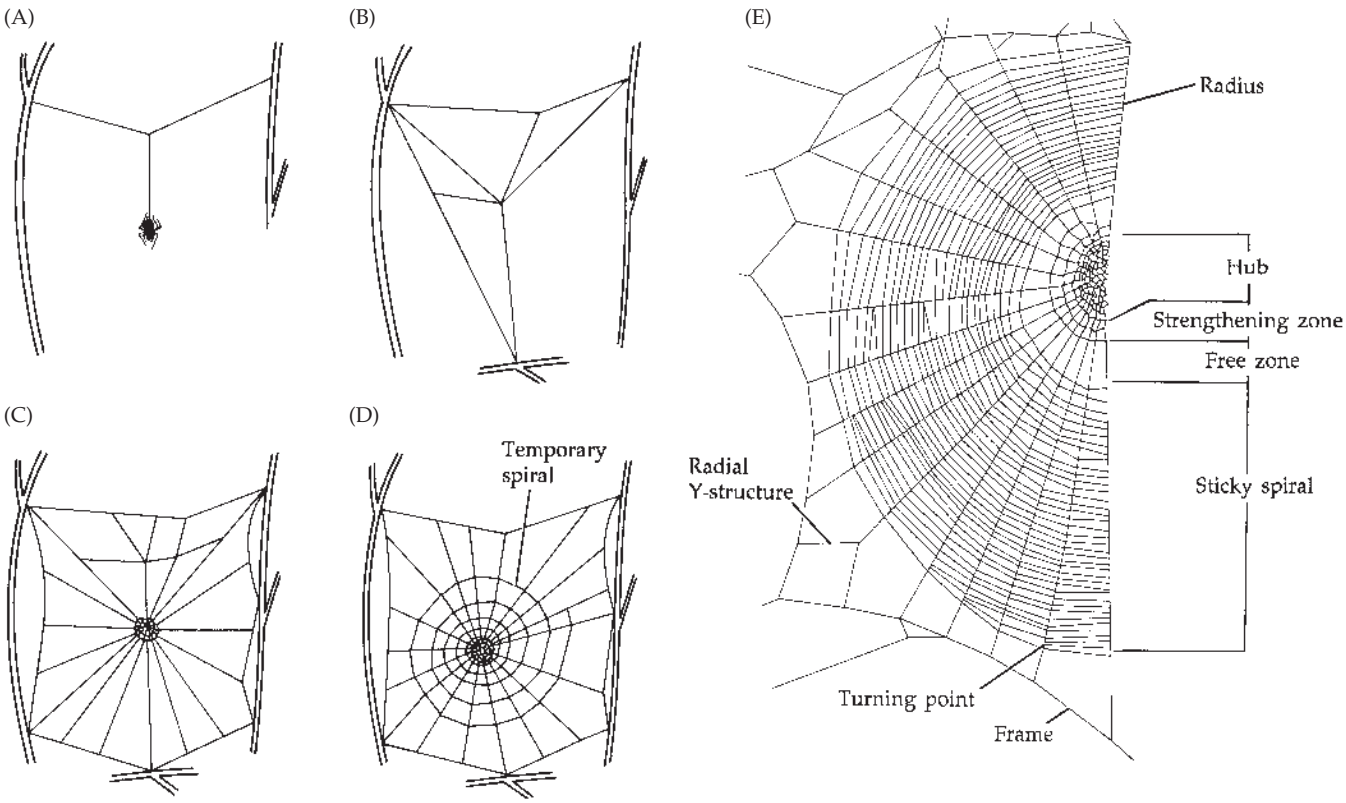

FIGURE 24.8 Construction of an orb web. (A) Formation of the Y-shaped frame. (B,C) Addition of radial threads. (D) Addition of the temporary spiral or working platform. (E) A portion of the completed orb web, with the temporary spiral replaced by the sticky spiral. (E after R. Foelix. 2011. *Biology of Spiders*. Oxford Univeristy Press, Oxford.)

as birds of the otherwise difficult to see webs (and thus prevent web damage), and to act as a visual guide to lure prey towards the web (by reflecting UV light and imitating floral patterns). Many orb-weavers (e.g., *Araneus*) can spin an entire web in less than 30 minutes, and most build a new web every night, but some have long-lasting webs (e.g., species of the araneids *Nephila* and *Cyrtophora*). When building a new orb web, spiders do not "waste" the silk of the old web, but eat it before or during the production of the new one. Radioactive labeling experiments show that the silk proteins from eaten webs appear at the spigots in new threads soon after ingestion, often within a few minutes!

Orb web building behavior is highly stereotypical and programmed, although there is some plasticity in the process, as spiders can, to some extent, adapt their web building behavior to a specific situation. In general, web architecture is fairly constant within species, in the sense that under similar circumstances and physical conditions, different individuals of the same ontogenetic stage and sex will build very similar webs. Among orb-weavers of the same species, the number of radii and spiral turns varies little. Web building appears to depend entirely on tactile input—normal webs are produced at night and by experimentally blinded spiders. Even gravity does not seem to be necessary, as illustrated by two famous orb-weaver spiders sent into space aboard Skylab.

Orb-weavers are an ancient group, with the oldest fossils being of Jurassic age and the oldest fossilized orb web spiders from the Cretaceous. Three groups of spiders make similar orb webs using different types of silks but with presumably homologous stereotypical behaviors. These are the deinopids and uloborids (formerly grouped under the superfamily Deinopoidea, no longer recognized as a natural group), which use cribellate silk for the capture spiral, and the araneoids (Araneoidea, a lineage comprising 17 families), which use a novel type of sticky, viscid, and gluey silk. During the last few decades the dominant paradigm has been that deinopoids and araneoids are reciprocally monophyletic and that together they form a clade (known as Orbiculariae). In recent years, several molecular studies (including phylogenomic approaches using thousands of genes) have rejected the long-accepted monophyly of Orbiculariae and of Deinopoidea, by placing the cribellate orb-weavers (Deinopidae and Uloboridae) with other groups and not with the ecribellate orb-weavers (Araneoidea). Orb webs have a complex evolutionary history, and while some studies support a single origin of orb webs, more recent results suggest that orb webs have likely evolved several times independently.

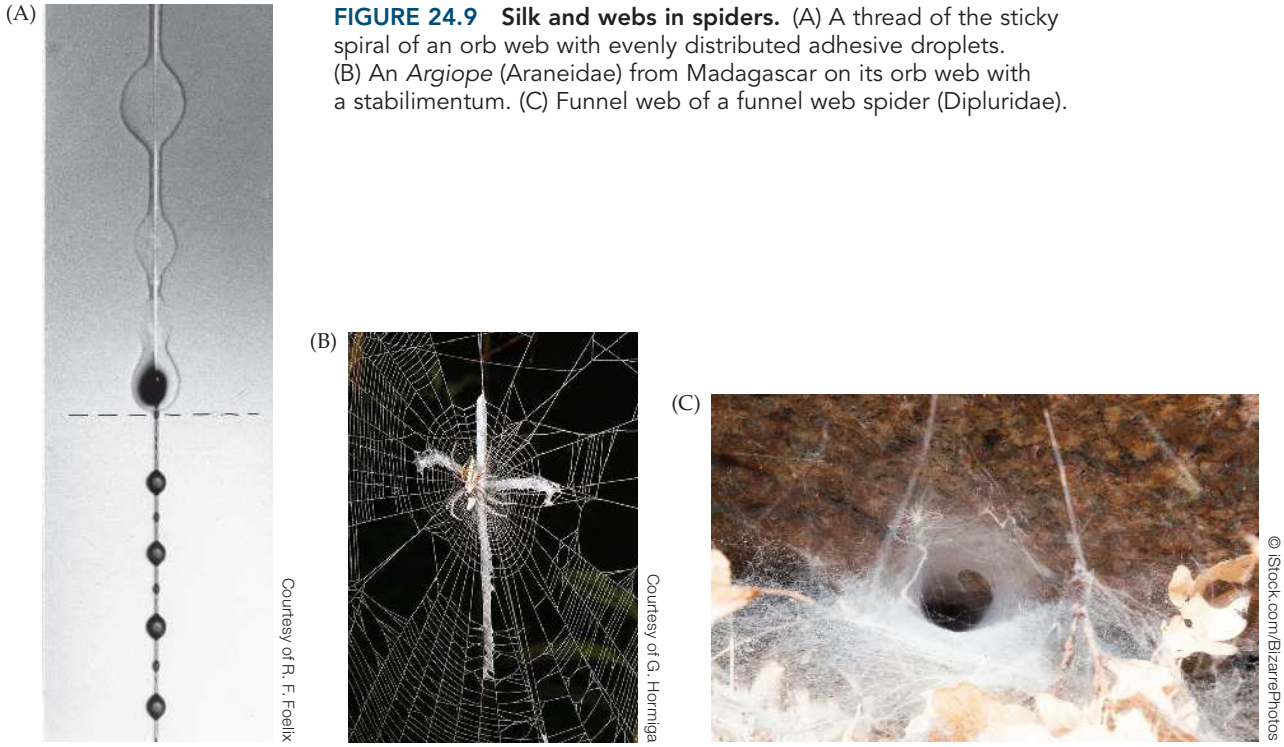

FIGURE 24.9 Silk and webs in spiders. (A) A thread of the sticky spiral of an orb web with evenly distributed adhesive droplets. (B) An *Argiope* (Araneidae) from Madagascar on its orb web with a stabilimentum. (C) Funnel web of a funnel web spider (Dipluridae).

For over a century specialists have debated about the origin and evolution of spider silk and webs. The silks and fibrous proteins found in many arthropod groups (e.g., in Lepidoptera and numerous other insect taxa, pseudoscorpions, tanaid crustaceans, and others) seem to have evolved independently of the silks of spiders. Silk production is ancestral in spiders, and all spiders retain both the ancestral and less complex silk types and the more recently evolved silk glands. This implies that silk gland evolution is correlated with selection for additional, not alternative, silk types and functions. It has been suggested that spider silk glands are derived from epidermal invaginations. In males, the epiandrous silk glands are derived from dermal glands. Silk gland spigots may have evolved from setae (cuticular "hairs") or from sensory setae (such as morphologically similar chemoreceptor setae of mygalomorphs). It is unclear why spider silk first evolved, but many researchers favor the idea that its origin was linked to wrapping and protecting eggs. The recent discovery of spinnerets with spigots in the mid-Cretaceous fossil arachnid *Chimerarachne yingi* allows for the possibility that spinnerets and the concomitant abdominal silk glands could have evolved before the most recent common ancestor of spiders. A recent book by Eberhard (2020) provides an encyclopedic treatment on the biology of spider webs and web building behaviors.

Some spider species cooperate in web building, prey capture, and even spiderling rearing. Such social activity has been reported for some 20 species in at least six families. In spiders, group living takes two different forms: cooperative (nonterritorial permanently social or quasi-social) and colonial (territorial permanently social or communal). Cooperative social species (e.g., several species in the theridiid genus *Anelosimus* and in the eresid *Stegodyphus*) have communal nests and communal capture webs that they inhabit throughout the entire lifetime of the individual, with colony members cooperating in prey capture and raising young. Colonial species (e.g., the uloborid *Philoponella republicana*) form aggregations, but individuals in the colony generally forage and feed alone, and there is no maternal care beyond the egg stage.

The theridiid *Anelosimus eximius* (Figure 24.15A), and some other species in this genus of cobweb weavers, exhibit the highest level of sociality known to spiders. These social species can form very large colonies, up to thousands of individuals, sometimes covering entire trees. These individuals live in a communal web and cooperate in brood care, prey capture, feeding, and web building.

Locomotion

Eucheliceratе locomotion follows the principles of arthropod joint articulation and leg movements discussed in Chapter 20. Except for the xiphosurans and a few aquatic arachnids, the legs must also be strong enough to support the body on land. Walking by terrestrial eucheliceratеs demands that the body be supported off the substratum and that the four pairs of legs move in sequences that maintain the animal's balance.

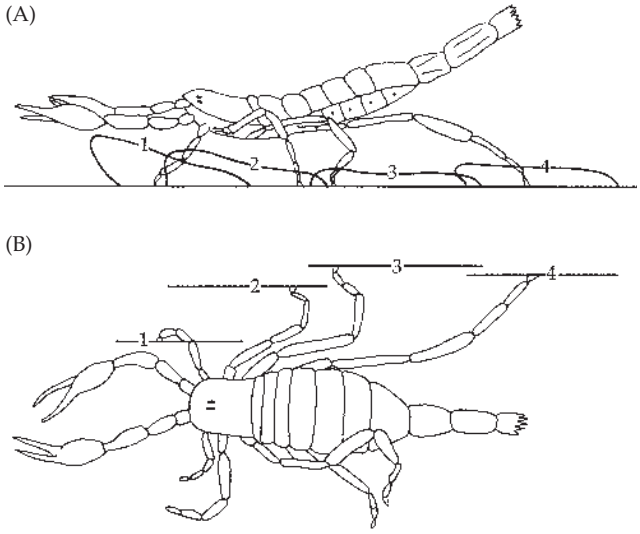

FIGURE 24.10 Walking in scorpions. Numbers denote legs 1–4. (A) The paths of the leg tips during their recovery strokes. Notice that the anterior legs are lifted higher off the ground than are the posterior legs. (B) Distance of each leg tip from the body.

The xiphosurans are slow benthic crawlers and shallow burrowers, utilizing their stout prosomal limbs to push their heavy bodies over and through the sand. The legs are close together (Figure 24.2B), and thus coordination of movement sequences is essential. Horseshoe crabs are also able to swim, upside down, by beating the opisthosomal appendages.

The details of scorpion walking patterns are fairly well understood. During simple forward walking, each of the eight limbs moves through the usual power and recovery strokes. In scorpions (and many other arthropods) the joints between the coxae and the body are virtually immovable and do not contribute to the overall motion of the limbs. Not all of the walking legs move in the same pattern. The tips of the anterior legs are brought quite high off the ground during their recovery strokes; they may be used to feel ahead as the animal moves (Figure 24.10A). Also, the tips of each pair of legs extend different distances from the body, allowing for stride overlap without contact between legs (Figure 24.10B). Leg movements in scorpions do not follow the usual metachronal model. Rather, the typical sequence of movement along one side of the body is leg 4, then 2, then 3, and finally 1, with the legs on the opposite side being generally, but not precisely, out of phase. The somewhat staggered overlap of the movement sequences produces a smooth gait during forward walking, unlike the jerky motion of an insect moving by the alternating tripod pattern described in Chapter 22. Like many arthropods, scorpions are also able to change speeds, turn abruptly, walk backward, and burrow in loose sand.

Spiders have evolved a number of methods of locomotion, all involving the usual leg motions inherent in jointed arthropod limbs, which involve flexors and extensor muscles. However, in spiders the femur-patella and the metatarsus-tarsus joints lack extensor muscles. In these latter joints, extension is accomplished by increasing hemolymph pressure through a hydraulic mechanism. During normal spider walking, the eight ambulatory limbs move in a so-called diagonal rhythm sequence (Figure 24.11). That is, legs 2 and 3 on one side of the body are moving simultaneously with legs 1 and 4 on the opposite side. This gait maintains a four-point stance while distributing the body weight more or less equally among those appendages in contact with the substratum. During very slow walking, however, posterior to

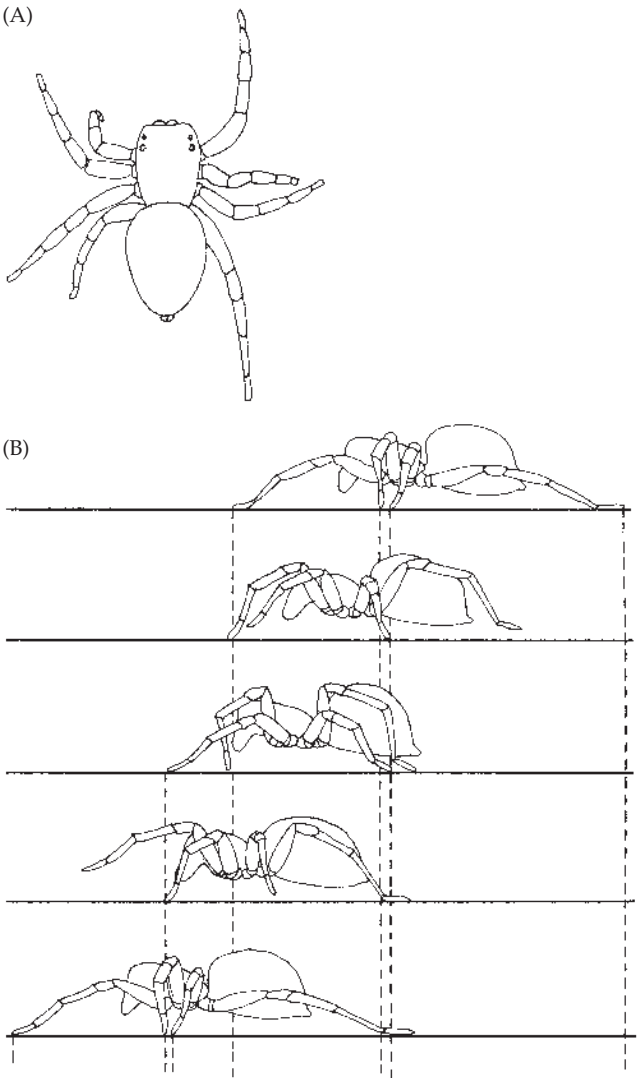

FIGURE 24.11 Walking in spiders. (A) A salticid with legs in walking positions (dorsal view). (B) A lycosid during slow walking (lateral view). Vertical dotted lines connect each leg through its power and recovery strokes relative to the forward progress of the body. Note the large degree of overlap in leg movements, particularly of the first two legs. Tangling is prevented in part by keeping the tips of adjacent legs at different distances from the body. (After R. Foelix. 2011. *Biology of Spiders*. Oxford University Press, Oxford.)

for more ebook/ testbank/ solution manuals requests? email 9012673446@qq.com

anterior metachronal waves of limb motion are detectable. The stride lengths of the legs overlap somewhat and vary with speed and direction of movement. The placement of the legs on the body, and the arcs through which they swing, prevent contact between legs.

A number of spiders (e.g., members of the family Salticidae, or jumping spiders) are also capable of jumping (Figure 24.12A). Propulsion is achieved primarily by a rapid extension of the fourth pair of legs. Once the spider is airborne, the front legs are extended forward and used in landing. Salticids jump during normal locomotion and also when capturing prey and escaping from predators.

Silk plays an important role in various methods of spider locomotion. When walking or jumping, most spiders continually produce a strong thread behind them, called a dragline (Figure 24.12B), produced by the major ampullate silk glands. The dragline is periodically cemented to the substratum with silk from the **piriform glands**, providing a safety line for the wandering spider. Thus, a spider brushed from a surface does not fall to the ground; instead, it pays out dragline silk and dangles like a tethered mountaineer who has lost his/her footing. Silk is also used to provide a substratum on which spiders move. Web spinners crawl over (e.g., diplurids and agelenids) or under (e.g., linyphiids and cyatholipids) their sheet webs with limb movements more or less like those used in normal walking, except that stride lengths must correspond to the distances between threads in the web. Many spiders are able to move about on a single thread (Figure 24.12C). This may involve dropping vertically as a thread is paid out from the spinnerets, climbing up a vertical thread, or moving while hanging upside down on a horizontal thread (they do not walk atop single threads, tightrope fashion). Most spiders that are capable of these sorts of activities possess intricately fashioned "thread clamps" on some or all of the leg tips (Figure 24.12D,E).

FIGURE 24.13 Aquatic spiders and their adaptations. (A) A wolf spider walking on the surface of water. (B) A diving spider (*Argyroneta*) with its "diving bell."

Many spiders also excavate burrows, and a few lycosoids (such as the fishing spiders of the genus *Dolomedes*) and some daddy longlegs can walk on water (Figure 24.13). One species, *Argyroneta aquatica* (family Dictynidae), actually lives underwater. *Argyroneta* can walk on submerged substrates and can build a "diving bell" that allows gas exchange to oxygenate the air trapped in it; they spend most of their time in this bell when not wandering around in search of prey. There are also several intertidal species (e.g., *Desis bobmarleyi* in the family Desidae) that can tolerate submergence at high tides, in some cases by utilizing the air bubbles trapped in empty barnacle shells or other such structures.

Some daddy longlegs with extreme long legs have the ability to break off legs to avoid enemies, and many function well missing one or several legs, which do not regenerate.

Feeding and Digestion

Feeding The basic chelicerate feeding strategy is one of prey capture followed by extensive external digestion and then ingestion of liquefied food or, more rarely, of small particulate material. There are exceptions to this pattern, of course, most of which involve drastic modifications of the mouthparts. For example, we have already mentioned the varied feeding habits among the mites and ticks, many of which are herbivores or parasites with piercing mouthparts. Whereas many chelicerates are highly specialized in terms of their feeding behavior, others are generalists. Horseshoe crabs, for example, commonly feed on a variety of invertebrates, including worms, molluscs (especially bivalves), crustaceans, and other infaunal and epibenthic creatures, but they also scavenge on almost any organic material. Food is gathered by any of the chelate appendages and passed to the gnathobases along the ventral midline, where it is ground to small bits and then moved forward to the mouth, as in many nonchelicerate arthropods. This mode of feeding by ingesting solid food is also found in Opiliones.

Scorpions feed mostly on insects, although some large species occasionally eat snakes and lizards. Most are nocturnal and detect prey mainly by highly sensitive mechanoreceptors. A fascinating method of prey location by the Mojave Desert sand scorpion, *Paruroctonus mesaensis*, has been described by Phillip Brownell and colleagues (see References). Brownell noticed that *Paruroctonus* ignores both airborne vibrations (e.g., wingbeats) and visual input but responds immediately to nearby prey that are in contact with the sand. This scorpion is even able to detect buried prey, which it immediately uncovers and attacks. Apparently the scorpion senses subtle mechanical waves set up in the loose sand by movements of the prey. Special mechanoreceptors in the walking legs are stimulated as the waves pass beneath the scorpion's limbs. The information is processed to determine the direction and approximate distance to the prey source.

Once a scorpion locates a victim, the prey is grasped by the chelate pedipalps. The opisthosoma is arched over the prosoma, bringing the telson and stinging apparatus into position to inject venom (Figure 24.14). Muscular contractions force the venom through a pore in the aculeus and into the prey. The venom is a neurotoxin that can quickly paralyze and kill most prey; in fact, some scorpion venoms can kill large animals, including humans. Perhaps the most familiar of these dangerous scorpions are two species that occur in the American Southwest: the bark scorpion (*Centruroides exilicauda*) and the stripe-tailed scorpion (*Vaejovis spinigerus*). A North African species, *Androctonus australis*, produces a venom considered to be as potent as that of cobras. Other genera of potentially dangerous scorpions include *Buthus* and *Parabuthus* (southern Europe, Africa, and the Middle East) and *Tityus* (South America). Small doses of venom can also be used to "tame" the mate during the precopulatory dance.

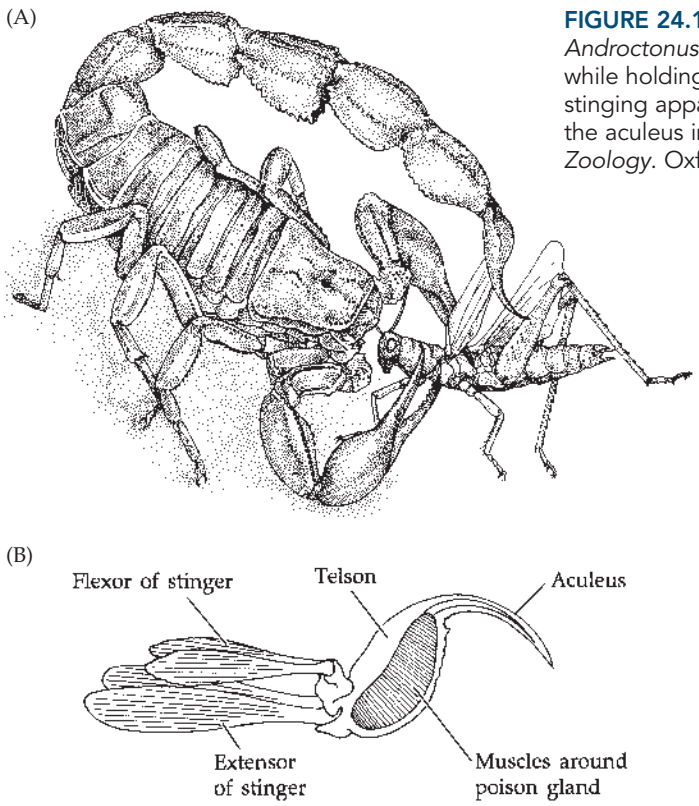

FIGURE 24.14 Stinging apparatus in scorpions. (A) The scorpion *Androctonus australis*, applying its stinging apparatus to a grasshopper while holding the prey with its pedipalps. (B) The scorpion's telson and stinging apparatus. The telson is normally held flexed; extension drives the aculeus into the prey. (B after P. A. Meglitsch. 1972. *Invertebrate Zoology*. Oxford University Press, London.)

The sequence of events in the ingestion of food by scorpions is typical of many arachnids. Once it has been captured and stung, the prey is passed to the chelicerae, which tear it into small bits. The gnathobases grind and mash the food as digestive juices are released through the mouth; this process reduces the food to a semiliquid form. As this organic "soup" is ingested, the hard parts are discarded, and more bits of food are moved between the gnathobases for processing.

Virtually all spiders are predatory carnivores, although young spiderlings in certain families may consume pollen and fungal spores caught on web silk. In some rare cases, some species exploit other food sources, such as nectar, but the vast majority are generalist carnivores. With the exception of a few families (e.g., Salticidae, Oxyopidae, Thomisidae, and Lycosidae), spiders hunt or feed mainly at night. Most spiders can be separated into two broad categories based on prey-capture strategies. The first is the more sedentary spiders that use some sort of silken web, trap, or net to catch prey. The second is the "wandering" spiders that actively hunt or ambush prey without the direct use of silk (although many wrap their victims after capture).

Earlier, we described the construction of the familiar orb web (Figure 24.8). When a potential prey item, such as a flying insect, strikes and adheres to a web, its movements send out vibrations that alert the spider to the presence of food. The spider then moves rapidly to the victim and bites it. The immense majority of spiders are solitary, but as we have mentioned, a few live and feed communally, so in this case they tend to move in synchronized bursts—to distinguish vibrations of trapped prey from those of their moving mates (Figure 24.15A).

Another type of silken trap is the horizontal sheet web produced by members of several families, such as the Linyphiidae and Agelenidae. Sheet webs are often suspended by a network of supporting threads (Figure 24.15B). Insects become entangled in the sheet web, sometimes first getting caught in the supporting threads and then dropping to the sheet. Once on the sheet, the prey is captured.

Many theridiid spiders build vertical frame webs (Figure 24.15C). Near their attachment to the substratum, the vertical trap threads are beaded with a gluey, sticky coating from silk glands (aggregate glands). Walking prey contact these sticky droplets and become trapped, and if they are attached to multiple trap lines, the tension of these silk lines will pull the prey upward, off the ground. Upon sensing movement in the web, the spider rushes to the prey, wraps it in silk, and bites it.

Members of the genus *Hyptiotes* (family Uloboridae) spin modified orb webs consisting of only three sectors (Figure 24.15D). The spider produces a tension thread from the point of convergence of the radii and also a short attachment thread stuck to the substrate; the spider's body acts as a bridge between these two silk threads. When an insect strikes the web, the spider releases the tension thread, and the web, called a spring trap, collapses around the prey.

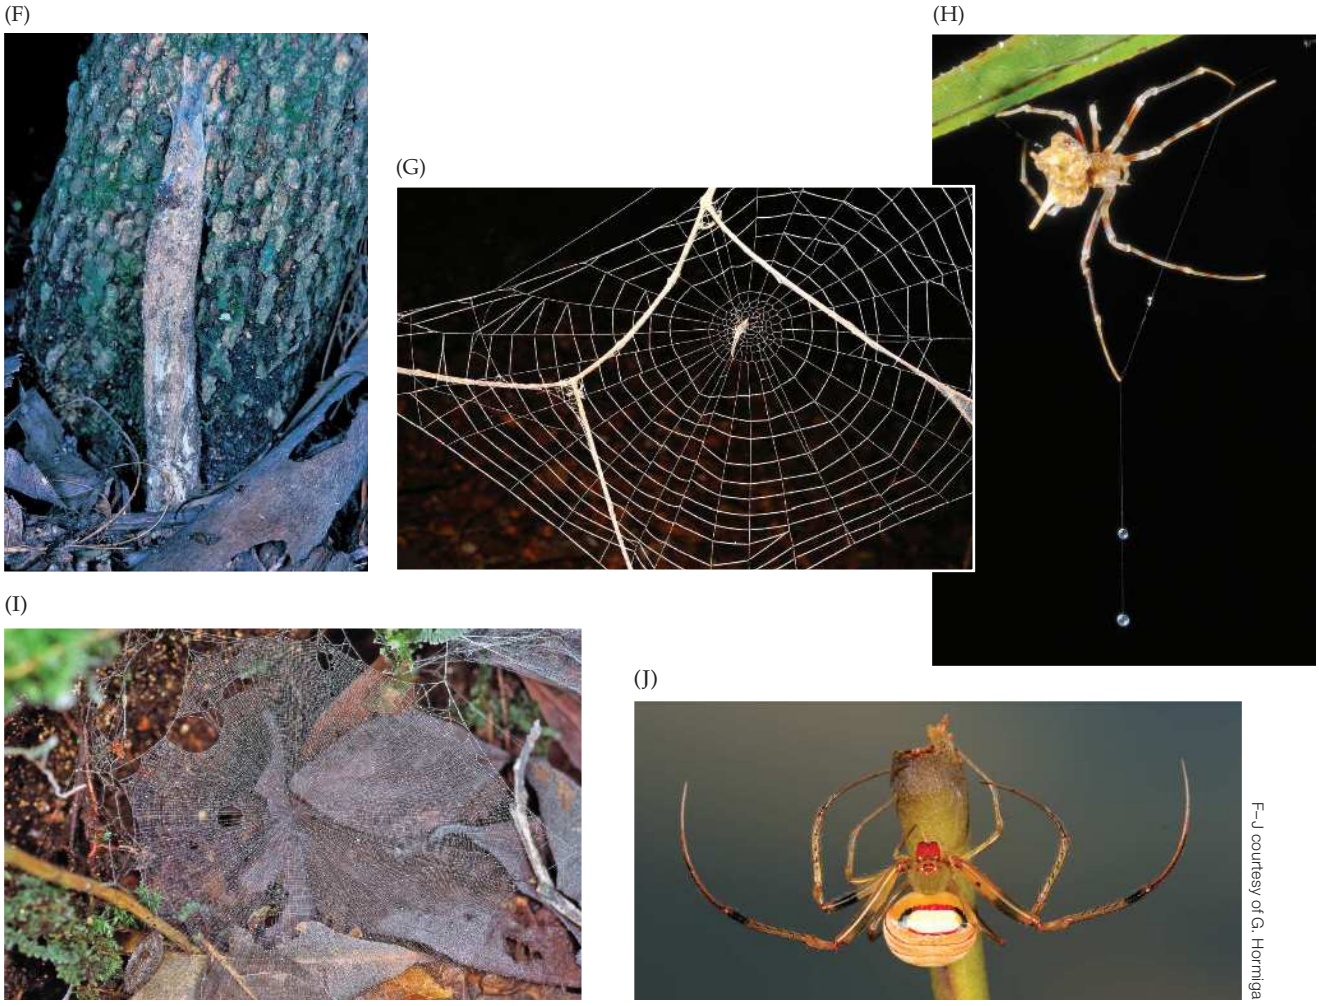
Although it is not known what the ancestral web architecture of spiders might have been, araneologists have traditionally looked at liphistiids (Mesothelae; Figure 24.5N), the sister group to the lineage that includes all other extant spiders (the Opisthothelae), to conjecture about the biology of primitive spiders. Many liphistiids build simple subterranean silken tubes with a single opening from which threads radiate outward (Figure 24.5N). The spider resides in the tube, and the threads serve as "fishing lines" or trip lines that allow the spider to detect passing prey, thus extending its sensory zone as far as these lines reach. An interesting modification of this system is seen in the purse web of some atypids (family Atypidae), such as *Atypus* and *Sphodros* (Figure 24.15F). Here the silken tube is mostly buried beneath the soil, with just a short portion of the blind end lying horizontally above the

When the spider senses the presence of an insect on the tube, it stalks it through the silk with its formidable chelicerae. (G) The cribellate orb web of *Sybota*, an uloborid from Chile. (H) *Exechocentrus lancearius* (Araneidae), a bolas spider from Madagascar that presumably uses chemical mimicry to lure its prey. (I) The micro-orb web of *Patu* (Symphytognathidae) built on the forest leaf litter in the Dominican Republic. Symphytognathids include the smallest known adult spiders (less than half a millimeter). (J) The araneophagic pirate spider *Gelanor latus* (Mimetidae), from Brazil. Mimetids are members of the ecribellate orb-weaving clade and have abandoned building capture webs.

surface or vertical against a tree trunk or a rock. Insects crawling over the exposed tube are detected by the spider, and their large orthognathous chelicerae make two parallel slices in the tube wall near the prey. Their large cheliceral fangs are extended through the incisions to grab the victim and pull it through the tube wall. After the prey is killed, the tear in the tube is repaired.

Most spiders simply set their "traps" and wait for prey, but others actually manipulate silken structures to catch insects. The ogre-faced spiders (family Deinopidae) produce a rectangular web of cribellate threads, which is a highly modified orb web, and hold it between their front walking legs. Deinopids forage at night and have extraordinary visual capabilities, especially *Deinopis*, with a pair of enormous posterior median eyes that are ultrasensitive to light (Figure 24.21A). When an insect is visually detected, the spider sweeps the net around it. The bolas spiders, such as *Mastophora* (family Araneidae), are among the most bizarre and specialized hunters. While hanging from a suspension thread, the bolas spider "throws" a catching thread tipped with sticky liquid to capture its prey (Figure 24.15H). Bolas spiders of the genus *Mastophora* hunt at night using chemical mimicry: they specialize

for more ebook/ testbank/ solution manuals requests: email 9012673467@qq.com



in feeding on male moths of the genus *Spodoptera*. *Mastophora* releases an airborne chemical that mimics the sex pheromone of the female *Spodoptera*, thus attracting males within reach of the catching thread and greatly increasing the likelihood of capture success.

Whereas most sedentary spiders detect their prey by sensing web vibrations, the "wandering" spiders use a variety of methods. Some wolf spiders and most jumping spiders locate prey visually, while many others sense vibrations (e.g., wingbeats or walking movements) or rely simply on accidental contact. Some actually chase prey; others, such as certain trapdoor spiders, lie in ambush and wait for victims to come close enough to grab.

Among jumping spiders, members of the genus *Portia* require special mention. Unlike most spiders, whose behaviors appear to be genetically programmed, *Portia* species exhibit trial and error strategies and learning in their predation on other spiders. *Portia* really doesn't look much like a spider; rather, it resembles crumpled leaves or twigs. Some species utilize this camouflage in what has been described as aggressive mimicry. To do so, *Portia* climbs onto the web of another spider and begins to generate vibrations that mimic those of a trapped insect. When the resident spider responds, *Portia* attacks and kills it. More remarkable is that *Portia* often tries various vibration patterns on a web, and when a successful one is found, it continues to use only that one on the webs of the same prey species in the future. Aggressive mimicry is also used by pirate spiders (Mimetidae) (Figure 24.15J), which feed mainly on other spiders.

Regardless of the method of prey location and capture, once contact is made, spiders pull their prey to their chelicerae and bite it, inserting the fangs and injecting venom from the poison glands within the prosoma (Figure 24.16A). The prey is quickly immobilized or killed by the poison. An interesting exception to this grabbing-and-biting pattern is displayed by the spitting spiders (family Scytodidae), some of which are social. The poison glands of *Scytodes* include a posterior glue-producing portion along with the usual venom-secreting cells in the anterior region. A mixture of venom and glue is shot very fast from pores in the cheliceral fangs by muscular contraction of the glands; thus the prey is captured without direct contact (Figure 24.16B).

Many spiders wrap their prey in silk to some extent prior to feeding, even if silk is not used in the actual capture. Many hold the victim and wrap it prior to

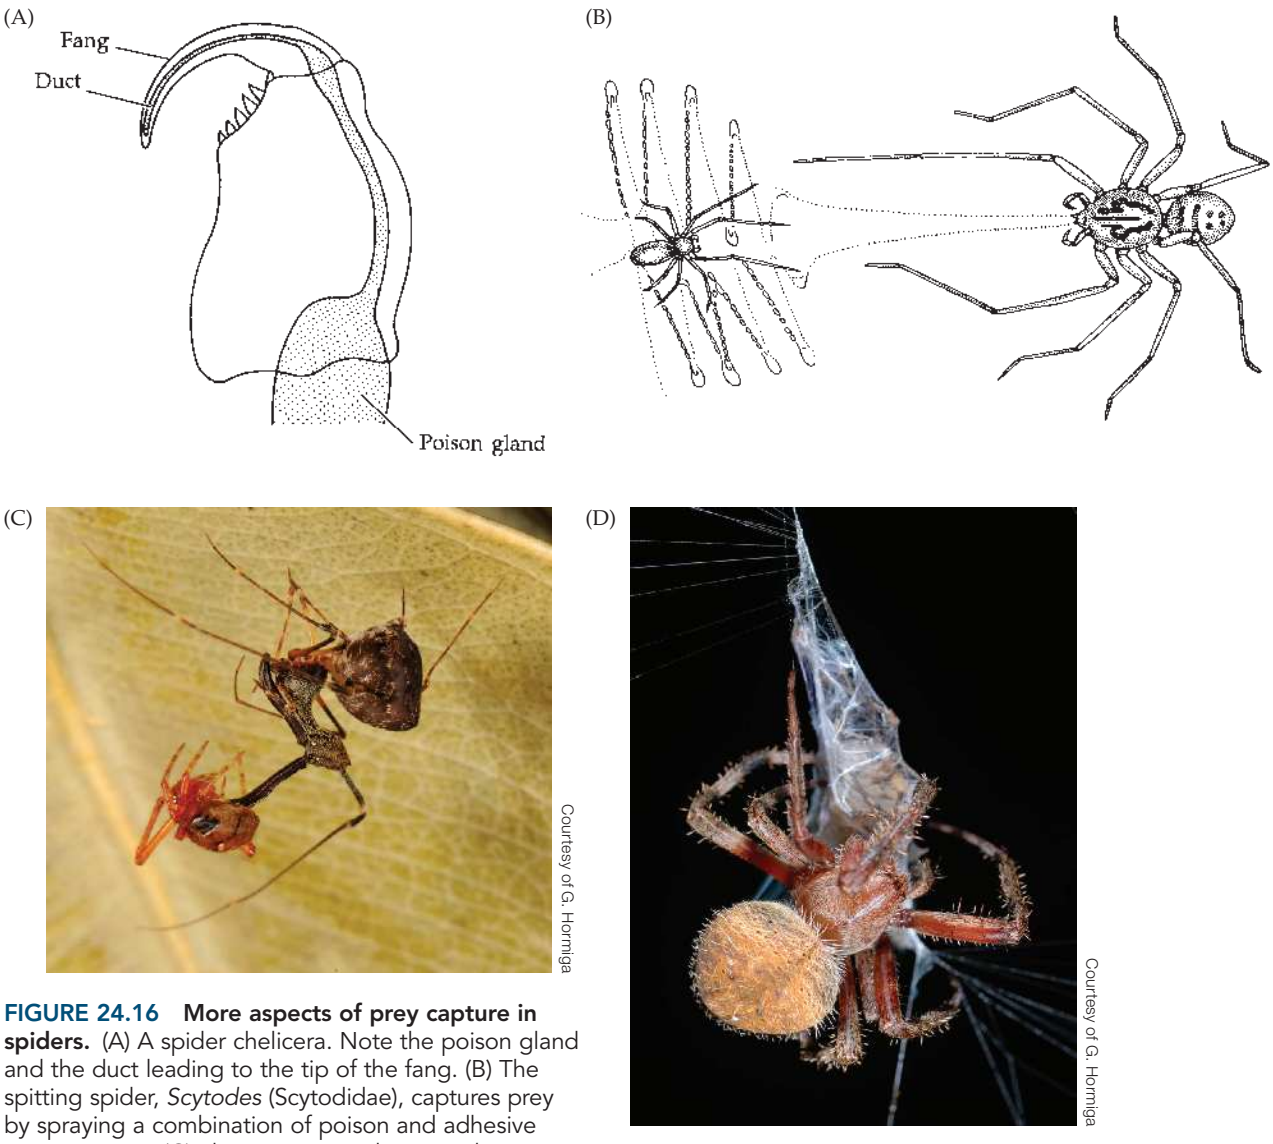


FIGURE 24.16 More aspects of prey capture in spiders. (A) A spider chelicera. Note the poison gland and the duct leading to the tip of the fang. (B) The spitting spider, *Scytodes* (Scytodidae), captures prey by spraying a combination of poison and adhesive over its victim. (C) The assassin spider *Eriauchenus* (Archaeidae), from Madagascar, stalks a theridiid spider. Notice the extremely long chelicerae (only the left chelicera is extended) and the bizarre shape of the cephalothorax with a long and narrow "neck." (D) *Neoscona arabesca*, an araneid orb-weaver, wrapping its insect prey (USA). (B after R. Foelix. 1996. *Biology of Spiders*. Oxford University Press, Oxford.)

biting it (e.g., theridiids and araneids). Very active insects caught in orb webs are generally wrapped immediately, which prevents possible damage to the web or its owner (Figure 24.16D). Potentially dangerous prey, such as large stinging insects, are generally handled in this manner.

Nearly all spiders possess poison glands that produce proteinaceous neurotoxins, although venom composition is highly heterogeneous and varies widely across species. Venom glands have been lost in all members of the family Uloboridae and in the Anapidae genus *Holarchaea*. The toxicity of spider venom is quite variable, and only about two dozen species are considered dangerous to humans. Among these are the black widows (*Latrodectus* species), a Brazilian wolf spider (*Lycosa erythrognatha*), the brown recluse spiders (such as *Loxosceles reclusa*), the Australian funnel-web spiders (such as *Atrax robustus*), and some species belonging to the tropical wandering spider family Ctenidae (e.g., *Phoneutria fera*).

Uloborid spiders lack the poison glands typical of almost all other spiders and wrap their prey with up to hundreds of meters of silk that severely compresses and physically damages the prey's cuticle. This compaction probably functions to facilitate these spiders' unusual method of feeding, which involves covering the entire surface of the prey with digestive fluid, cyclically regurgitating and sucking up the fluid from the outer surface of the prey package. Spiders, like most other chelicerates, ingest their food in a liquid or semiliquid form. The chelicerae of most spiders have dentate gnathobases with which the prey is mechanically pulverized, while at the same time the food is flooded with digestive juices. Except for the hard parts, the prey is thus reduced to a partially digested broth. Bristles bordering the mouth and thousands of overlapping cuticular plates in the

for more ebook/ testbank/ solution manuals requests: email 9012673467@qq.com

pharynx serve as filters so that only very small particles (<1 μm) enter the gut. Members of some families (e.g., some species in Theridiidae and Thomisidae) lack cheliceral teeth. These spiders simply puncture their prey's cuticle and then flush digestive juices in and out of the wound. The liquefied innards of the victim are then sucked out of its body and ingested.

The fascinating biology of two species of jumping spiders (Salticidae) that feed preferentially on mosquitoes was recently described; both are highly specialized mosquito assassins. One species, *Evarcha culicivora*, like an eight-legged vampire, is particularly drawn to female mosquitoes whose guts are filled with blood (especially species of *Anopheles*). Eating blood-filled mosquitoes also allows this spider to acquire a scent that is attractive to members of the opposite sex. Another species, *Paracyrba wanlessi*, preferentially feeds on mosquito larvae lurking in pools of water inside bamboo.

Digestion The digestive system of chelicerates follows the basic arthropod plan of foregut, midgut, and hindgut, the first and last parts being lined with cuticle (Figure 24.17). The foregut is often regionally specialized. In the xiphosurans (e.g., *Limulus*), the foregut loops anteriorly to form an esophagus, crop, and gizzard, the last of these bearing sclerotized ridges that grind ingested particles (Figure 24.17A). In many arachnids, portions of the foregut are modified as pumping organs for sucking in liquefied food. In scorpions this function is served by a muscular pharynx, and in spiders by an elaborate sucking stomach (Figure 24.17B). The pharynx of spiders may contain chemosensory cells that function as taste receptors.

The eucheliceratе midgut bears paired digestive ceca and is the site of final chemical digestion and absorption (Figure 24.17C). Xiphosurans have two pairs of ceca arising from the anterior part of the midgut, followed by an intestine, a short rectum (the hindgut), and the anus on the posterior margin of the opisthosoma. In *Limulus*, enzymes are produced by the midgut wall and secreted into the lumen. Apparently only preliminary protein digestion occurs extracellularly, and final breakdown takes place in the cells of the digestive ceca after absorption.

Most spiders possess four pairs of digestive ceca in the prosoma and frequently additional branched ceca in the opisthosoma (Figure 24.17B,C). Near its junction with a short rectum, the midgut expands as a spacious "mixing chamber," called the stercoral pocket. Malpighian tubules arise from the midgut wall near the origin of the stercoral pocket. The anus is located on the opisthosoma near the spinnerets, opening on an anal tubercle that could be homologous with the pygidium of other arachnids.

The midgut of scorpions bears six pairs of digestive ceca (Figure 24.17D). The first pair, the salivary glands, lies within the prosoma and produces much of the digestive juice used in preliminary external digestion. The remaining five pairs are highly convoluted and lie in the opisthosoma. These ceca produce the enzymes for final digestion and are the site of absorption of the digestive products. Two pairs of Malpighian tubules arise from the posterior region of the midgut, just in front of the short rectum. The anus is on the last opisthosomal segment.

Circulation and Gas Exchange

The eucheliceratе circulatory system, like that of other arthropods, consists of a dorsal ostiate heart situated within a pericardial sinus and giving rise to various open-ended vessels (Figures 24.17 and 24.18). Blood leaves these vessels and enters the hemocoel, where it bathes the organs and supplies the structures of gas exchange before returning to the heart. The complexity of the system is primarily a function of body size; some very tiny eucheliceratеs (e.g., palpigrades and some mites) have lost much or all of their circulatory structures—for them, gas exchange is cutaneous. On the other hand, xiphosurans are large animals, and their body plan demands a substantial circulatory mechanism to move the blood around inside the rigid body covering. The large tubular xiphosuran heart bears eight pairs of ostia, and it is attached to the body wall by nine pairs of ligaments that extend through the pericardium (Figure 24.17A). The organs of these big creatures are supplied with blood through an extensive arterial system arising from the heart and opening into the hemocoel close to the organs themselves. In the opisthosoma, a major ventral vessel gives rise to a series of afferent branchial vessels to the book gills. Efferent vessels carry oxygenated blood to a large branchiopericardial vessel leading back toward the heart.

The gas exchange organs of xiphosurans are unique among the chelicerates. The presence of gills is, of course, associated with their aquatic lifestyle. The structure of these opisthosomal book gills provides an extremely large surface area, a necessity for adequate gas exchange by these large animals (Figures 24.2B and 24.18A). Each gill bears hundreds of thin lamellae, like pages in a book. The blood within the lamellae is separated from the surrounding seawater by only a thin wall. Water is moved over the lamellae by metachronal beating of the gills; these movements also cause blood flow into (on the forward strokes) and out of (on the backward strokes) the gill sinuses.

The heart of a spider lies within the opisthosoma and bears two to five pairs of ostia (Figure 24.18B). It is suspended within the pericardial sinus by several ligaments attached to the inside of the exoskeleton. These suspensory ligaments are stretched during systole as blood is pumped from the heart into arteries. The elasticity of the ligaments then effects diastole, expanding the heart and drawing blood into it from the pericardial sinus. The routes of the major arteries ensure that an ample supply of oxygenated blood reaches the major organs,

In A and D the digestive ceca have been removed; only their points of attachment to the midgut are shown. (B,C after R. Foelix. 2011. *Biology of Spiders*. Oxford University Press, Oxford.)

particularly the central nervous system, muscles, and hemocoelic spaces in the limbs in which blood pressure aids in leg extension. From the hemocoel, blood is channeled back to the pericardial sinus and the heart.

Aerial gas exchange structures in spiders include book lungs and tracheae. Generally, liphistiomorphs, mygalomorphs, and some basal araneomorphs have two pairs of book lungs but no tracheae, whereas members of Araneomorphae usually have one pair of anterior book lungs and a posterior system of tracheal tubes. In some groups of very small araneomorphs (such as the minute Synaphridae), the anterior book lungs are modified into tubular tracheae; in other groups there are anterior and posterior tracheal systems, while in a

Foelix. 2011. *Biology of Spiders*. Oxford University Press, Oxford.)

few their respiratory system consists of only anterior tracheae. Since the tracheae occur only in more distal groups among spiders, it is likely that they evolved separately from those of other arachnids and, of course, independently from those of insects and myriapods. Phylogenetic analyses, both morphological and molecular, support this contention and place spiders with the other pulmonate arachnid orders, including scorpions.

Spider book lungs are located in the second, or the second and third, segments of the opisthosoma. They open to the outside via spiracles, or lung slits, near the epigastric furrow (Figure 24.5C). Since they are localized and do not extend far into the body, book lungs must receive sufficient circulating blood to ensure adequate distribution of oxygen throughout the body and removal of carbon dioxide from the internal organs. Just inside each lung slit is an expanded chamber, the atrium, from which numerous flattened air spaces extend into the hemocoel (Figure 24.18D). These leaflike pockets of air are separated from one another by thin blood-filled extensions of the hemocoel. Although the book lungs are themselves relatively small, this structural arrangement provides a very large surface area between the "pages" of the book lungs and the circulatory fluid. Blood that has passed by these surfaces returns directly to the pericardial sinus via the lung vein (Figure 24.18B).

Spider tracheae open to the outside through one or two spiracles located posteriorly on the third opisthosomal segment (Figures 24.5B,C and 24.17C). These tracheae probably evolved from the book lungs and muscle apodemes on this segment in more primitive spiders. Tracheal spiracles open inward to simple or branched tubes. In spiders, the open inner ends of the tracheae do not bring the oxygen supply into direct contact with tissues, as they do in many insects; rather, a small amount of blood is necessary as a diffusion medium. When the tracheal system is extensive, there is usually a reduction in the structural components of the circulatory system. There is a great diversity of tracheal structures and arrangements in some groups of spiders. In araneomorph spiders the posterior book lungs evolved convergently into similar tracheal systems multiple times independently after the origin of aerial webs and the evolution of novel silk glands. It has been hypothesized that the evolution of similar tracheal systems via convergence in the early-diverging web-building spiders was prompted by the novel energetic demands for web spinning.

The circulatory system of scorpions is very similar to that of spiders, except that it is constructed to accommodate an elongate and generally larger body. The tubular heart bears seven pairs of ostia and extends through most of the mesosoma (Figure 24.17D). An extensive set of arteries delivers blood to the hemocoel throughout the body and to four pairs of mesosomal book lungs, and a network of capillaries supplies the large prosomal ganglion.

Except where reduced or absent, the circulatory system of other euchelicerates is built along the same general plan as described previously. Gas exchange is cutaneous in palpigrades and some mites, but in other euchelicerate groups it occurs through book lungs (Uropygi, Schizomida, and Amblypygi) or tracheae (Ricinulei, Pseudoscorpiones, Solifugae, Opiliones, and many mites).

The blood of chelicerates has been most extensively studied in spiders and in xiphosurans. Because *Limulus* is large, its blood chemistry has been especially well studied, and many horseshoe crabs have made the supreme sacrifice for science at the hands of laboratory physiologists—so many, in fact, that many populations of the American species (*L. polyphemus*) have become threatened. Hemocyanin, the common respiratory pigment in chelicerates, is dissolved in the blood plasma. At least in spiders, hemocyanin serves primarily for oxygen storage rather than for immediate transport and delivery of oxygen to the tissues. Hemocyanin has a very high affinity for oxygen, releasing it only when surrounding oxygen levels are quite low. Some spiders are able to survive for days after their air supply has been cut off experimentally by covering the spiracles. Apparently they obtain sufficient oxygen from their hemocyanin-bound stores and some cutaneous exchange.

Chelicerate blood also contains various cellular inclusions, but the functions of most of them are not well understood. The blood of *Limulus* includes amebocytes that may provide clotting agents. Several kinds of blood cells occur in spiders. Interestingly, it seems that all of them originate as undifferentiated cells from the muscular portion of the heart wall itself. These cells are released into the blood, where they mature and differentiate. Functions that are attributed to chelicerate blood cells include clotting, storage, combating infections, and aiding in sclerotization of the cuticle.

Excretion and Osmoregulation

Xiphosurans have two sets of four coxal glands each, arranged along each side of the prosoma near the coxae of the walking legs. On each side of the body, the glands converge to a coelomic sac, from which a long, convoluted duct arises. The duct leads to a bladderlike enlargement that connects to an excretory pore at the base of the last walking leg. Surprisingly little is known about excretory physiology in xiphosurans. Apparently the coxal glands extract nitrogenous wastes from the surrounding hemocoelic sinuses and carry them to the outside. The coxal glands and their associated tubule system also function in osmoregulation, as evidenced by the production of a dilute urine when the animal is in a hypotonic medium. The digestive ceca probably aid in excretion of excess calcium by removing it from the blood and releasing it into the gut lumen.

The problems of excretion and water balance are obviously much more critical to terrestrial euchelicerates than to horseshoe crabs, and land-dwelling arachnids display a variety of structural, physiological, and behavioral adaptations to cope with them. The main excretory structures of arachnids are coxal glands and Malpighian tubules, although many groups possess additional supplementary nitrogenous waste removal mechanisms. Coxal glands persist in many arachnids (spiders, scorpions, palpigrades); in these animals, the glands lie within the prosoma and open on the coxae of some walking legs. The degree to which coxal glands function in excretion and osmoregulation varies among arachnids, but they are considered far less important than the Malpighian tubules.

The Malpighian tubules of arachnids arise from the posterior midgut. They are not homologous with the Malpighian tubules of insects or myriapods, which arise from the hindgut and are thus of ectodermal origin. The tubules branch within the hemocoel of the opisthosoma, where they actively accumulate nitrogenous waste products and release them into the gut for elimination along with the feces (Figure 24.17C). In spiders, the wastes from the tubules and the gut are mixed in the stercoral pocket prior to release from the anus. The excretory action of the Malpighian tubules is often supplemented by other mechanisms, such as the coxal glands. Nitrogenous wastes also are accumulated in the cells of the midgut wall and released into the lumen. In addition, waste products are picked up and stored by special cells called nephrocytes, which form distinct clumps in various parts of the prosoma.

Terrestrial arachnids produce complex, insoluble, nitrogen-containing excretory compounds. The major excretory product is guanine, although uric acid and other compounds also occur. Because these compounds are of low toxicity, they can be stored and excreted from the body in semisolid form, thus conserving water.

Terrestrial arachnids also display various behavioral adaptations to avoid desiccation. Most arachnids are nocturnal, remaining in cooler or more-humid protected places during the daytime. Some spiders actively drink water during dry periods or when they lose blood through injury. Desert scorpions must tolerate not only low humidity but also very high daytime temperatures. To avoid this, they typically bury themselves in sand or soil or hide under rocks or tree bark during the day. In addition, some species exhibit an adaptive behavior called stilting, wherein the body is raised off the substratum to allow air to circulate underneath. While thought to be mainly a cooling strategy, this behavior, by lowering the body temperature, probably also slows the rate of evaporative desiccation. Some scorpions are also able to withstand large losses of body water—as much as 40% of their body weight—with no ill effects.

Nervous System and Sense Organs

As in all arthropods, the external body form of euchelicerates is generally reflected in the structure of the

for more ebook/ testbank/ solution manuals requests: email 2601267346@qq.com

central nervous system. These animals show various degrees of compaction and fusion of the body somites and the associated nervous system components while still conforming to the basic arthropod plan. The cerebral ganglia, or brain, includes the protocerebrum (which innervates the eyes), the deutocerebrum (which innervates the chelicerae), and the tritocerebrum (which innervates the pedipalps). The deutocerebrum was traditionally thought to be absent in euchelicerates, and therefore the chelicerae were thought to be innervated by the tritocerebrum, until Hox gene expression data showed homology of the chelicerae of euchelicerates with the deutocerebral appendages of mandibulates in the late 1990s. The tritocerebrum generally contributes to the circumenteric connectives, which unite ventrally with a large ganglionic mass formed in part by the fusion of paired anterior ganglia of the ventral nerve cord, and thus it looks like the pedipalps innervation is from the ventral ganglionic mass. In xiphosurans and scorpions this subenteric neuronal mass includes all of the prosomal ganglia, whereas in spiders even the opisthosomal ganglia fuse anteriorly. Thus in most spiders the adult nervous system is no longer obviously segmented (except in some members of the suborder Mesothelae), although a chain of ventral ganglia is evident during early embryonic development. The ventral nerve cord persists in the opisthosoma of xiphosurans and has five segmental ganglia; in scorpions it has seven ganglia (Figures 24.17A,D and 24.19).

The protocerebrum and deutocerebrum give rise to nerves to the eyes and chelicerae, respectively, and are dorsal. The ventral (subenteric) ganglionic mass, which includes the fused segmental prosomal ganglia and the tritocerebrum, gives rise to nerve tracts to the pedipalps and walking legs and, in spiders, bears a pair of abdominal ganglia from which arise branching nerves to the opisthosoma. Segmental ganglia on the ventral nerve cord in xiphosurans and scorpions serve the opisthosomal appendages, muscles, and sense organs.

Chapter 20 discussed some of the qualities of arthropod sense organs in terms of the imposition of the exoskeleton. Xiphosuran sense organs include tactile mechanoreceptors in the form of various spines and bristles, proprioceptors in the joints, chemoreceptors, and photoreceptors. The prosoma bears two simple eyes near the dorsal midline and two lateral compound eyes (Figure 24.2A), in addition to a series of hidden eyes. The median eyes are of the pigment-cup type, but each contains a distinct cuticular lens. The lateral eyes are compound rhabdomeric units—structures not found in any other chelicerate. The thousand or so ommatidia per eye are very large and rather loosely packed together. While the resolving power of xiphosuran eyes has long been debated, certainly *Limulus* can detect movement and changes in light intensity and direction. It has been demonstrated that the light sensitivity of these receptors is regulated on a 24-hour cycle by instructions from the brain. At night, these signals increase the eyes' sensitivity to light by up to a million times over daytime levels. Thus, *Limulus* may see as well at night as it does during daylight hours. It may also be capable of perceiving clear images, as male horseshoe crabs have been experimentally shown to be attracted to "models" of females.

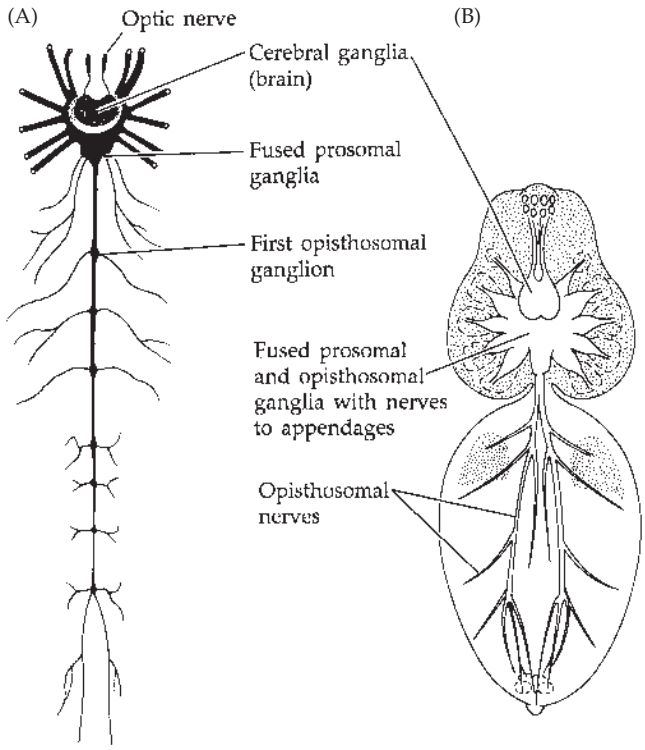

FIGURE 24.19 The central nervous system. (A) Scorpion. (B) Spider. (B after R. Foelix. 2011. *Biology of Spiders*. Oxford University Press, Oxford.)

Arachnids possess well-developed sense organs upon which much of their complex behavior depends. The typical "hair" on a spider or scorpion body is a mechanoreceptor called a **hair sensillum**, which occurs in several types. Simple tactile hairs (or setae) cover much of the body surface and respond to direct physical contact. Setae of the second type, called trichobothria, are found on the appendages of many arachnids. They are less abundant and much thinner than simple tactile setae and are extremely sensitive (Figure 24.20B). *Cupiennius*, a tropical wandering spider (Trechaleidae) that has been extensively studied as a model organism, has close to one thousand trichobothria in its legs and pedipalps. Trichobothria are stimulated by airborne vibrations, such as those caused by beating insect wings, natural air currents, and probably some sound frequencies.

Additional mechanoreceptors of arachnids include slit sense organs (Figure 24.20A,C). These structures may occur singly, as a **slit sensillum**, or in groups of parallel slits called **lyriform organs**. A slit sensillum is a deep groove in the cuticle associated with sensory neurons. It detects a variety of mechanical stimuli that impose physical deformation on the cuticle around the slit. Depending on its location and orientation, a spider

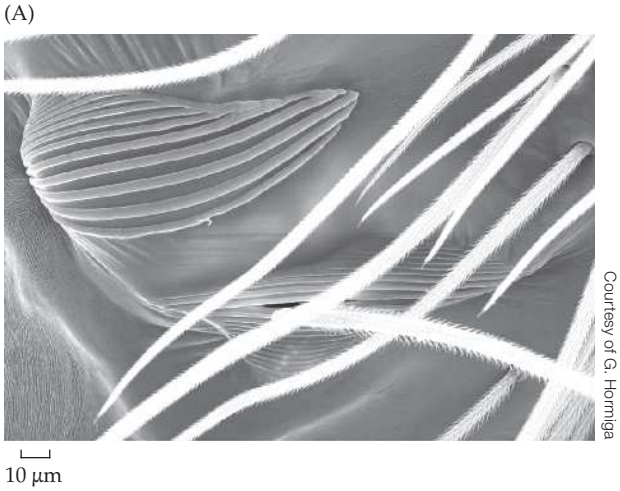

FIGURE 24.20 Mechanoreceptors and chemoreceptors in spiders. (A) Lyriform organs (groups of slit sensilla) on the leg patella of *Amaurobius similis* (SEM, 1.76K×). (B) The organization of a trichobothrium in its socket; from *Tegenaria*. (C) A slit sense organ from the leg of *Cupiennius* (cutaway view). (D) A chemosensitive hair. The mechanoreceptor neurons terminate at the base of the hair (arrow in illustration), whereas the chemoreceptor neurons extend through the hollow shaft to the tip (photo). (E) A humidity receptor, or tarsal organ, of the orb-weaver *Araneus*. (B,C after R. Foelix. 2011. *Biology of Spiders*. Oxford University Press, Oxford.)

slit sensillum serves as a proprioceptor (by sensing leg movements and position), as a georeceptor (by measuring bending of the pedicel under the weight of the opisthosoma), as a direct mechanoreceptor (by sensing direct external pressure on the cuticle), as a vibration sensor, and even as a phonoreceptor.

Not all of the setae of spiders are sensory in function. We have already described the calamistrum, a row of modified macrosetae in the fourth metatarsus of cribellate spiders that is used to comb the silk produced by the cribellum. Another interesting type of specialized setae is found in the New World tarantulas (Theraphosidae). These mygalomorphs have modified abdominal barbed setae that can be released by their hind legs. These setae become airborne and are highly urticating, providing a defensive mechanism against some predators. Efficient proprioceptors occur in the walking legs and pedipalps

for more ebook/ testbank/ solution manuals requests: email 2601267346@qq.com

of all chelicerates and are particularly well developed in arachnids. By virtue of their position and number in different joints, they convey information about the direction and velocity of appendage motion as well as the position of the limbs relative to the body and to one another. These "true" proprioceptors appear to work in concert with the lyriform organs.

Chemoreception in arachnids involves sensing both liquid and airborne chemicals that contact the body. This dual ability can be likened to capacities for both taste (contact chemosensitivity) and smell, or olfaction (distance chemosensitivity). The olfactory sense plays major roles in prey location and, for those species in which females release sex pheromones, in mating. The most important chemoreceptors are probably the hundreds of erect, hollow setae (called **sensilla chaetica**) with open tips that are present on the pedipalps and other areas around the mouth and are most abundant on the tips of limbs that contact the substratum. Dendrites of sensory neurons extend through the hollow hair shaft to the open tip, where they are directly stimulated by chemicals (Figure 24.20D). Spiders also bear humidity detectors called tarsal organs (Figure 24.20E).

Scorpions have a pair of large, unique, comblike structures, the pectines, on the ventral surface of the mesosoma (Figure 24.6C). After detailed studies of their innervation, Foelix and Schabronath (1983) suggested that the pectines act as both mechanoreceptors and chemoreceptors. Other work has shown them to be capable of detecting subtle differences in sand grain size. These versatile structures are usually held laterally erect, free to swing back and forth while the scorpion is actively moving about. Solifuges have other mysterious sensory structures called malleoli (or racquet organs) on the coxae and trochanters of the fourth pair of legs.

The importance of vision varies greatly among the arachnids. Most species possess some sort of photoreceptors, although Ricinulei and Palpigradi are entirely blind. At least some species in the other groups are also blind (e.g., some members of the orders Schizomida, Pseudoscorpiones, and different mite orders), and within the Opiliones suborder Cyphophthalmi, four of the six families are entirely blind. Certain spiders depend on photoreception for prey and mate location, particularly the errant hunters (e.g., some lycosids and most salticids) (Figure 24.21B,C). Vision is relatively unimportant to many sedentary species, such as many web builders that depend more on tactile cues, vibrations, and chemosensitivity. Web builders are not blind, however, and many respond behaviorally to variations in light intensity, while some exhibit distinct escape responses when they visually detect potential predators. Nevertheless, these spiders are generally able to build their webs, capture prey, and mate with little or no visual input. Some spiders are capable of perceiving polarized light, presumably as a means of spatial orientation.

Spiders possess single-lensed rhabdomeric eyes, but the sensory units of each are simple ocelli in a cluster. Thus they are quite different from the compound eyes of xiphosurans and most other arthropods. Each eye includes a thickened cuticular lens over a vitreous body, which is a layer of cells derived from the epidermis and covering the retina (Figure 24.21D). The retina is composed of the sensory (receptor) cells and the pigment cells. The membranes of the sensory cells bear interdigitating microvilli, confirming the rhabdomeric nature of the eyes.

Two forms of this basic eye structure occur among spiders. The anterior median eyes—the main eyes—have the light-sensitive portions of the sensory cells directed toward the lens, whereas other eyes—secondary eyes—are inverted, with the light receptor elements directed away from the lens (Figure 24.21D,E). Most of these secondary eyes contain a crystalline reflective layer called the tapetum, which may serve to collect and concentrate light in poorly lit conditions (e.g., during night hunting). The reflective nature of the tapetum produces the effect in some spiders of eyes that "shine in the dark" (Figure 24.21F).

Scorpion eyes are of the direct type and differ from spider eyes in having the retinal layer external to the epidermis. Most work suggests that scorpions depend much more on mechanoreception and chemoreception than on visual input.

There is no question that spiders, and perhaps other arachnids, are capable of modifying their behavior based on experience—that is, they can learn. Some examples of such activity were noted earlier. Memory and association centers in the protocerebrum are responsible for much of this integrative activity. No doubt, at least in spiders, the ability to remember, learn, and make appropriate adaptations in behavior has played an important role in their evolutionary success. A recent collection of papers on spider behavior can be found in Herberstein (2011).

Reproduction and Development

Eucheliceratesare gonochoristic and generally engage in complex mating behaviors that ensure fertilization. A few are known to be parthenogenetic (e.g., some scorpions, harvestmen, and schizomids). A penis (sometimes a spermatopositor organ) occurs only in the males of harvestmen and some mites. Free spawning never occurs, and fertilization takes place either internally or as the eggs leave the body of the female. The eggs are generally very yolky except in xiphosurans; the developmental strategy is direct in spite of the various juvenile stages through which most eucheliceratespass. We first present a summary of reproduction and development in *Limulus*, then turn to the arachnids, concentrating again on spiders (the best known arachnid developmental model) and scorpions. More recently,

Foelix. 2011. *Biology of Spiders.* Oxford University Press, Oxford.)

development in Opiliones has received more attention, from both behavioral and genetic points of view.

The reproductive system of male and female xiphosurans is similar. In both sexes the gonad is a single, irregularly branched mass of tissue (Figure 24.22A). Paired gonoducts lead from the gonad to a pair of pores on the ventral midline. The first pair of opisthosomal appendages lies over the gonopores, forming a genital operculum.

At the onset of the breeding season, horseshoe crabs migrate into the shallow waters of protected bays and estuaries. On the east coast of North America, this

for more ebook/ testbank/ solution manuals requests: email 9012673446@qq.com

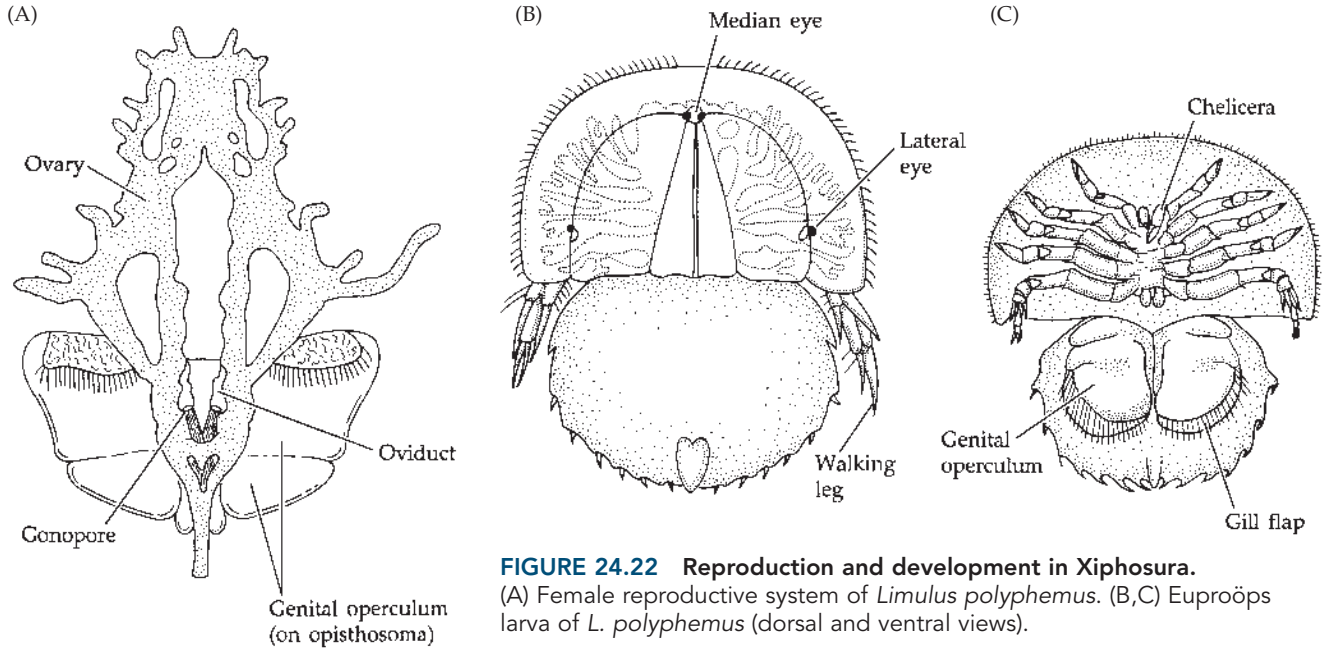

FIGURE 24.22 Reproduction and development in Xiphosura. (A) Female reproductive system of *Limulus polyphemus*. (B,C) Euproöps larva of *L. polyphemus* (dorsal and ventral views).

migration takes place in the spring and summer, and huge numbers of *Limulus* can be seen gathering near the shore in preparation for mating (Figure 24.2C). Mating is initiated when the male climbs onto the back of the female and grasps her with his modified first pair of walking legs, which are the pedipalps. The clasped pair moves to the shallow water, usually at a high spring tide, and the female excavates one or more shallow depressions in the sand and deposits her eggs (2,000 to 30,000 eggs per mating). The male releases sperm directly onto the eggs as they are deposited. Then the mates separate, and the female covers the fertilized eggs with sand. As the waters recede, it is common to find these mating pairs outside of the water or covered with wet sand.

Early development takes place in the sand or mud "nest." Cleavage is holoblastic, producing a stereoblastula with most of the yolk contained in the inner cells. As development continues, the surface cells at the anterior and posterior ends of the embryo divide rapidly, forming two germinal centers. Some of these rapidly proliferating cells migrate inward as the presumptive endoderm and mesoderm. The anterior germinal center gives rise to the first four segments of the prosoma, and the posterior center to the rest of the body. All of the prosomal segments fuse and are eventually covered by the developing carapace-like dorsal shield.

As the yolk reserves become depleted, the embryo emerges from the sediment as a **euproöps larva** (or "trilobite larva"), so named because of its resemblance to the fossil Carboniferous xiphosuran *Euproöps* (which superficially resembled trilobites; Figure 24.22B,C). The larvae swim about and periodically burrow in the sand. Segments are formed and appendages added through a series of molts until the adult form is reached, a typical mode of development observed in other arthropod groups. The early developmental stages are supplied with an investment of yolk by the female and are protected by the nest she constructs, but the young emerge as independent feeding larvae prior to maturation.

The reproductive biology of arachnids is directly related to their success on land. They have evolved a variety of sophisticated mating behaviors, clever methods of sperm transfer, and various devices for protecting developing embryos, thereby ensuring successful procreation in terrestrial habitats. A comparison of the functional anatomy of the reproductive systems of spiders and scorpions provides a background for discussing arachnid courtship behavior and developmental patterns. But many other interesting behaviors are known from groups like amblypygids, uropygids, ricinuleids, and harvestmen, among others.

The male reproductive system of spiders consists of a pair of straight or convoluted tubular testes in the opisthosoma, which lead to a common sperm duct that opens into the epigastric furrow through a gonopore (Figure 24.23A). Each developing sperm usually bears a distinct flagellum with an unusual 9+3 axonemal pattern of microtubules (Figure 24.23B) (members of the sister families Pimoidae and Linyphiidae share a unique 9+0 pattern). The spermatozoa of spiders exhibit remarkably high structural diversity. Prior to copulation, the flagellum wraps around the head of the sperm, and a protein capsule forms around the gamete (Figure 24.23C). The sperm remains in this nonmotile state until after mating.

Although male spiders lack a penis (like almost all other arachnids), the pedipalps of the adults are modified for sperm storage and transfer and serve as copulatory organs. Sperm released from the male gonopore are placed on a specially constructed silken sperm web

Comstock. 1910. *Ann Entomol Soc Am* 3: 161–185.)

(Figure 24.23D). From here the sperm are picked up by the pedipalps, where they are held in special pouches or chambers, and eventually transferred to the female. The pedipalps of adult male spiders vary greatly in form and complexity, generally being simple in certain mygalomorphs and more complex in most araneomorphs. In the simplest form, each pedipalp bears on its modified tarsus (called the **cymbium**) a teardrop-shaped process known as the palpal organ (Figure 24.23E). A pointed tip, or **embolus**, bears a pore that leads inward to a blind coiled sperm duct (the spermophor). Sperm are drawn into this tube from the sperm web and held until transferred to the female. Until very recently no nerves or sensory organs had been found in the palpal bulb, suggesting that spider male copulatory organs are numb and blind to sensorial stimuli. The presence of neurons and a nerve inside the male palpal organ was documented for the first time in the Tasmanian cave spider *Hickmania troglodytes* (Gradungulidae) in 2015. Subsequent studies across many spider lineages have

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

demonstrated that the innervation of the male copulatory organ is part of the ground pattern of spiders.

The more complex male copulatory organs are formed of structures with varying degrees of sclerotization (sclerites) and a diversity of soft parts, such as sacs that can expand through increased hemolymph pressure (hematodochae) and various types of membranes. Often some of these cymbial sclerites, as well as the cymbium itself, and other pedipalpal articles bear processes called apophyses of wildly diverse morphology (Figure 24.23F), such as the "retrolateral tibial apophysis," which characterizes a large lineage of araneomorph families (the "RTA Clade") that includes, among others, the salticids and the wolf spiders. Although often difficult, assessing the homology of the highly variable structures across species is an important part of morphological phylogenetic inference, particularly in araneomorphs. Because genitalia vary across species, and because in closely related species somatic morphological features often vary little, genitalia, both male and female, are extensively used in spider taxonomy. Although male genitalia need to fit with the mating organs of conspecific females, the key-and-lock hypothesis to explain the evolution and huge interspecific diversity of genitalic structures of spiders has been empirically rejected. This variation is probably part of a series of mechanisms to prevent interspecific mating, although nonproductive interspecific encounters are prevented primarily by species-specific courtship behaviors (discussed below). Following the uptake of sperm through the embolus and insertion of the palpal organ into the female's receiving structure (the epigynum), the soft hematodochae are inflated with hemocoelic fluid, thereby causing an erection of the sclerites within the female parts. Once the partners are thus coupled, sperm are injected into the female's copulatory openings and ducts. In some species, sperm transfer is preceded by copulation before the palps are charged with sperm ("pseudocopulations"). A somehow analogous mechanism of sperm transfer with a diversity of sclerites and hemocoelic fluid pressure occurs in Ricinulei, where adult males have the third pair of legs modified for sperm transfer.

Female spiders have a pair of ovaries in the opisthosoma. The lumen of each ovary leads to an oviduct, and the two oviducts unite to form a uterus (also called the vagina), which opens to the outside in the epigastric furrow (Figure 24.23G). Eggs are produced mainly on the exterior of the ovaries, giving the ovaries a bubbled texture; how the eggs move to the internal ovarian lumen is not well understood.

Just inside, or lateral to, the female gonopore, there is usually a pair of copulatory openings that lead through coiled connecting ducts to paired seminal receptacles (or spermathecae). In entelegyne spiders a second pair of tubes, called the fertilization ducts, connects the seminal receptacles to the uterus (Figure 24.23G). Many spiders have a complexly structured sclerotized plate just in front of the epigastric furrow. This plate, called the epigynum, extends over the genital pore and bears the copulatory openings to the seminal receptacles through copulatory ducts or folds. The morphology of the epigynum, the position and length of the copulatory openings and connecting ducts, and other external features provide a particular topography that matches the palpal organs of conspecific males. As with male pedipalps, the morphology of the female genitalia is used by taxonomists to discriminate species. These differences in external anatomy, as well as in body size and overall courtship behavior, result in a variety of species-specific copulatory positions among spiders. Once sperm are inside the seminal receptacles, they are stored there until the female deposits her eggs, which may be months after copulation. At that time, the sperm pass through the fertilization ducts to fertilize the ova during egg laying.

The reproductive system of scorpions lies within the mesosoma, and both testes in males and ovaries in females are in the form of interconnected tubules (Figure 24.24). The gonads are drained by lateral sperm ducts or oviducts. The sperm ducts bear various storage chambers (seminal vesicles) and accessory glands and unite

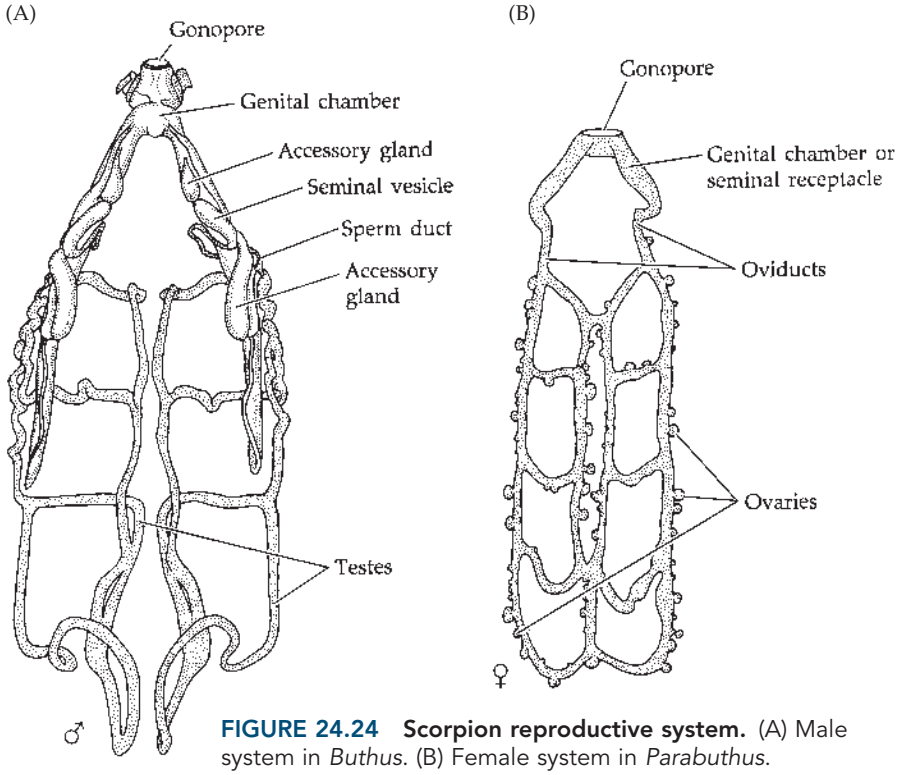

FIGURE 24.24 Scorpion reproductive system. (A) Male system in *Buthus*. (B) Female system in *Parabuthus*.

as a genital chamber just inside the gonopore on the first segment of the mesosoma. Some accessory glands are responsible for the production of spermatophores. Each oviduct is enlarged as a genital chamber, or seminal receptacle, near its union with the gonopore.

With few exceptions, sperm transfer in arachnids is indirect, as described above for the spiders. That is, the sperm leave the body of the male and are then somehow manipulated into the body of the female or deposited on the eggs outside the female's body. The only exceptions to this rule occur in most harvestmen (all members of the Phalangida) and some mites, in which the male possesses a penis through which sperm pass directly to the reproductive tract of the female. In all other arachnids, including mite harvestmen in the suborder Cyphophthalmi and many mites, either the sperm are inserted into the female's body by modified appendages of the male, or they are placed on the ground in spermatophores and then retrieved by the female. Modified appendages are used to transfer sperm in the orders Araneae (pedipalps), Uropygi (pedipalps), Ricinulei (third walking legs), some members of Solifugae (chelicerae), and some mites (chelicerae or third legs). In other arachnids (orders Scorpiones, Schizomida, Amblypygi, Pseudoscorpiones, and many Solifugae and mites), the males deposit spermatophores on the ground and the females simply pick them up, but in Cyphophthalmi (Opiliones) it seems that the male may deposit a spermatophore with a spermatopositor organ near the female gonostome. We hasten to point out, however, that the reproductive biology of many species in these taxa, and of some entire groups (e.g., Palpigradi), has been little studied.

The events leading up to insemination often include species-specific courtship behaviors that serve as cues for species recognition. These behaviors must, of course, be compatible with the particular method of sperm transfer (Figures 24.25 and 24.26). Again, we can look to spiders and scorpions for examples. Among spiders, courtship behaviors not only ensure conspecific copulation, but also prevent the usually smaller males from being mistaken for prey by the females, as well as having an arousal function. Platnick (1971) classified spider courtship behaviors into three general levels. First-level courtship involves necessary contact between male and female. Among many thomisids and clubionids, mating involves the male simply climbing over the female, positioning her abdomen, and inserting a palpal organ. The males of some thomisids (e.g., *Xysticus*) and at least some species of the golden orb-weaver *Nephila* (Araneidae) place silk threads over the bodies or legs of the female preparatory to copulation. These threads are apparently only part of the recognition ritual, because they are not strong enough to actually restrain the female (Figure 24.25C). A few other spiders, including certain tarantulas (Theraphosidae), also use body contact and leg touching as courtship behavior.

Second-level courtship behaviors involve the release of sex pheromones by the female spider. Some of the most complex behavior patterns occur in male spiders that detect females by olfaction, although other recognition devices may also be involved. Some male araneids are apparently led to the female's orb web by her pheromones, and the web is then recognized by contact chemoreception. Once in touch with the edge of the web, the male announces his presence to the female by plucking the threads of the orb itself or by attaching a special mating thread to her orb, which he then plucks (Figure 24.25E). If properly orchestrated, the male's "tune" eventually attracts the female, and contact is made.

Males of some species of wolf spiders (Lycosidae) respond to pheromones emitted along with the female's dragline. When he detects a female visually, the male begins a specific set of actions in an effort to win her favor. These male behaviors involve abdomen bobbing and pedipalp waving, coupled with drumming of the pedipalps on the substratum and stridulation (Figure 24.25F). If attracted by these cues, the female responds by slowly approaching the male and sending out signals of her own in the form of particular leg movements. Stridulation, using modified pedipalps, also occurs in some uloborids and many other families (Figure 24.25G).

Among the most interesting second-level courtship behaviors are those of certain nursery-web spiders (*Pisaura*; Pisauridae). After locating a female emitting pheromones, the male captures an insect (usually a fly), spins a silk wrapping around it, and offers it to the female. Acceptance of the nuptial gift and of the male are one and the same, for the successful male copulates with the female while she devours the insect. Alas, unsuccessful males are eaten along with the offering. Postcopulatory cannibalism by females is not uncommon in certain groups of spiders. Contrary to popular belief, the males of the North American black widow (*Latrodectus mactans*) are often unharmed after copulation. In other widow species, such as *L. geometricus* and *L. hasselti*, males are cannibalized by the females.

Another interesting second-level courtship behavior occurs in the Sierra dome spider (*Neriene litigiosa*) of western North America. Upon encountering a mature virgin female, a male attacks her pheromone-laden web and packs it into a small, tight mass. This behavior hinders the evaporation and dispersal of the male-attracting pheromone, thereby reducing the likelihood of additional males locating the female and competing for her favors.

Third-level courtship behaviors depend primarily on visual recognition of prospective mates and are best known in jumping spiders (Salticidae), which often exhibit conspicuous sexual dimorphism and striking coloration. A male locates a female and then begins a series of behaviors that identify him as a conspecific individual. Usually the male approaches the

Robinson. 1978. In P. Merrett [Ed.], *Arachnology. Symposia of the Zoological Society of London, Number 42*, pp. 17–29. Academic Press, London.)

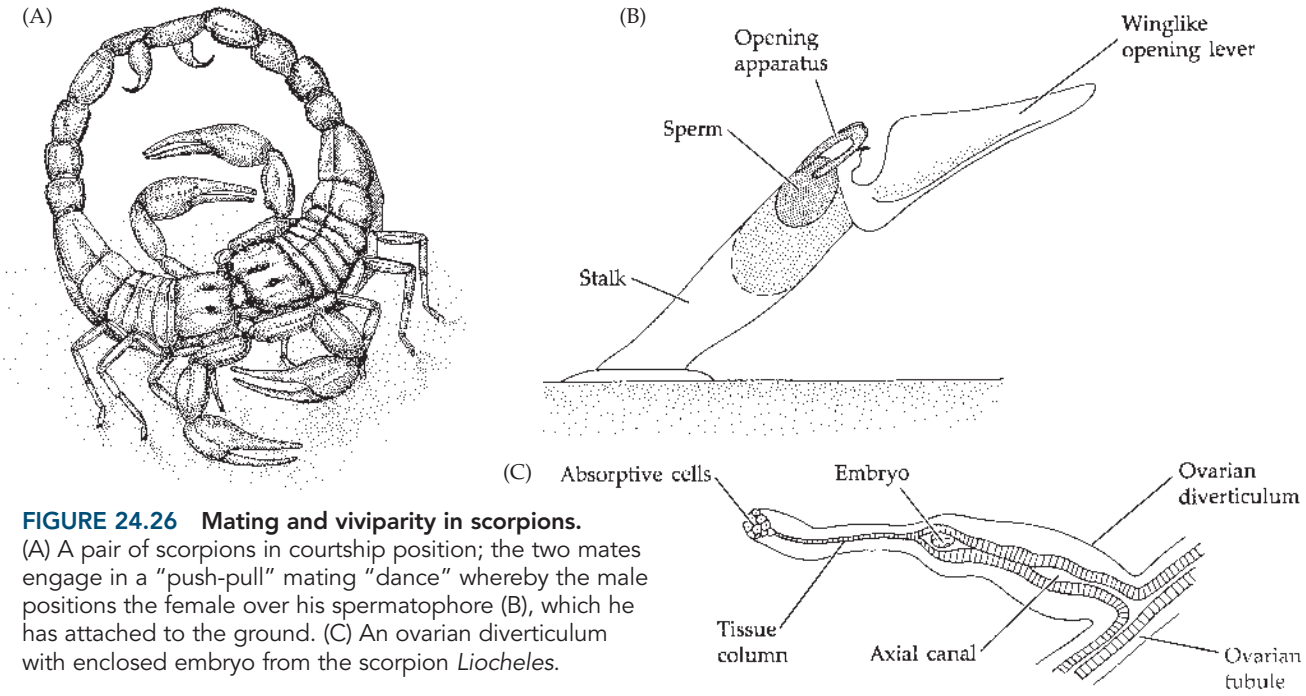

FIGURE 24.26 Mating and viviparity in scorpions. (A) A pair of scorpions in courtship position; the two mates engage in a "push-pull" mating "dance" whereby the male positions the female over his spermatophore (B), which he has attached to the ground. (C) An ovarian diverticulum with enclosed embryo from the scorpion *Liocheles*.

female along a zigzag path and then performs specific movements of the opisthosoma, pedipalps, and front walking legs (Figure 24.25H). The female signals her approval and receptiveness by sitting still in a visually recognizable position. The male eventually contacts her, caresses her briefly, mounts her, and copulates.

Sex-related behaviors among spiders are not restricted to male-female encounters. Conspecific males frequently exhibit agonistic behavior in competition for a mate. When males encounter one another in the presence of a female, or even in a mating "territory" (such as on the web of a female), they may assume various threatening postures and in some cases actually engage in combat. Usually, however, one of the males retreats before any real damage is done, leaving the dominant male free to pursue his sexual interests.

The courtship behavior of scorpions does not involve copulation in any form, but instead involves deposition of spermatophores onto the ground. Courtship behaviors appear to be relatively similar among those species that have been studied, although subtle species-specific differences allowing species recognition undoubtedly occur. In a typical case, the male initiates the ritual by grasping the female's pedipalps in his and, in this face-to-face position, dances her around in a series of back-and-forth steps (Figure 24.26A). Eventually the male releases a spermatophore and cements it to the ground. He then continues to move the female around until she is precisely positioned with her genital operculum over the packet of sperm. The spermatophore is a complex, species-specific structure, and it bears a special process called an opening lever (Figure 24.26B). The pressure of the female's body on this lever causes the spermatophore to burst, releasing the sperm, which can then enter her gonopore.

Arachnids undergo a variety of developmental patterns, all of which may be considered direct in terms of their life history strategies. Most species produce very yolky eggs, providing the embryos with nourishment through much of their development. By the time of hatching, many resemble miniature adults or still contain enough yolk to carry them through subsequent development to the juvenile stage. In some acarines and all ricinuleids, the young hatch as six-legged "hexapod larvae" (Figure 24.27L). These immature individuals add the last pair of legs later through molting. In most arachnids the developing embryos are protected by some sort of egg case or cocoon, or they are brooded in or on the body of the female.

Nearly all spiders cement their eggs together in clusters and wrap them in silken egg sacs, the sizes and shapes of which vary among species (Figure 24.27). The egg sac provides physical protection for the embryos and also insulates them from fluctuations in environmental conditions, particularly changes in humidity. Additional

protection results from placing the egg sac underground, in a nest, or in other secluded spots. Some species camouflage their cocoons with bits of detritus; others guard their cocoons or actually carry them on their bodies.

The early development of spiders includes intralecithal nuclear divisions followed by migration of the nuclei to the periphery of the embryo. The nuclei are then isolated by cytoplasmic partitioning, a process that produces a periblastula around an inner yolky mass. Gastrulation follows by formation of a germinal center of presumptive endodermal and mesodermal cells that migrate inward. Additional germinal centers produce the precursors of segments and limbs. The immature individuals of different spider species hatch from their egg membranes at different stages, but they always remain inside the cocoon and utilize their yolk reserves until they are able to feed. Most workers recognize three postembryonic, preadult stages in spider development (Figure 24.27I–K). The majority of spiders hatch from their egg membranes as immobile "prelarvae," characterized by incomplete segmentation and poorly developed appendages. The "prelarva" matures into a "larva" and then into a "nymph," or juvenile, which physically resembles the adult. In some spiders these early developmental changes take place in a special molting chamber inside the cocoon (Figure 24.27B). The emergence from the cocoon usually occurs at an early "nymphal" stage, when the young are fully formed spiderlings. Many female spiders even engage in postnatal care by carrying their young on their bodies or by feeding them (Figure 24.27E). (It is important to note that the terms "prelarva," "larva," and "nymph," as used here, do not carry the same meanings as they do when used to describe indirect or mixed development, in which the larva is an independent, free-living individual, as in insects or crustaceans.)

Scorpion development is direct and may be either ovoviviparous or viviparous. Viviparity is perhaps best studied in the Asian scorpion *Liocheles australasiae*. In this species the zygotes lie in tiny diverticula on the walls of the ovarian tubules (Figure 24.26C). Certain cells of the tubule wall absorb nutrients from the adjacent digestive ceca and supply them to the developing embryos. The eggs of *Liocheles* contain very little yolk and undergo holoblastic, equal cleavage. Ovoviviparous scorpions, on the other hand, produce yolky eggs that cleave meroblastically. The embryos of these species are brooded in the ovarian tubules but depend on their yolk supplies for nutrients. The young eventually emerge from the female's gonopore and crawl onto her back. Here they stay until they are old enough to make periodic excursions away from their parent and eventually assume an independent life. Juvenile scorpions molt through several instars until they mature, about a year after birth.

Many other arachnids also brood their embryos, usually externally on the mother's body, as in Amblypygi, Uropygi, Ricinulei, and Schizomida. Members of these groups carry their young in some sort of sac near the female gonopore. Pseudoscorpions spin cocoons from their cheliceral silk glands. Solifuges and harvestmen are oviparous, and some deposit their eggs in the soil or in leaves or logs. In all cases the young hatch and pass through a few or many instars before they mature, and the maturation process may take several years in groups like Ricinulei. Again, except for the "hexapod larvae" of mites and ricinuleids (Figure 24.27L), arachnids hatch as small immature adults, and although various names are given to these immature stages, development is strategically direct. Some harvestmen are known for their parental care, which can be in the form of maternal (Figure 24.27M), paternal, or biparental care. Paternal care is extremely rare in other groups of animals, but it is the norm in sea spiders, discussed in the following section.

The Class Pycnogonida

Pycnogonids (Greek *pyc*, "thick," "knobby"; *gonida*, "knees"), or pantopods, are usually called "sea spiders" because of their superficial similarity to true, terrestrial spiders (Figures 24.28 and 24.29). Pycnogonids

had been problematic in terms of their placement among the other arthropod taxa for decades. Since the turn of the twentieth century they have been associated at one time or another with virtually every major group of arthropods, as well as with the onychophorans and polychaetes. The principal problem has been uncertainty concerning homologies of the various body regions and appendages. The unique pycnogonid "proboscis," for example, has been homologized with everything from the prostomium of polychaete worms to the lips of onychophorans to various anterior regions of other arthropods. However, recent anatomical and molecular studies place the pycnogonids solidly within arthropods, as the sister group to all other chelicerates (what we call euchelicerates).

Several characters are apparent shared apomorphies between the euchelicerates and pycnogonids, including the first appendages (chelicerae/chelifores) and second appendages (pedipalps/palps)—based on the assumption that these appendage pairs, and their somites, are indeed homologous, and nervous innervation tends to support this contention. Two other apparent synapomorphies are the stenopodous uniramous legs (with certain functional similarities) and a feeding method that is largely liquid/suctorial. Pycnogonids also possess several striking unique features, synapomorphies not found in any euchelicerate or in any other arthropod group, such as the odd anterior "proboscis," the **ovigers** (specialized appendages between the pedipalps and first walking legs, used for a variety of purposes but most notably for brooding in males), multiple gonopores (on the second coxal segment of some or all of the walking legs), and the unique body form, discussed in the Pycnogonid Body Plan section, with a reduced abdomen. When compared with euchelicerates, pycnogonids are much more labile in the presence or absence of several appendages (including chelifores, palps and ovigers), and even the number of segments sometimes varies within species or closely related groups.

There are about 1,368 described extant species of pycnogonids, in nearly a hundred genera, with many more yet to be discovered. Pycnogonids are strictly marine; they occur intertidally and to depths of nearly 7,000 m and are distributed worldwide. Most are small, with leg spans less than a centimeter (*Austrodecus palauense* has a leg span of only 2 mm); however, some deep-sea and polar species have leg spans to almost 60 cm. The largest species are members of the genus *Colossendeis*, which live in deep waters worldwide and are common, together with other giants, near shore in Antarctica. Many are errant benthic animals, but others live on seaweeds or on other invertebrates, particularly sea anemones, hydroids, bryozoans, and tunicates. One or two species live on the bells of pelagic medusae, and six species have been collected in hydrothermal vents often associated with, or on the huge vestimentiferan tube worms. A review of the biology of sea spiders can be found in Arnaud and Bamber (1987).

Pycnogonid systematics has remained unsettled for a while, but recently a large community effort has produced a comprehensive tree of life for pycnogonids using a multidisciplinary approach (Ballesteros et al., 2021). Historically, the few known fossil species (which date back to the Upper Carboniferous, as the Cambrian fossil *Cambropycnogon klausmuelleri* is not considered a pycnogonid by most authors) were "dumped" into the single order Palaeopantopoda, and the living forms into the order Pantopoda. The most commonly used classification, with subsequent modifications, was that of Hedgpeth (1982), who recognized just 8 families, based largely on appendage structure (particularly the reduction or loss of various appendages), but many of these families are not monophyletic. Several updates of this system have been proposed in the past two decades and currently pycnogonids include 11 families, 2 of which (Ascorhynchidae and Callipallenidae) are not monophyletic.

The Pycnogonid Body Plan

External Anatomy

The bodies of pycnogonids are not as clearly divided into recognizable tagmata as are those of other arthropods (Figures 24.28 and 24.29), especially since they have a miniaturized abdomen. The first body "region" bears an anteriorly directed proboscis with a terminal mouth, which varies in size and shape among species. The proboscis contains a chamber and bears an opening at its distal end (Figure 24.29A); most researchers now consider the mouth to be at the end (tip) of the proboscis. This anterior-most body "region" also bears paired appendages in the forms of **chelifores**, palps, first walking legs, and, when present, ovigers (Figures 24.29A and 24.31). The chelifores may be chelate or achelate, or absent altogether; they receive a different name from that of the similar appendages in other chelicerates, the **cheliceres**, but it is now clear that these appendages are homologous and innervated by the deutocerebrum. The ovigers are modified legs that serve a variety of functions, including grooming (Figure 24.29C), food handling in some species, courtship, mating, egg transfer (female to male) in many species, and brooding of the embryos by males in most species. Also located on the first segment of most species is a tubercle with four simple median eyes.

The following body segments form the "trunk" and may be variably fused, but each bears a pair of lateral processes, called **pedestals**, on which are borne the walking legs. Because of the orientation of the pedestals, the walking legs are arranged somewhat radially around the body. The posterior-most body segment

carries a dorsally inserted posterodorsal tubercle, which may be a vestigial abdomen and which bears the anus. Perhaps the most distinctive synapomorphy of the pycnogonids, compared with other arthropods, is the presence of multiple gonopores, found on some or all of the walking legs.

One of the most unusual aspects of pycnogonid morphology is the existence of polymerous species, which have more than four pairs of walking legs. This phenomenon is unique to pycnogonids and occurs in the genera *Pentanymphon*, *Pentapycnon*, and *Decolopoda* (with five pairs of legs; decapodous), and *Sexanymphon* and *Dodecolopoda* (with six pairs of legs; dodecapodous). *Callipallene brevirostris* typically bears four pairs of legs, but one specimen has been found with only three pairs. This polymery is poorly understood phylogenetically and developmentally.

Variation among different pycnogonids also occurs in appendage shape and length, spination, proboscis structure, reduction or loss of chelifores and palps, and many other external features. Several examples are shown in Figures 24.28 and 24.29 to illustrate this diversity. In all, however, the body is remarkably reduced and narrow, a feature compensated for by extensions of the gut ceca and gonads into the legs.

Locomotion

The walking legs of pycnogonids are typically nine-segmented. The junction of the first coxal segment and the pedestal is a more or less immovable joint and does not contribute to the action of the leg. The joint between the first and second coxae is hinged to provide antero-posterior movement, and the rest of the joints provide the usual flexion and extension. However, the coxal joints also allow a certain amount of "twisting" and thus accentuate the anterior–posterior swing of the appendage tips during the power and recovery strokes. Some joints lack extensor muscles, and limb extension is effected by hydrostatic pressure, as in many arachnids. Note that pycnogonid specialists have given names to the leg articles that do not parallel those used for any other arthropod group (Figure 24.29B).

Most of the commonly encountered intertidal pycnogonids are quite sedentary and move very slowly. These small forms have short, thick legs that are somewhat prehensile and serve more for clinging to other invertebrates or algae than for rapid locomotion. Deep-water benthic pycnogonids tend to be more active, and these errant pycnogonids have longer and thinner legs than the sedentary forms, and they tend to walk on the tips of the legs (Figures 24.28E and 24.29C). However, some of the very large forms (e.g., *Colossendeis*) may depend more on slow ocean currents to roll them around on the bottom than on their own locomotory powers.

Many pycnogonids are also known to swim periodically by employing leg motions similar to those used in walking. Some species are known to "hang" from the water's surface, utilizing a combination of small body mass and surface tension. Several studies also report a characteristic "sinking behavior" in a number of species. When dropping to the bottom, these pycnogonids elevate all of the appendages over the dorsal surface of the body in a basket configuration. This behavior eliminates much of the frictional resistance to sinking and allows the animal to drop quickly through the water column (presumably to avoid predation), a behavior also commonly found in some ophiuroids.

Feeding and Digestion

In most species of pycnogonids, feeding habits are dictated by the form of the proboscis, and food is limited to material that can be sucked into the gut. Even with this basic structural constraint, pycnogonids feed on a variety of organisms.

A few pycnogonids feed on algae, but most are carnivorous, many being generalized predators on hydroids, polychaetes, nudibranchs, and other small invertebrates. Some, perhaps many, also scavenge. Species that consume other animals usually use three cuticular teeth at the tip of the proboscis to pierce the body of their prey, and then they suck out body fluids and tissue fragments. Some pycnogonids that live on hydroids use the chelifores to pick off pieces of the host and pass them to the proboscis opening. In most species, however, the chelifores cannot reach the tip of the proboscis, and their function in feeding is questionable. Some species (e.g., *Achelia echinata*) feed on bryozoans by inserting the proboscis into the chamber that houses an individual and sucking out the zooid (Figure 24.28D). An interesting phenomenon in Antarctic pycnogonids is the large number of species and individuals that carry, on their cuticle, bryozoans—a major source of food for them! This may be advantageous to the bryozoan colonies, even if used as a food source by the pycnogonids, as they get some protection from ice scour. Others (e.g., *Pycnogonum litorale*, *P. rickettsi*) feed on sea anemones in a similar fashion, but the anemones are rarely killed, due to the large difference in size between predator and prey.

Very little is known about the feeding habits of the deep-sea benthic forms. Undersea photographs and direct observations of aquarium specimens of the giant *Colossendeis colossea* indicate that it may walk slowly along the bottom, sweeping its palps across the substratum to sense prey that it might suck from the mud.

The digestive tract extends from the mouth, at the tip of the proboscis, to the anus, which opens on the posterodorsal tubercle on the peglike abdomen (Figure 24.30A). A chamber within the proboscis bears dense bristles that strain and mechanically mix ingested food, which continues to the pharynx. The pharyngeal and the esophageal regions have a foregut lumen that is

(D) A female pycnogonid with developing ova stored in the femoral portions of the gonad diverticula. (E) Protonymphon larva.

Y-shaped in transverse section. The muscles of the foregut supply the suction for ingestion. A short esophagus connects with the elongate midgut or intestine, from which digestive ceca extend into the bases of each leg, providing a high surface area for digestion and absorption. A short proctodeal rectum leads to the anus.

Digestion is predominantly, if not exclusively, intracellular. The cells of the midgut and cecal walls differentiate from the basal layer and contain a bewildering array of secretion droplets, lysosomes and phagosomes, and include phagocytes that engulf ingested food materials. Some of these cells actually break free from the gut lining and phagocytize food particles while drifting in the gut lumen. Apparently these loose cells reattach to the gut wall after they have "fed." It has been suggested that upon reattachment these errant cells first pass their digested food contents to the fixed cells of the gut wall, then assume an excretory function by picking up metabolic wastes, detaching again, and being eliminated via the anus. In the absence of a hepatopancreas, the midgut serves both digestive and absorptive functions.

Circulation, Gas Exchange, and Excretion

Pycnogonids lack special organs for gas exchange. The digestive ceca and the overall body plan together present a very high surface-area-to-volume ratio, and exchange of gases probably occurs largely by diffusion across the body and gut wall, through gut peristalsis. However, cutaneous respiration often poses a limit to size in arthropods, as the cuticle also has a structural function. Recent studies have shown that larger pycnogonids maintain steeper oxygen gradients and higher effective diffusion coefficients of oxygen in the cuticle than vertebrates do, and diffusion modeling has shown that gas exchange occurs mostly through pores in the cuticle.

Traditionally, pycnogonids have been thought to have no excretory organs at all and to use the high surface-area-to-volume ratio or the wandering cells of the midgut for excretion. Recently an excretory structure has been located in at least one ammotheid, *Nymphopsis spinosissimum*, in which a simple, but standard, excretory gland has been found in the scape of the chelifore. It consists of an end sac, a straight proximal tubule, a short distal tubule, and a raised nephropore.

The circulatory system includes an elongate heart with incurrent ostia, but no blood vessels. As in other arthropods, the heart is located dorsally, within a pericardial chamber separated from the ventral hemocoel by a perforated membrane. Blood leaves the heart anteriorly and flows through the hemocoelic spaces of the body and appendages. Contraction of the heart causes a lowered pressure within the dorsal pericardial body chamber, and blood is thus drawn through the perforations in the membrane and toward the heart. Upon relaxation, the blood flows through the ostia into the heart lumen.

Nervous System and Sense Organs

The central nervous system of pycnogonids includes cerebral ganglia above the esophagus, circumenteric connectives, a subenteric ganglion, and a ganglionated ventral nerve cord (Figure 24.30A,B). The nerve cord bears a ganglion for each pair of walking legs, with additional ganglia present in the polymerous species.

The cerebral ganglia, as in most extant arthropods, include protocerebrum, deutocerebrum, and the subesophageal tritocerebrum. The protocerebrum innervates the eyes, and the deutocerebrum innervates the chelifores, an arrangement similar to that in euchelicerates. Recently some authors postulated that the chelifores were innervated by the protocerebrum, as in the "great appendages" of some Cambrian stem-group arthropods, but this was later shown to be an artifact due to the fusion of protocerebrum and deutocerebrum in the second embryonic stage. The cerebral ganglia also give rise to a well-developed ganglionated proboscis nerve.

Little work has been done on pycnogonid sense organs. Tactile reception is provided by touch-sensitive setae and probably by the palps. On the body surface, just dorsal to the cerebral ganglia, is a central tubercle with four simple eyes that provide 360° vision. Some deep-sea species lack eyes entirely.

Reproduction and Development

Pycnogonids are gonochoristic. Mating is typically followed by a period of brooding, during which the embryos are held by the male's ventrally articulated ovigers, then by the release of unique **protonymphon larvae** (Figure 24.30E). The protonymphon has six legs and usually lives in a symbiotic relationship with cnidarians, molluscs, or echinoderms. These relationships are poorly understood, but in some cases they appear to be parasitic or commensalistic, encysting in the cnidarian host. This life cycle strategy has been replaced by direct development in some species wherein the larval stage is passed within an egg case.

Sexual dimorphism is common among pycnogonids. The males bear the unique ovigers associated with the first body segment; these appendages are absent in females of some families (e.g., Phoxichilidiidae, Endeidae, and Pycnogonidae) and reduced in the females of other families (Figure 24.31). Female pycnogonids usually have enlarged limb femora.

Internally, the reproductive system of males and females is similar and relatively simple. In both, the gonad is single and U-shaped, with extensions into the legs where gametes are produced and stored. The expanded femora in females provide space for storing unfertilized eggs (Figure 24.30D). The multiple gonopores are usually located on the ventral surface of the second coxae of two or all pairs of legs and are thus close to the regions of gamete storage. During mating, the male typically hangs beneath the female or

for more ebook/ testbank/ solution manuals requests: email 9601267346@qq.com

assumes a stance over her back. As the female releases her eggs, the male fertilizes them. Following fertilization, the male gathers the eggs, either one by one or as a single mass, and glues them to his ovigers using a sticky secretion from special femoral glands (Figure 24.29A). Pycnogonids are one of the few groups of animals in which brooding of eggs and developing embryos is conducted exclusively by the males, and in some species males also brood the young.

Knowledge of pycnogonid development has increased considerably in the past few years, with several studies focusing on the identity of the pycnogonid appendages with those of other arthropods, using neurogenesis and Hox gene expression. Earlier in embryogenesis, there is some variation among members of different genera, but cleavage is usually holoblastic and leads to the formation of a stereoblastula. The inward movement of the presumptive endodermal and mesodermal cells is frequently accompanied by a disappearance of some cell membranes, a process leading to the formation of some syncytial tissues in the gastrula. Germinal centers become apparent as appendage buds form. The most common hatching stage is a free-swimming protonymphon larva. Through a

FIGURE 24.31 Proposed phylogeny of the pycnogonid families and reconstruction of the cephalic appendage evolution, with emphasis on the chelifore. Reconstruction of adult chelifores is mapped on the topology, and appendage complement for males and females is indicated for each family. Ancestral state reconstruction is based on equally weighted parsimony. Note the omission of functional adult chelifores in colossendeids with supernumerary segments (a derived state within the genus *Colossendeis*). Specimens in counterclockwise order from top left: male *Austrodecus glaciale*, male *Endeis spinosa*, female *Phoxichilidium femoratum*, egg-bearing male *Ascorhynchus ramipes*, male *Stylopallene cheilorhynchus*, male *Nymphon gracile*, female *Ammothella longipes*, female *Colossendeis angusta*, female *Pycnogonum litorale*, female *Rhynchothorax australis*.

series of molts, the protonymphon adds segments and appendages to produce a juvenile. In some species, the developing larva becomes encysted in a hydroid or stylasterine coral, emerging later with three pairs of legs. A few species are known to produce all of the appendages at once, with subsequent molts simply increasing the size and segment number of the legs (the "atypical protonymphon larva"). In *Pycnogonum litorale*, at the fifth larval molt, the three pairs of larval legs and the larval proboscis are lost; the adult proboscis appears and, at later molts, the adult limbs develop.

Chelicerate Phylogeny

Although over 150 years have passed since the discovery of pycnogonids, arguments still ensue as to their phylogenetic relationships. However, as we mentioned earlier, recent morphological, paleontological, and molecular studies point to a chelicerate ancestry. The chelifores and palps of pycnogonids are now considered homologous with the chelicerae and pedipalps of the other chelicerates. We thus recognize Pycnogonida as the sister group to the remaining Chelicerata, or Euchelicerata.

Figure 24.32 is a cladogram depicting a working hypothesis of the relationships among the major chelicerate clades. However, we caution readers that the phylogenetic relationships among the Chelicerata are still being debated. Resolving the phylogenetic relationships of chelicerates remains remarkably difficult due to their ancient rapid radiation and the elevated evolutionary rates in several lineages. Until recently, the subclass Arachnida was considered a monophyletic group, although some workers have suggested that it might be diphyletic, having arisen from two separate invasions of land (one leading to the scorpions, the second to all other orders), a view that no longer has much support. Phylogenetic relationships among the orders of Arachnida remain controversial; see Ballesteros and Sharma (2019) for a recent study using transcriptomic data and Shultz (2007) for a recent analysis based on morphological data. Recent phylogenomic studies, even when integrating morphological data, place Xiphosura

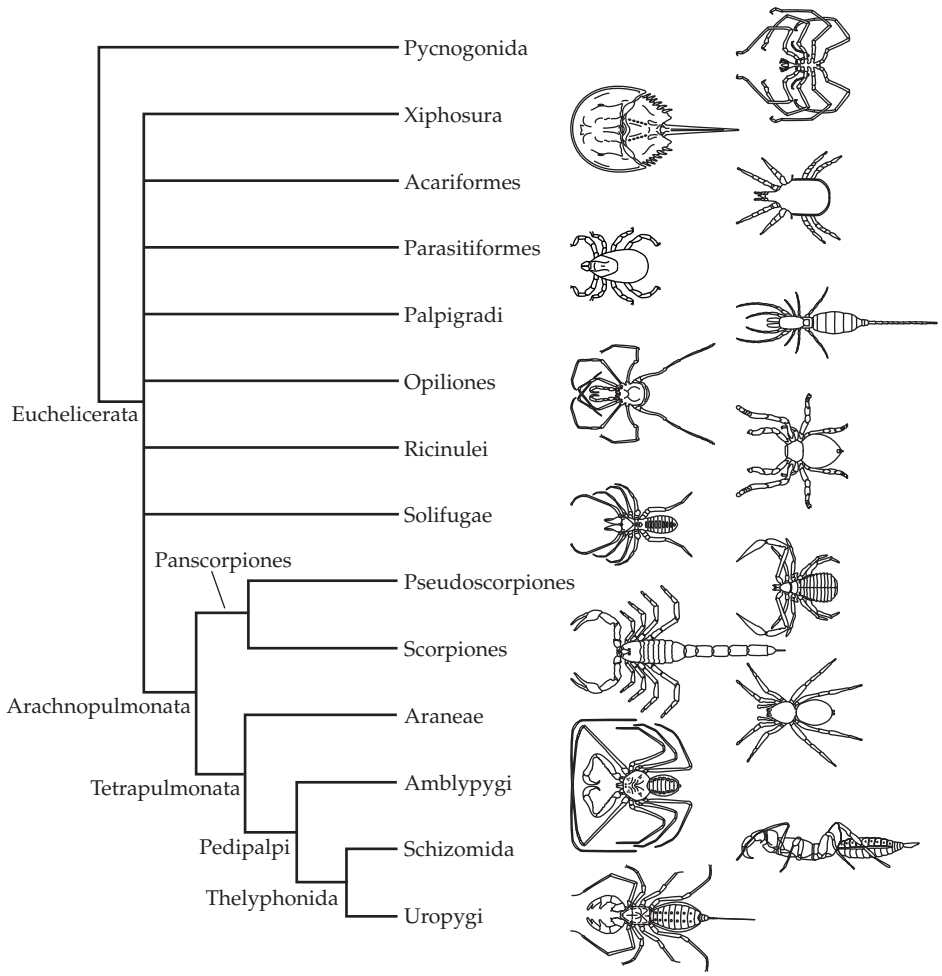

FIGURE 24.32 A cladogram depicting a working hypothesis for the relationships among Chelicerata. Note the unresolved positions for a good number of arachnid orders as well as the unresolved position of Xiphosura with respect to the other orders.

(horseshoe crabs) as distally placed arachnids, with combined analyses recovering Merostomata (the marine orders Xiphosura, Eurypterida, and Chasmataspidida) as nested within Arachnida. These studies recover older origins of chelicerate groups than previously inferred, suggesting a more complex history of terrestrialization in chelicerates than previously envisioned, with multiple recolonizations of aquatic habitats.

The earliest xiphosuran, eurypterid, and chasmataspidid fossils are from the Ordovician, but putative chasmataspidid impressions are found in the late Cambrian. Like the myriapods (and perhaps the insects), arachnids probably invaded land early in the Silurian, at the same time the land plants were becoming well established, although molecular calibrations suggest an earlier origin of arachnids, probably Ordovician or even earlier. Whether the earliest Paleozoic scorpions (Silurian) were aquatic remains contentious, but fully articulated fossil scorpions have been found in the marine Devonian Hunsrück Slate environment.

A series of phosphatized larval instars from the late Cambrian Orsten of Sweden were considered the oldest putative pycnogonids, but the consensus now is to exclude the Orsten fossils from Pycnogonida, at least from the crown group. The oldest sea spiders come from the Upper Ordovician William Lake Konservat-Lagerstätte deposit in Manitoba, Canada, followed by fossils from the Silurian Herefordshire Konservat-Lagerstätte in England and a suite of taxa from the Early Devonian Hunsrück Slate of Germany.

Chapter Summary

This chapter introduced you to the oldest group of extant arthropods (the first to appear in the fossil record), the Chelicerata, a clade that includes some primitive marine groups (Pycnogonida, Xiphosura) and a plethora of terrestrial counterparts, including large numbers of predators (spiders, scorpions) and parasites (many acarine lineages). Despite their variety of form, chelicerates are characterized by a common body plan with chelicerae as the first pair of appendages (deutocerebral), followed by more or less modified pedipalps (tritocerebral), and then four pairs of walking legs. All of these appendages concentrate in a body region called the prosoma. The prosoma also bears the eyes, with a variety of simple eyes in the different chelicerate lineages, and also with compound eyes in the horseshoe crabs. The opisthosoma, or second body tagma, is externally segmented in most groups (but not in most spiders), although tagmosis in the acarine groups follows a different scheme. The opisthosoma may bear appendage-derived structures, such as the spinnerets of spiders or the pectines of scorpions. Among the chelicerates, the taxon Arachnida has been recognized for a long time, but current molecular phylogenetic analyses have questioned the monophyly of this group, placing horseshoe crabs within the terrestrial arachnids, a result that has raised skepticism among some biologists and that would imply a return to a marine environment for the horseshoe crab ancestors. Arachnids are an important component of terrestrial ecosystems and have developed some of the most fascinating tools used in the animal kingdom for prey capture, venoms and silk.

In addition to the question of the position of horseshoe crabs there is the challenge of classifying arachnids, especially the apulmonate groups (those that typically use tracheae for respiration). Currently, the monophyly of those with book lungs is strongly supported molecularly and morphologically, in a clade known as Arachnopulmonata, which includes Araneae, Amblypygi, Uropygi, Schizomida, Scorpiones, and probably the apulmonate Pseudoscorpiones. Understanding the relationship of the other apulmonates and the plethora of extinct arachnid lineages has been a fruitful but relatively frustrating area of inquiry.

CHAPTER 25

Introduction to Deuterostomia, and the Phylum Hemichordata

The two great clades of Bilateria—Protostomia and Deuterostomia—have been recognized for well over a century. You were briefly introduced to these clades in Chapters 8 and 10. With this chapter, we begin our formal studies of the deuterostomes. Although there are only three phyla in the clade Deuterostomia, the clade has long loomed large in zoological lore because one of them, the phylum Chordata, contains the vertebrates (which happens to include *Homo sapiens*), and another contains perhaps the most iconic of marine invertebrates, the echinoderms (Figure 25.1). The third deuterostome phylum, Hemichordata, is little known to most zoologists except through courses in invertebrate zoology. Four other phyla were formerly assigned to Deuterostomia (Chaetognatha, Phoronida, Bryozoa and Brachiopoda), but some years ago molecular phylogenetics showed these to belong to the clade Protostomia. In addition, some authors consider Chordata to be three phyla instead of one: Cephalochordata, Urochordata (or Tunicata), and Vertebrata (or Craniata).

Introduction to the Deuterostomia

The groups Protostomia and Deuterostomia were long defined on the basis of embryological principles. In protostomes the blastopore (the region in the embryo that typically gives rise to endodermal tissues) was said to give rise to the mouth (protostome meaning "mouth first"). Typically in deuterostomes, the blastopore gives rise to the adult anus, the mouth thus forming secondarily at a different location (deuterostome means "secondary mouth"). In both lineages, the blastopore sits at the vegetal pole of the embryo when gastrulation begins. Also, it was long thought that

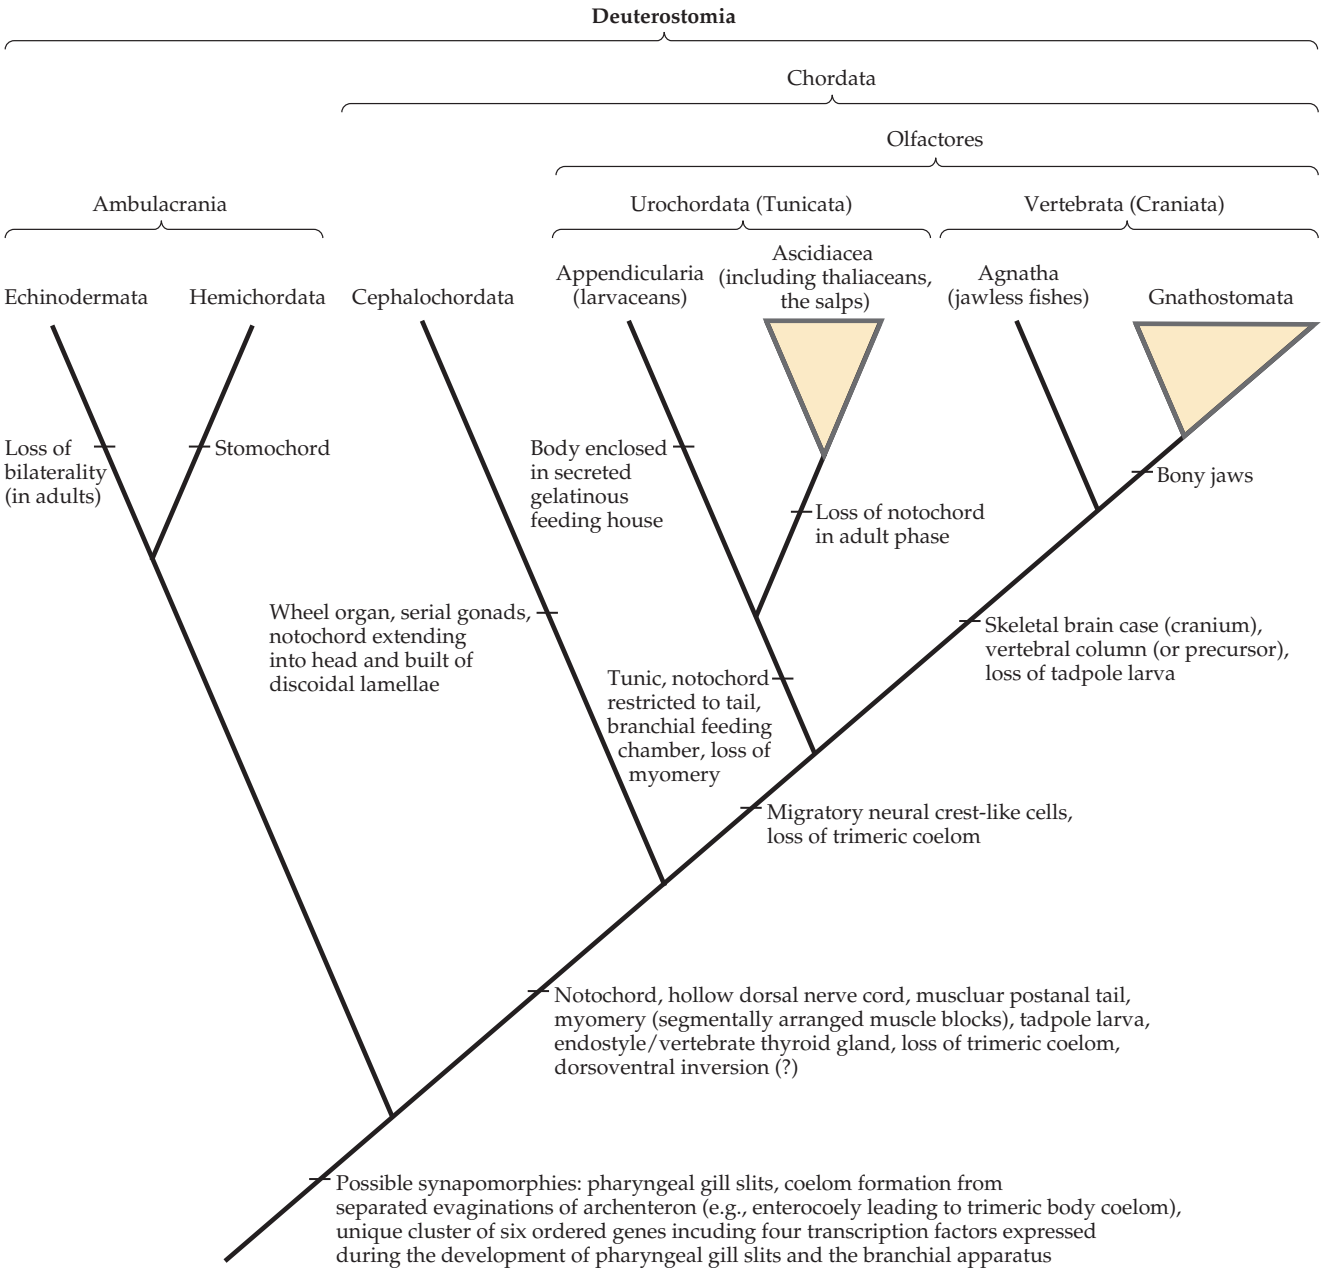

FIGURE 25.1 A phylogeny of Deuterostomia.

radial cleavage defined deuterostomes. However, new embryological patterns have begun to emerge.

It turns out that the blastopore doesn't consistently give rise to the anus in deuterostomes. And among the protostomes, gastrulation is now known to be much more variable, and some protostome phyla display deuterostomous development (e.g., Nematomorpha, Priapula, some Brachiopoda); that is, the mouth opens separately from the blastopore, which may become the anus. And it has been long known that radial cleavage occurs in some nondeuterostomes. So, evidence is accumulating that mouth formation from oral ectoderm (in the animal hemisphere), development of the anus from the blastopore, and radial cleavage, all once thought to define deuterostome embryogeny, may be ancestral in both protostomes and deuterostomes, and thus in Bilateria itself. Hence, most of the embryological features that once defined these two great clades of bilaterians no longer unambiguously do so, and our current definition of Protostomia and Deuterostomia is based primarily on molecular phylogenetic evidence. However, the legacy names Protostomia and Deuterostomia continue to be used for these two animal lineages. Unambiguous morphological or developmental synapomorphies probably exist that define these two clades, but they have not yet been fully identified.

One possible synapomorphy of the Deuterostomia is enterocoelic development and a trimeric condition of its coelomic cavities, at least primitively, but this feature is lacking in the phylum Chordata, and therefore it could be a feature of Ambulacraria. During deuterostome enterocoelic embryogeny, the coelomic cavities form via

for more ebook/ testbank/ solution manuals request Email 9601267340@qq.com

archenteric pouching, in which each of the three coeloms forms from the gut, pinching off and becoming a coelomic cavity (Figure 4.12). These coelomic compartments are called (anterior to posterior) protocoel, mesocoel, and metacoel; the equivalent body regions are the prosome, mesosome, and metasome. By definition, the walls of the pouches are mesoderm. However, schizocoelic coelom formation (Figure 4.11) has also been reported from a few deuterostomes, including scattered mesodermal cells in the tornariae of some enteropneusts. Another probable synapomorphy of Deuterostomia is a widely conserved cluster of six ordered genes, including four transcription factors expressed during the development of pharyngeal gill slits and the branchial apparatus.

Within the deuterostome clade, recent morphological and molecular work (and also Hox gene motifs) suggest that echinoderms and hemichordates are sister groups, constituting a clade called Ambulacraria, and this is the sister group to the phylum Chordata. If this assessment is correct, it means the features shared between chordates and hemichordates (formerly long thought to comprise sister groups), such as gill slits, may have been ancestral within Deuterostomia but lost in the echinoderm line (and also in some hemichordate lineages), as suggested by the putative presence of gill slits in some extinct echinoderms. Gill slits in Deuterostomia have been shown to be homologous based on their gene expression patterns. Several other deuterostome animals with gill slits are known from the fossil record (Saccorhytida, Vetulocystida, Vetulicolia, Yunnanozoa), although it is not yet certain whether these belong to stem urochordates, to stem echinoderms, to stem chordates, or to unique but extinct lineages.

A long-recognized feature shared between the Hemichordata and Chordata is the stomochord/notochord, once viewed as homologues. It is now thought that these structures might have had much earlier origins and may or may not be homologous, or that a group of vacuolated cells in ancestral deuterostomes gave rise to these structures independently in hemichordates and chordates. Within Chordata, Urochordata is the sister group to Vertebrata (a clade known as Olfactores), and Cephalochordata is the sister group to those (Figure 25.1). There is some older evidence that a fourth group, Xenoturbellida (or even the whole clade Xenacoelomorpha) might be near the base of the deuterostome line, but more convincing evidence suggests Xenacoelomorpha as an ancestral bilaterian clade that arose prior to the divergence between protostomes and deuterostomes, and that is the view we follow in this book.

Deuterostomia is an ancient lineage, and dated phylogenetic trees (using fossils to date branching points) suggest the ancestral line existed well into the Precambrian. The oldest definitive fossil of Deuterostomia is a 530-million-year-old creature called *Yunnanozoon*, from the lower Cambrian Chengjiang biota of the Yunnan Province, China, although the affinities of yunnanozoans are still uncertain. An even older fossil from the basal Cambrian of Shaanxi, China, is the meiofaunal *Saccorhytus coronarius*, although the affinities of this fossil are a bit more controversial.

Phylum Hemichordata: Acorn Worms and Pterobranchs

The hemichordates constitute a phylum of exclusively marine, benthic, bilaterally symmetrical deuterostome invertebrates (Box 25A). They inhabit all sea bottoms of the world, from intertidal environments to abyssal depths. The phylum includes about 140 species,

The section on phylum Hemichordata was revised by Christopher Lowe.

BOX 25A Characteristics of the Phylum Hemichordata

1. Bilaterally symmetrical deuterostomes, body vermiform or saccate and fundamentally trimeric, with prosome, mesosome, and metasome, each with coelomic compartments; solitary or colonial; pterobranchs with mesocoelic extensions into the arms and tentacles
2. With mesocoelic ducts and pores
3. With pharyngotremy (communication from the gut to the exterior is via ciliated pharyngeal gill slits and pores)
4. Well developed, open circulatory system in enteropneusts but simplified in pterobranchs
5. Unique excretory structure, the glomerulus
6. Gonads extracoelic, in metasome
7. Complete gut; deposit or suspension feeders
8. With buccal diverticulum or stomochord as supporting structure for the prosome; stomochord not homologous with the chordate notochord
9. Circular and longitudinal muscles present in body wall of proboscis and collar of enteropneusts; pterobranchs with longitudinal muscles only, as in the trunk of enteropneusts
10. Collagenous skeletal structures in the proboscis and gill bars of enteropneusts derived from basement membrane of adjacent epithelia
11. Short, dorsal, mesosomal, occasionally hollow nerve cord (neurochord), probably homologous with chordate nerve cord
12. Gonochoristic, with external fertilization and indirect development through a unique tornaria larva; some species with direct development; asexual reproduction common
13. Cleavage radial, holoblastic, more or less equal; although blastopore denotes posterior end of body, both mouth and anus forming secondarily, subsequent to closure of the blastopore; mesoderm and body cavities forming by enterocoely
14. Strictly marine and benthic

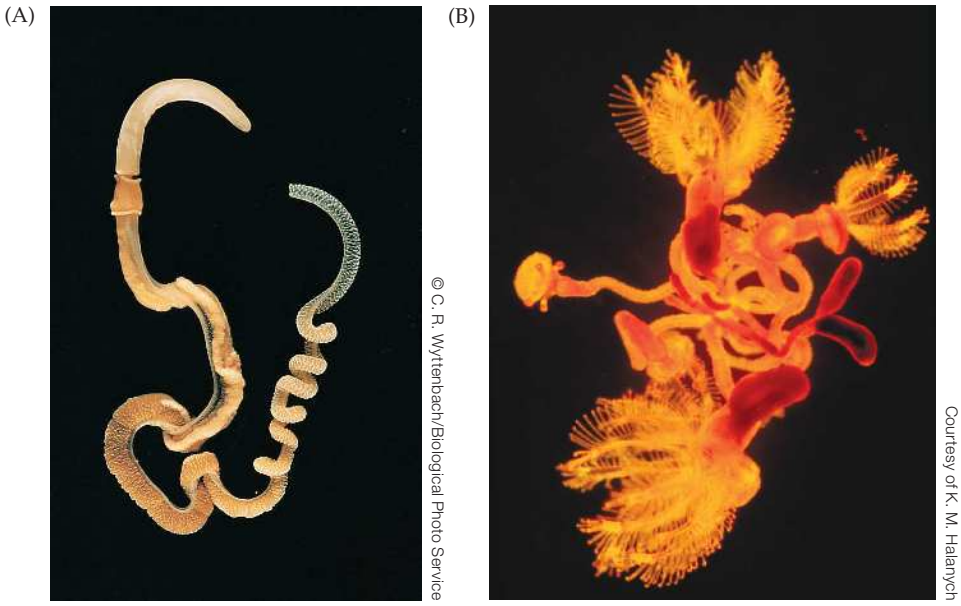

FIGURE 25.2 Representative hemichordates. (A) The acorn worm *Saccoglossus* (class Enteropneusta). (B) Portion of a *Cephalodiscus* colony (class Pterobranchia), showing several individuals at different stages of development.

most (108) of which are benthic burrowers known as acorn worms (or tongue worms) grouped in the class Enteropneusta (Figures 25.2A and 25.3A–D, and chapter opener photo). The remaining species belong to the class Pterobranchia—largely colonial forms of zooids superficially resembling bryozoans (Figures 25.2B and 25.3E–H).

The first known hemichordate, a specimen of *Ptychodera flava* (an enteropneust), was discovered in 1821 and recorded by the Baltic German naturalist Johann Friedrich von Eschscholtz in 1825 as an aberrant holothurian. The German anatomist Johannes Müller discovered in 1850 the first specimen of a tornaria larva, although it was considered to be an echinoderm larva until Metschnikoff recognized it as an enteropneust in 1869. The first pterobranch specimens described were individuals of *Rhabdopleura* dredged by G. O. Sars in 1866, although they were misidentified as bryozoans. Sidney Frederic Harmer later proposed their relationship with *Cephalodiscus* specimens recovered by the *Challenger* expedition and the relation of both with enteropneusts. Harmer also adopted the name Hemichordata for the whole group as proposed by William Bateson in 1885. Most relevant contributions to the knowledge of hemichordate biology in late nineteenth and early twentieth centuries are from J. W. Spengel, C. Dawydoff, and C. van der Horst. Nowadays hemichordates continue to provide exciting discoveries, such as the genus *Saxipendium* from hydrothermal vents, and the bizarre deep-sea enteropneust family Torquaratoridae (Figure 25.3D). Recently, a minute acorn worm, *Meioglossus psammophilus,* has been reported from Belize and Bermuda, living permanently in coral sand as part of meiofauna communities. Developmental biology of hemichordates has played an increasing role in revealing basic organizational principles of the body plan.

Enteropneust worms generally live buried in soft sediments, among algal holdfasts, or under rocks; they have been considered largely intertidal, but recent discoveries point to a substantial and undocumented enteropneust diversity occurring in the deep sea. Of the few deep-water acorn worms known, one species, *Saxipendium coronatum* (the "spaghetti worm"), is a member of hydrothermal vent communities; some other deep-water forms construct highly branched burrow systems, and recent videotaping records confirm that some deep-sea enteropneusts are epibenthic (Figure 25.3D) and use the water column to move between feeding sites. As we have seen in so many other benthic, sessile, and sedentary invertebrates, the hemichordates include a planktonic dispersal phase in their life history strategies. The life cycle of acorn worms includes a free-swimming tornaria larva, although direct development occurs in some species. Tornaria can spend many months in the plankton, whereas direct developers have an abbreviated developmental time course to adult, with a limited planktonic period of hours to days.

Pterobranchs are colonial, tube-dwelling hemichordates that feed with ciliated arms and tentacles (Figure 25.3E–H). Many species have been found in Antarctic waters, although some colonies are found in shallow tropical waters attached to the undersides of rocks, bivalve mollusc shells, or coral rubble. Pterobranchs typically live in colonies formed by extensive aggregations of tubes called **coenecia**, with one individual in each tube. Zooids of *Rhabdopleura* are connected via a stalk or stolon of living tissue, while zooids of *Cephalodiscus* are connected to a basal disk. Colonies of pterobranchs

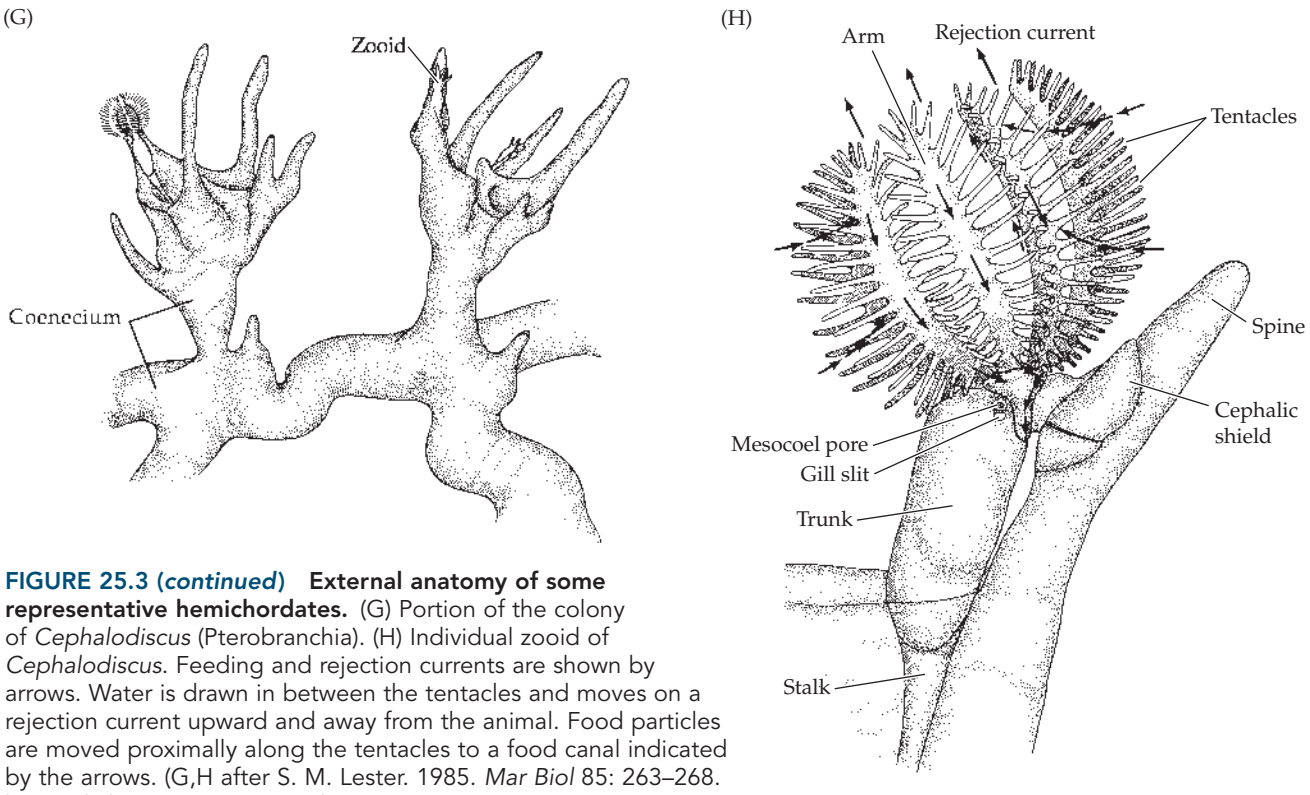

FIGURE 25.3 (*continued*) External anatomy of some representative hemichordates. (G) Portion of the colony of *Cephalodiscus* (Pterobranchia). (H) Individual zooid of *Cephalodiscus*. Feeding and rejection currents are shown by arrows. Water is drawn in between the tentacles and moves on a rejection current upward and away from the animal. Food particles are moved proximally along the tentacles to a food canal indicated by the arrows. (G,H after S. M. Lester. 1985. *Mar Biol* 85: 263–268. https://link.springer.com/article/10.1007/BF00393246)

grow through asexual reproduction by budding. Sexual reproduction involves a swimming, ciliated larva that settles to form a new colony. This pattern is common among small sessile animals, which cannot afford to produce huge numbers of eggs but depend on at least a short-lived dispersal phase.

HEMICHORDATE CLASSIFICATION

The classification presented herein follows the traditional division of the phylum into two classes, Enteropneusta and Pterobranchia.

CLASS ENTEROPNEUSTA Acorn, or tongue worms. Vermiform, with 3 body regions as proboscis, collar, and trunk; coeloms reduced by muscle development; gut elongate, straight; mouth ventral at anterior end of collar; long dorsolateral series of gill slits; dorsal, hollow nerve cord in the collar; anus posterior, terminal; marine, burrow in soft sediments or nestle under rocks or in algal holdfasts; largely intertidal although deep-water species are increasingly being discovered. About 121 described species in 4 families: Harrimaniidae (*Harrimania, Protoglossus, Horstia, Meioglossus, Mesoglossus, Ritteria, Saccoglossus, Saxipendium, Stereobalanus, Xenopleura*); Spengelidae (*Glandiceps, Schizocardium, Spengelia, Willeyia*); Ptychoderidae (*Balanoglossus, Glossobalanus, Ptychodera*); and Torquaratoridae (*Allapasus, Coleodesmium, Tergivellum, Torquarator, Yoda*). The former class Planctosphaeroidea was erected to include *Planctosphaera pelagica*, discovered in 1932, and viewed by most contemporary authorities as the larva of a yet unknown enteropneust.

CLASS PTEROBRANCHIA Pterobranchs. Body sacciform; with 3 body regions as preoral disc (= cephalic shield), tentaculate mesosome, and metasome subdivided as trunk and stalk; neurochord lacking; pharynx with 1 pair of gill slits or none; gut U-shaped; marine; generally small (less than 1 cm), aggregating, or colonial. About 22 species, in 2 families: Rhabdopleuridae (*Rhabdopleura*) and Cephalodiscidae (*Cephalodiscus* and *Atubaria*). The genus *Atubaria* is represented by a single species (*A. heterolopha*), known only from 43 specimens collected in 1935 in Japan. These animals are nearly identical to *Cephalodiscus* but were found as solitary forms, without secreted casings, hence their name. However, they have never been found again, and individuals of *Cephalodiscus* are known to abandon their casing when stressed, making *Atubaria* doubtful as a valid genus and thus currently considered a nomen dubium.

The Hemichordate Body Plan

The two classes of Hemichordata have very different appearances and ways of life: enteropneusts are burrowing, vermiform, solitary animals, whereas pterobranchs are sessile, tube dwelling, and colonial—although both share a common trimeric body plan, attesting to the evolutionary plasticity of their basic deuterostome

for more ebook/ testbank/ solution manual request: email 9601267344@qq.com

architecture. The hemichordate body is divided into prosome, mesosome, and metasome. The prosome—the enteropneust proboscis and the pterobranch preoral disc or cephalic shield—is joined by a slender peduncle to the mesosome or collar. In pterobranchs, the latter bears two to several arms on which tentacles are located. The metasome or trunk is elongated in enteropneusts and globular to pyriform in pterobranchs, differentiated in the former by the specializations of the gut into branchiogenital, hepatic, and posterior regions, and extended posteriorly in the latter to form a tail or stolon where new individuals form by budding. Diagnostic characters of the phylum also include the presence of a dorsal buccal diverticulum called the **stomochord**; paired gill slits that connect the pharynx to the exterior; a proboscis excretory complex formed by heart vesicle, heart sinus, glomerulus, and proboscis pore; and a dorsal nerve cord in the mesosome. Enteropneusts and pterobranchs look so different and have such different ways of making a living that they are occasionally treated as separated phyla, and we discuss them separately here.

Class Enteropneusta (Acorn Worms)

External Anatomy

Enteropneusts are solitary, elongate, vermiform animals, ranging in length from less than 1 mm to over 2 m. Their bodies are clearly divided into three regions, named **proboscis**, **collar**, and **trunk** (Figure 25.3), homologous with the prosome, mesosome, and metasome of other deuterostomes. The proboscis is short and pyriform to conical. A short, thin proboscis stalk connects the proboscis dorsally to the collar, the latter bearing the ventral mouth at its anterior end. The anus terminates at the posterior end of the long trunk. The trunk bears middorsal and midventral longitudinal ridges that correspond to the locations of certain longitudinal nerves and blood vessels. In addition, the trunk is variably differentiated into regions along its length, mostly by specializations of the gut (Figure 25.3A,B). Most species bear a clear, anterior, branchiogenital region characterized by the presence of two dorsolateral series of gill (= branchial) pores. Gonads also occur along this region, and in species from at least one family (Ptychoderidae) the gonads develop within external longitudinal genital wings (Figure 25.3B). The anterior portion of the intestine shows a dorsolateral series of outpocketings that protrude visibly to the exterior, generally exhibiting a dark greenish color and referred to as the hepatic region. In a number of genera, no clear body subdivisions occur, except for the branchial region.

The epidermis of enteropneusts is formed by tall multiciliated cells, with a basiepithelial nerve plexus. It is usually richly supplied with gland cells, many of which are involved in production of mucus—a very characteristic and abundant secretory product with a distinctive iodine-like odor. Mucus secretion is particularly abundant on the proboscis and collar, where it is involved in trapping food particles for feeding. In some enteropneusts, certain epithelial cells produce noxious mucopolysaccharide compounds that may repel predators.

The epidermis, together with its associated nerve plexus, rests on a well-developed extracellular matrix formed by collagen fibers embedded in a ground substance. The extracellular matrix of the epidermis faces the extracellular matrix of the underlying mesothelium that lines the coelomic cavities. Both extracellular matrices fuse extensively except in places where blood lacunae occur, occupying spaces from blastocoelic origin.

Support Structures

The extracellular matrix is hypertrophied at some locations, forming skeletal supporting structures, namely the **proboscis skeleton** and the **gill bar supporting rods**. The proboscis skeleton is a single piece of cartilage shaped like an inverted *Y*, ventrally juxtaposed to the buccal diverticulum and with the two "horns" or **furcae** directed backward and ventrally to the collar (Figure 25.4A,B). The gill apparatus—bars and slits—are supported by two dorsolateral sets of skeletal, collagenous pieces, each shaped like an elongated trident or *m*. The central rod of the *m* lies inside primary gill bars, while secondary, or "tongue" bars bear two rods from adjacent pieces (Figure 25.4D,E).

In adult acorn worms, the buccal diverticulum, or stomochord, is a hollow and blind stiff rod formed by a highly vacuolated epithelium. It has a structural, supportive function working to antagonize the contractile pericardium, which pumps blood through the heart and into the glomerulus (Figure 25.4A). Nevertheless, body support is primarily a function of the hydrostatic nature of the body cavities, supplemented by the structural integrity of the body wall, connective tissues, and skeletal structures already described.

Coelomic Cavities

The arrangement of coelomic spaces follows the deuterostome trimeric body plan as a single protocoel in the proboscis and paired mesocoels and metacoels in the collar and trunk. The protocoel is open to the exterior through a single, left pore at the proboscis stalk in most enteropneusts; the mesocoel connects to the first, anterior-most branchial sac through two ciliated ducts, and the metacoel is blind. The metacoel sends two pairs of coelomic extensions with strong musculature into the collar, the so-called **perihemal** and **peribuccal coeloms**, to reinforce support and movement. Contraction of the longitudinal muscle fibers lining these cavities helps to retract the proboscis into the collar, thereby closing the mouth, like inserting a cork in a bottle, and may also help to pump blood into the heart.

Musculature and Locomotion

The musculature of enteropneusts derives from mesothelial linings of coelomic spaces. The arrangement of myofibrils is mostly of the smooth type. Both circular and longitudinal muscles are present in the wall of the proboscis and anterior collar of acorn worms, accounting for peristaltic movements in crawling or burrowing, but elsewhere only longitudinal fibers predominate (Figure 25.4C). Although most enteropneusts are probably strictly benthic and largely sedentary, at least one species (*Glandiceps hacksi*) sometimes swarms at the surface in shallow water, where it feeds on phytoplankton. Recent videotaping of torquaratorid enteropneusts from the deep sea show the animals detaching from the seafloor and entering the water column, presumably to be transported by currents to a new location.

Feeding and Digestion

The digestive tract of enteropneusts is a straight, regionally specialized tube extending from the mouth to the anus. Gut musculature is scant, and the food is moved along largely by cilia. The mouth leads to a buccal cavity inside the collar and can be closed by retraction of the proboscis against the latter. A buccal diverticulum or stomochord projects forward from its roof into the proboscis stalk. The pharynx follows the buccal cavity in the anterior part of the trunk. The pharynx bears two dorsolateral series of gill slits separated by a low, middorsal epibranchial ridge. Two lateral parabranchial ridges divide the pharynx of ptychoderids into a dorsal branchial chamber and a ventral, digestive chamber (Figure 25.4D). The gill slits number from 1 pair (e.g., *Meioglossus*) to over 100 pairs. Each is a U-shaped opening in the wall of the pharynx that leads to a branchial sac and then to a dorsolateral gill pore through which water exits to the outside (Figure 25.4A,D). A septum between adjacent gill slits is a **primary gill bar**, and the partition between the arms of the U of each slit is a **secondary gill bar** or tongue bar. Primary bars are solid, whereas tongue bars contain an extension of the trunk coelom (Figure 25.4E). Both primary and secondary bars are supported by skeletal elements derived from the basement membrane of the gut lining and are supplied with a complex arrangement of blood vessels and sinuses. Short bridges called **synapticles** join the pharyngeal edges of primary and secondary gill bars in the family Ptychoderidae, undoubtedly contributing to the structural stability of the entire gills (Figure 25.4E).

Behind the pharynx is an esophagus, which at least in some (e.g., *Saccoglossus*) bears openings to the outside through the dorsal body wall, probably to eliminate excess water. In most species the wall of the anterior intestine folds deeply, forming two series of dorsolateral outpocketings that protrude visibly to the exterior in *Schizocardium* and the family Ptychoderidae (Figures 25.3B and 25.4A); the gut epithelium is full of dense green or brown inclusions that give a characteristic aspect to this hepatic region of the trunk. The intestine extends, more or less undifferentiated, to a short rectum terminating in the anus. The anus is dorsal in juveniles of harrimaniids, leaving behind it a postanal region.

Enteropneusts are generally assumed to be deposit feeders, in some cases sedimentivorous (ingesting the substratum [*Balanoglossus*]) or detritivorous (trapping food particles from the sediment surface [*Saccoglossus*]). Others tend to be suspension or filter feeders that create ciliary currents to drive water with suspended particles into the gut. In fact, both classical and recent studies show that most species are probably capable of feeding by both methods—deposit and filtering—even simultaneously. Food material, including detritus and live organisms, is trapped in mucus secreted over the surface of the proboscis and moved posteriorly by ciliary currents (Figure 25.5). The sorting occurs at the proximal end of the proboscis, and the stalk passes most large particles over the lip of the collar; these particles are then removed by special rejection currents. Most of the food is moved ventrally around the proboscis stalk, over a horseshoe-shaped structure called the **preoral ciliary organ**, and condensed into a mucous cord that is then passed into the inhalant flow of the mouth. The preoral ciliary organ

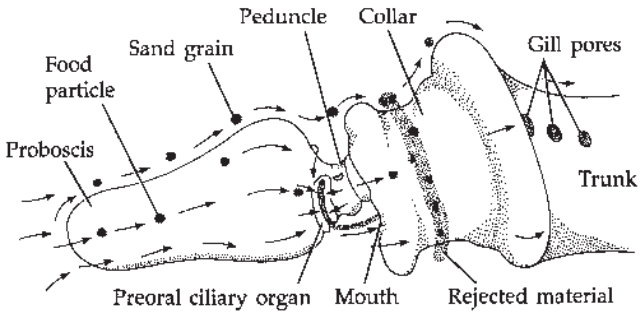

FIGURE 25.5 Food sorting and rejection currents (arrows) on the proboscis and collar region of the enteropneust *Protoglossus koehleri*.

includes a concentration of sensory neurons and probably also functions in chemoreception. The inhalant water current is powered by the long lateral cilia of the gill bars, leaving the body through the branchial sacs and gill pores. Particles of adequate size are retained by pharyngeal mucus and transported ventrally to form a mucus-food cord that is directed posteriorly. The esophagus squeezes excess water from the food. Digestion and absorption of nutrients take place at the hepatic sacculations, first extracellularly in the most anterior diverticuli and then intracellularly in the posterior ones, whose cells store wastes and also transport nutrients to the subjacent blood sinuses. Sedimentivorous species leave characteristic sediment casts outside their U-shaped burrows (Figure 25.3C,D).

Circulatory System

Enteropneusts possess a well-developed, partly open circulatory system of blood vessels and sinuses. The blood is pumped both by contractile cells in the walls of blood spaces by the muscular action of the perihemal coeloms in the collar, and by a contractile heart vesicle located in the proboscis (Figure 25.4A). Two main longitudinal vessels lie in the dorsal and ventral mesenteries along the length of the trunk and in the collar (Figure 25.4A,D). Blood flows anteriorly in the **dorsal vessel** and posteriorly in the **ventral vessel**. The dorsal vessel expands in the collar as the venous sinus, which also receives blood anteriorly from a pair of lateral proboscis veins. The venous sinus leads to a larger, elongate, central sinus or heart in the proboscis, lying between the buccal diverticulum and the dorsal **heart vesicle**. The heart vesicle is a closed cavity of ectodermal origin with myoepithelial walls, whose contraction presses the central sinus against the stomochord below. This sends the blood to the excretory glomerulus in the protocoel with an increased pressure to facilitate ultrafiltration of metabolic waste. The glomerulus, buccal diverticulum, heart, and heart vesicle comprise what is often referred to as the **proboscis complex** of enteropneusts (Figure 25.4A). Blood leaves the glomerulus through two peribuccal vessels that join midventrally to form the ventral longitudinal vessel. Along the trunk, blood passes from the ventral vessel into networks of sinuses supplying both the gut and the body wall. In the pharynx, gut ventral sinuses drain into two lateral parabranchial vessels that send vessels dorsally into primary gill bars. After branching ventrally into secondary bars, these send a vessel dorsally to reach the median trunk dorsal vessel. Enteropneust blood is colorless or pale pink. The pinkish pigment particles are carried in solution and correspond in size to hemoglobin, although that pigment has yet to be confirmed in hemichordates. The blood also contains few amebocyte-like cells.

Excretory System

The main excretory organ in enteropneusts is the **glomerulus**, a structure unique to the hemichordates. It is formed of fingerlike outpocketings of protocoelic mesothelium associated with blood sinuses. Mesothelial cells are differentiated as podocytes, a cell type specialized for ultrafiltration. Pressed by the contraction of the pericardium or heart vesicle, the blood leaving the heart or central sinus is forced to pass through the glomerular sinuses, where metabolic wastes are filtered through the podocyte lining to the protocoel cavity. The primary urine is then presumably evacuated through the protocoel pore, located on the proboscis stalk in most species. Podocyte cells also line the walls of branchial sacs, suggesting a supplemental excretory role for the pharynx.

Gas Exchange

Gill bars have long been thought of as the place of gas exchange, a hypothesis undoubtedly biased by our understanding of chordate gills. However, the epithelial structure of gill bars makes the hypothesis unlikely. Little work has been done on the matter of gas exchange, and it may be that other structures, such as the branchial sacs or the body surface, are also involved in this activity.

Nervous System

Most of the nervous system of hemichordates consists of a netlike, intraepithelial/basiepidermal nerve plexus lying among the bases of the epithelial cells, both of ectodermal (epidermis) and endodermal (gut) origin. In enteropneusts this plexus is thickened, forming longitudinal tracts of neurons along the middorsal and midventral lines of the trunk (hence both dorsal and ventral, intraepithelial/basiepidermal longitudinal nerve cords are present) and at the base of the proboscis. Additionally, a subepidermal (not intraepidermal) dorsal cord, or **collar neurochord**, is present in the mesosome, and its cellular organization and ontogenetic neurulation process have led to comparisons with the chordate neural tube.

Acorn worms possess sensory cells over most of the body, probably serving as touch receptors, chemoreceptors, and photoreceptors that give these cryptic animals some information about their surroundings. As mentioned earlier, they also bear a preoral ciliary organ with a presumptive chemoreception function for feeding.

Reproduction and Development

Asexual reproduction Asexual reproduction in enteropneusts is directly related to their well-known ability to regenerate tissues and body parts that are lost or damaged. They are very fragile worms and easily

for more ebook/ testbank/ solution manuals request: email 9601267340@qq.com

break when handled. Acorn worms have been described to undergo multiple transverse fissions of the body (**architomy**), leading to several regenerating individuals. Recently, **paratomy** has been described in the interstitial species *Meioglossus psammophilus*, in which new individuals develop aligned to the body axis through tissue regeneration and subsequent transverse fission, a process well known in Annelida and Acoela.

Sexual reproduction Acorn worms are gonochoristic but possess no outward evidence of sexual differences. Numerous sacciform gonads lie in the trunk, outside the mesothelium (retroperitoneal), from the branchial region to the hepatic one; they are often very elongate, and in the family Ptychoderidae they occupy two dorsolateral, flaplike extensions of the body called **genital wings** (Figure 25.3B). Each gonadal sac opens to the exterior through a duct and gonopore located dorsolaterally on the anterior trunk.

Fertilization is always external. Spawning in enteropneusts involves the release of mucoid egg masses by the females, followed by shedding of sperm by neighboring males. Once the eggs are fertilized, the mucous coat breaks down, thereby freeing the eggs into the seawater, where all subsequent development occurs. In some direct developers, eggs are shed into the burrow of the female, lining the walls, and all development occurs within the burrow and contained in the vitelline envelope, with hatching releasing competent juvenile worms.

Development Cleavage is holoblastic, radial, and more or less equal, attesting to the deuterostome nature of acorn worms. A coeloblastula forms, which gastrulates by invagination. The blastopore is at the presumptive posterior end, but it closes and the anus and mouth form later. In indirect-developing species, at late gastrula the embryo has acquired cilia and hatches from the vitelline membrane. Coelomic cavities (the single protocoel plus paired meso- and metacoels) derive from the archenteric endoderm as independent pouching through enterocoely. In direct-developing species the coeloms all form during embryogenesis, whereas in indirect developers only the protocoel forms during embryogenesis, and the mesocoels and metacoels form late in larval development before the onset of metamorphosis. Other morphogenetic modes, including schizocoely, have been doubtfully reported in some species.

Some species (Harrimaniidae, e.g., *Saccoglossus*) have direct development from yolky eggs to juvenile worms, without an intervening larval phase (Figure 25.6A–F).

(M) Juvenile, 3 days after settlement. The telotroch has disappeared, and the first two U-shaped gill slits have formed.

Juvenile worms show a postanal tail that is likely to be homologous not with the chordate postanal tail despite some molecular patterning similarities, but most probably with the pterobranch stalk. In species that shed nonyolky eggs (Ptychoderidae, e.g., *Balanoglossus*), the hatching stage develops quickly to a characteristic, planktotrophic, **tornaria larva** with complex ciliary bands reminiscent of the dipleurula larva of echinoderms (Figure 25.6G–I). This free-swimming tornaria can spend weeks to months in the plankton feeding and growing. By the end of larval development, rudimentary gill pouches in the anterior larval pharynx have formed along with the two posterior coeloms. A radical metamorphosis begins with expansion of the protocoel and migration of the anterior gut posteriorly. Molecular patterning data demonstrate that the larval body plan represents essentially a "swimming head," with no trunk territory. During metamorphosis the posterior of the larva expands to create the trunk of the adult body plan. The elongating larva soon sinks to the benthos and differentiates the three typical body regions and organs (Figure 25.6J–L). Gill slits develop asymmetrically—left side first, from anterior to posterior—as outpocketings of the gut that eventually open to the exterior via dorsolateral gill pores (Figure 25.6M).

Class Pterobranchia (Pterobranchs)

The bodies of pterobranchs are small, usually pyriform or globular, but still retaining the ancestral tripartite regional division. The prosome in these odd creatures, called the **preoral disc** or **cephalic shield**, is a creeping

for more ebook/ testbank/ solution manuals request Deuterostomia: Hemichordata email 2601267344@qq.com

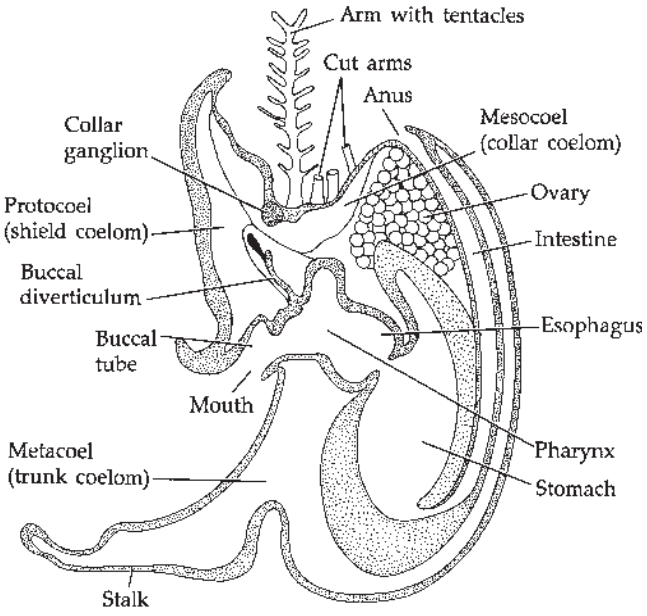

FIGURE 25.7 **Internal anatomy of the pterobranch *Cephalodiscus* (sagittal section).**

sole that folds ventrally over the mouth. The mesosome forms a collar that bears the anteroventral mouth and extends dorsally as one pair to nine pairs of tentaculated arms. The gut is U-shaped, and the anus opens anterodorsally (Figures 25.3G,H and 25.7). The metasome is subdivided into a trunk and posterior stalk.

Pterobranchs live in colonies (*Rhabdopleura*) or aggregations (*Cephalodiscus*) consisting of zooids housed within tubular secreted casings called **coenecia** (Figure 25.3E,G). In colonies of *Rhabdopleura*, the zooids are connected to one another by tissue extensions called **stolons** (Figure 25.3E), but no such interzooidal links occur in *Cephalodiscus*. The overall forms of the aggregations and colonies vary among species. In all cases, the associated zooids are products of asexual reproduction initiated by a single sexually produced individual.

Body Wall and Cavities

The pterobranch epidermis is very simple, composed of squamous cells. Only at the cephalic shield does the epidermis become high and glandular, with several types of secretory cells that produce materials for the coenecium and mucus for gliding. Coelomic spaces follow the trimeric body pattern, with a single protocoel in the cephalic shield, and paired meso- and metacoels in the collar and trunk. The protocoel opens to the exterior via two coelomic ducts and pores at the bases of the arms. The mesocoel penetrates into the arms and tentacles, and in *Cephalodiscus* it sends two collar canals posteriorly that open to the exterior, close to the single gill pore. The metacoel has no openings. No gills or pores have been identified in *Rhabdopleura*.

Support, Muscles, and Movement

The small size of pterobranchs correlates with a dramatic reduction of supporting structures. The proboscis skeleton is lacking, and the single gill opening of *Cephalodiscus* has no supporting rods. Moreover, the pterobranch stomochord is nearly solid and lacks vacuolated cells. Most body support and protection are provided by the secreted outer casing of the colony or aggregation. Pterobranchs possess only longitudinal muscles, in the ventral side of the trunk and stalk and in the cephalic shield, where they are well developed for crawling within their tubes. The protraction and retraction of individuals within their tubular houses are accomplished by hydrostatic pressure and contraction of longitudinal muscles, respectively.

Gut and Feeding

The mouth is located under the anteroventral edge of the collar. The gut is U-shaped, beginning with a buccal tube from which a buccal diverticulum arises dorsally. The pharynx bears one pair of gill slits in *Cephalodiscus*, but none in *Rhabdopleura*. When present, the gill apparatus is much simpler than that of enteropneusts, with no secondary bars nor supporting structures and less defined branchial sacs. The slits open through pores on the exterior. A short esophagus connects the pharynx to a sacciform stomach that occupies most of the space within the trunk (Figure 25.7). The ascending portion of the gut is the intestine, which leads anteriorly to the dorsal anus.

Feeding in pterobranchs is accomplished by the mesosomal arms; two pairs of arms in *Rhabdopleura*, one to five pairs in *Cephalodiscus* (depending on the species) (Figure 25.3F,H). Each arm bears two rows of ciliated tentacles. Pterobranchs are ciliary mucus suspension feeders. During feeding, they assume a position near an opening in the tubular case and extend their arms into the water; *Rhabdopleura* simply spreads its two featherlike arms out into the water current, whereas *Cephalodiscus* forms a so-called "feeding sphere" with its eight to ten arms and interdigitating tentacles (Figure 25.3F,H). Suspended particles and diatoms are trapped in the tentacular mucus and moved to the mouth by the action of cilia on the tentacles and arms. The single pair of gill slits of *Cephalodiscus* eliminates the excess water entering the mouth. Digestion occurs in the stomach and intestine, well supplied by blood sinuses.

Circulation and Gas Exchange

The circulatory system of pterobranchs is a reduced and simplified version of that of enteropneusts. There is a heart or central sinus and a heart vesicle associated with the buccal diverticulum and a glomerular vessel, which

have the same functions as the proboscis complex in enteropneusts. Dorsal and ventral vessels are present in the trunk, continuing into the stalk. Otherwise, the circulatory system is reduced to a net of basiepithelial lacunae.

It is quite improbable that the single pair of gill slits in *Cephalodiscus* actually aids in gas exchange; instead, the small diffusion distances throughout the body probably allow general cutaneous exchange, especially over the high surface areas of the tentacles exposed to water currents.

Nervous System

Little is known about the nervous system of pterobranchs. A neuronal concentration in the mesosome named the **collar ganglion** is the putative homologue of the collar neurochord of enteropneusts, giving off branches to the cephalic shield, gill openings, and tentacular system. Otherwise there is a simple intraepithelial/basiepidermal nerve net all along the body. Eyes are present in tornaria larvae. Touch receptors are presumably present in the tentacles.

Reproduction and Development

As in most colonial invertebrates, asexual reproduction by budding is an integral part of the life history of aggregating and colonial pterobranchs. In *Cephalodiscus*, the buds arise from near the base of stalks of adult individuals and may eventually detach from one another when mature, living as an aggregation of individuals (Figure 25.8). Budding in *Rhabdopleura* occurs along the stolons that grow from the tips of the stalks of adult zooids. However, in this genus, buds never detach from the mother zooids, thereby forming colonies. In both genera, the aggregations or colonies arise by budding after the formation of a single sexually produced individual.

Sexes are usually separate, although hermaphroditism has been reported in *Cephalodiscus*. Gonads are single in *Rhabdopleura* and paired in *Cephalodiscus.* In *Rhabdopleura* a single pore opens on the right side of the trunk; the gonopores of *Cephalodiscus* are at the base of the arms. The eggs are shed into the tubes of the colony or aggregation, where they are fertilized. Developing embryos are brooded within the coenecium. Among the pterobranchs, only *Rhabdopleura* has been studied embryologically, and even here the details are scanty. The large yolky eggs undergo radial, holoblastic, subequal cleavage. There is some argument about the precise nature of gastrulation. Coelom formation is classically reported to occur by archenteric pouching, but the sequence of production is not clear. However, more recent work on pterobranchs has raised the possibility that the meso- and metacoel may arise via schizocoely. The embryos escape the brooding area within the parental tube in a fully ciliated (but unnamed) planula-like larval stage. The swimming larvae settle within 24 hours after being released from the parental tube, although cultured larvae have remained swimming and unmetamorphosed for several months. The settled larva surrounds itself with a translucent, sealed cocoon within which it undergoes metamorphosis. First the oral shield is developed, followed by budding of the arms, posterior stalk, and tentacles. The formation of the gut, the last structure to become functional, begins with invagination of ectoderm to form the pharynx. The larva does not feed during metamorphosis. The metamorphosed juvenile builds a tube at an opening in the cocoon and begins to feed and secrete the coenecium for a new colony.

Hemichordate Fossil Record and Phylogeny

The hemichordate fossil record is almost entirely dominated by pterobranchs (notably the graptolites) whose tube skeletons have been well preserved. In fact, a recent study considers *Rhabdopleura* as just an extant graptolite, these being the sister taxon of cephalodiscids. Owing to their low preservational potential, fossil enteropneusts are exceedingly rare, although some fossil genera have been described (*Mazoglossus, Megaderaion, Mesobalanoglossus*), as well as several other genera from putative trace fossils. Recently several fossil taxa have provided important insights into early hemichordate evolution. The fossil enteropneusts

for more ebook/ testbank/ solution manuals request: email 9601267344@qq.com

Spartobranchus tenuis and *Oesia disjuncta* have been described from the middle Cambrian Burgess Shale, surprisingly associated with tubular casings. This finding complements the very recent discovery of deep-sea torquaratorid enteropneusts that build mucous tubes. Even more novel is a very recent finding of *Gyaltsenglossus senis*, another middle Cambrian fossil with characteristic soft-bodied features that define both pterobranchs and enteropneusts: notably, a proboscis and feeding tentacles emanating from the mesosome.

Two very different views have existed for the relationship between enteropneusts and pterobranchs. The classical one, based on morphology and paleontology, considered these taxa sister groups, usually ranked as classes. However, early 18S rRNA analyses suggested that pterobranchs might be an ingroup of the enteropneusts, which would make Enteropneusta paraphyletic and Pterobranchia a sister taxon to the family Harrimaniidae. But subsequent phylogenomic analyses have supported the classical view of the sister-group status of the two classes.

Since their discovery, hemichordates have played a pivotal and controversial role in the attempt to understand relationships among the three major deuterostome phyla (echinoderms, hemichordates, and chordates), as well as attempts to learn the nature of the deuterostome ancestor and to determine the evolutionary origin of chordates. Bateson coined the phylum name Hemichordata after recognizing similarities with chordate embryogeny, and for many years the hemichordates were actually ranked as a subphylum of Chordata. Hemichordate traits such as the presence of stomochord, collar neurochord, and gill slits also reinforced their phylogenetic proximity to chordates. However, current thinking is that the only morphological homology robustly supported by both anatomical and molecular data is the presence of gill slits. Hemichordate pharyngeal gill slits are used for filter feeding in the same way gill slits are used by cephalochordates, and they express the same early patterning genes as all chordates. In addition, a genomic analysis from Simakov and colleagues in 2015 showed that hemichordates and chordates even share the same chromosomal clustering of key pharyngeal patterning genes. These genes have also now been described even in echinoderms, supporting the view that gill slits arose in the stem lineage that gave rise to the Deuterostomia.

On the other hand, a close relationship with echinoderms has also been proposed through characters such as the excretory heart-kidney system and the tornaria-dipleurula larvae. Currently, a sister-group relationship between hemichordates and echinoderms (a clade called Ambulacraria) is generally favored and fairly consistently supported by molecular phylogenetic analyses.

The search for a deuterostome ancestor classically invoked an organism reminiscent of a solitary pterobranch zooid, influenced by the assumed position of pterobranchs as basal hemichordates. However, modern analyses, both morphological and molecular, and in good agreement with fossil findings, suggest that the deuterostome ancestor was a solitary enteropneust-like worm. Considerations of larval forms also agree with this hypothesis. The tornaria-dipleurula larva is shared by echinoderms and the enteropneust ptychoderids. In contrast, harrimaniids and pterobranchs have a very short-lived, nonfeeding larva and are usually considered to be direct developers. Recent findings of miniaturization (*Meioglossus*) and tube dwelling (*Spartobranchus* and Torquaratoridae) in enteropneusts illustrate the evolutionary plasticity of the enteropneust body plan.

Chapter Summary

This chapter introduced you to the bilaterian clade Deuterostomia, which contains just three phyla: Hemichordata, Echinodermata, and Chordata. This clade is defined primarily by molecular phylogenetic evidence, although enterocoelic development leading to a trimeric condition of the coelomic cavities is unique to the deuterostomes and might be a synapomorphy (though it is lacking in Chordata). The small phylum Hemichordata (about 130 described species) is exclusively marine and occurs worldwide at all depths. It contains two classes, Enteropneusta (acorn, or tongue, worms) and Pterobranchia (pterobranchs). Most enteropneusts have radial cleavage and free-swimming, planktonic tornaria larvae; adults are solitary vermiform animals, ranging in length from less than a millimeter to over 2 m. Pterobranchs are colonial, tube-dwelling creatures that also typically have swimming larvae. Adults in both groups have gill slits or gill pores, have an adult body of three regions, and rely on ciliary-mucus feeding, either from the sediment or by capturing particles out of seawater. Although modern phylogenetic analyses strongly suggest the two classes are sister groups, they are so different in appearance that some workers have, in the past, treated them as separate phyla. Owing to their low preservational potential, fossil hemichordates are rare and best represented by the fossilized tubes of certain pterobranchs (notably the graptolites). A sister-group relationship between hemichordates and echinoderms (a clade called Ambulacraria) is generally favored and fairly consistently supported by molecular phylogenetic analyses. Future work on Hemichordata will likely focus on phylogenomics, ecology, and developmental biology.

CHAPTER 26

Phylum Echinodermata

Starfish, Sea Urchins, Sea Cucumbers, and their Kin

Chapters 8 and 25 introduced the clade Deuterostomia, one of the three great lineages of Bilateria (the others being Protostomia and Xenacoelomorpha). Within the deuterostome clade, molecular, morphological, and paleontological studies now indicate that hemichordates and echinoderms comprise a sister group, a clade called Ambulacraria, and this is the sister group to Chordata. This chapter treats the echinoderms.

Members of the phylum Echinodermata (Greek *echinos*, "spiny"; *derma*, "skin") are familiar to many as iconic sea animals, in part because they are strictly marine and commonly seen along seashores. The phylum contains about 7,300 known living species and includes the sea lilies, feather stars, starfish (or sea stars), brittle stars, sea urchins, sand dollars, heart urchins, and sea cucumbers (Figures 26.1 and 26.2). Another 13,000 to 15,000 or so species are known from a rich fossil record dating back at least to early Cambrian times. Both extant and fossil forms display an enormous breadth of morphological disparity that makes the phylum a particularly interesting group in which to explore the origins of evolutionary novelty.

Echinoderms range in size from minute sea urchins, sea cucumbers, and brittle stars less than 1 cm across, to starfish that exceed 1 m from arm tip to arm tip, and sea cucumbers that exceed 3 m in length. Although some species tolerate brackish water, echinoderms have not evolved excretory, respiratory, or osmoregulatory mechanisms that would allow them to exploit terrestrial or freshwater habitats. However, in the ocean they can be found worldwide at all depths. It is said that echinoderms are largely bottom dwellers (benthic), and it is true that in some regions of the deep sea, the only

identifiable organisms in bottom photos are echinoderms. However, the statement that echinoderms are mostly benthic is true only for the adults (with the exception of a few pelagic and benthopelagic species, see Figure 26.1P,Q), because larval echinoderms are important members of pelagic communities. As larvae, they play important roles in the ecology of planktonic communities, and as adults they perform key roles in benthic marine ecosystems through their deposit and suspension feeding (notably sea cucumbers, sea lilies, and brittle stars), predation (especially certain starfish), herbivorous grazing (many sea urchins), wood eating

(some starfish and sea urchins), and sediment processing and turnover (many sea cucumbers and heart urchins).

Echinoderms are among the most unusual metazoans on Earth. As a body plan, bilateral symmetry is more familiar to us, but the secondarily derived pentaradiality of adult echinoderms challenges our thinking about evolutionary pathways. They have body systems unlike those of any other creatures, and they are missing body parts that it seems they should have. Add in the huge and bizarre fossil catalog, and this phylum can be uniquely challenging to understand. They might seem like mutated leftovers from a Precambrian alien's picnic. In fact, a somewhat complex and unique jargon has evolved just to describe the unlikely anatomy of

BOX 26A Characteristics of the Phylum Echinodermata

1. Calcareous, mesodermally derived endoskeleton composed of separate ossicles and plates made of an open meshwork structure called stereom, with the interstices being filled with living tissue (the stroma)
2. Adults with basic pentaradial symmetry; five rays extending outward from the oral region
3. Embryogeny fundamentally deuterostomous, with radial cleavage, endodermally derived mesoderm, enterocoely, and mouth not derived from the blastopore
4. Body divided into axial, perforate extraxial, and imperforate extraxial regions; axial region expressing radial symmetry derived from the rudiment; extraxial elements derived from the bilateral, larval body
5. With a water vascular system derived from the hydrocoel on left side of larva; composed of complex series of fluid-filled canals expressed externally as tube feet in ambulacra; oldest parts of the ray near the mouth, youngest at ray tips
6. Body wall containing mutable collagenous tissue
7. Gut complete, anus sometimes absent
8. No specialized, distinct excretory organs; excretion through specialized coelomocytes
9. Circulatory structures, when present, consisting of a hemal system derived from coelomic cavities and sinuses
10. Nervous system diffuse, decentralized, consisting of subepithelial nerve net, nerve ring, and radial nerves
11. Mostly gonochoristic; development direct or indirect

echinoderms, although we will do our best to keep this to a minimum.

All living echinoderms possess some form of a well-developed coelom, a mesodermally derived endoskeleton composed of unique calcareous elements, and five-part radial symmetry (**pentaradiality**). The endoskeleton consists of ossicles and plates formed by microscopic, secreted crystals of calcium carbonate that all orient along the same crystallographic axis. These microcrystals are associated with small amounts of organic tissue and come together to form a unique, porous skeletal material called **stereom**. The stereom consists of anastomosing struts called **trabeculae** that give it a spongelike appearance under high magnification. The hollow spaces in the stereom are occupied by living tissue (the **stroma**). In life, the ossicles and plates are attached to one another by connective tissues. Even earliest fossil echinoderm skeletons have been shown to have this unique form of mineralization in their endoskeleton.

As adults, echinoderms are the only fundamentally five-part, radially symmetrical animals, though this symmetry is modified in some lineages. Because echinoderms are deuterostome bilaterians, their embryology is frequently studied as exemplary of deuterostomy. However, these basic embryological patterns are true only of early, bilaterally symmetrical stages of echinoderm development. The remarkable pentaradial body plan is superimposed on earlier larval bilaterality, and echinoderm adult pentaradiality is evolutionarily and developmentally derived relative to all other animals.

Echinoderm adult pentaradiality is coupled with another unique body feature known as the **water vascular system**, a complex system of tubes and canals derived from a specific part of the coelom. The water vascular system serves a variety of functions, notably in giving rise to **tube feet** (also known as **podia**), which are crucial to nearly every interaction between echinoderms and their environment. These features are described in detail below. Because adult echinoderms are secondarily radially symmetrical, the terms "dorsal" and "ventral" do not have the same anatomical meanings as in other bilaterians, although these terms are still often used for convenience (and refer only to the animal's orientation on the substratum). The mouth is used as a reference point. Features on the mouth side of the adult are said to be on the **oral surface**, whereas those on the side opposite the mouth are **aboral**. For example, in a starfish, the oral region ("bottom" or "ventral") faces the substratum, and the aboral region is therefore at the "top" of the animal ("dorsal").

Taxonomic History and Classification

Echinoderms have been known since ancient times. Early Europeans collected fossil heart urchins and regarded them as divine "thunder stones," burying them with their dead, and likenesses of starfish appear in 4,000-year-old Minoan frescoes. Jacob Klein is credited with coining the name Echinodermata in about 1734 in reference to sea urchins. For nearly a century thereafter, echinoderms were allied with various other groups, including the cnidarians in Lamarck's Radiata. It was not until 1847 that Frey and Leuckart recognized the echinoderms as a distinct taxon. As noted above, recent molecular and embryological evidence place Echinodermata as a sister phylum to the Hemichordata in a clade known as the Ambulacraria. See Box 26A.

The large number of enigmatic echinoderm fossils is a rich source of argument because of varying opinions on the significance of characteristics such as feeding appendages, attachment structures, and even overall symmetry. Some have suggested that certain superficially bilaterally symmetrical fossils can be interpreted as representing the first echinoderms. Others find it more reasonable and congruent with the fossil record to suggest that these oddities exhibit secondary modification of earlier pentaradial morphology. The disparate morphologies of fossil echinoderms have caused some workers to emphasize differences, recognizing upwards of 25 separate classes. Others seek fundamental similarities with overarching homologies and recognize far fewer major clades. Some of the important extinct clades are introduced in the Echinoderm Phylogeny section of this chapter.

CLASSIFICATION OF ECHINODERMATA

SUBPHYLUM CRINOZOA One living class, the Crinoidea, with the mouth (oral surface) facing upward and encircled by branching arms.

CLASS CRINOIDEA Sea lilies and feather stars (Figures 26.1A and 26.2A,B). Arms radiate from central cup (calyx), with mouth directed upward; stem, when present, arising from aboral side of calyx; ambulacra on arms that bear pinnules; arms composed of confluence of axial and extraxial elements; both left and right somatocoels continuing from calyx into arms; ambulacra not calcified, forming soft tissue closure

of the coelomic cavities in arms, with external radial water vessel; each side of ambulacrum with palisade of cover plates; tube feet minute, lacking suckers; ambulacra can branch equally and repeatedly; madreporite, mouth, and anus on oral surface of calyx. About 625 living species.

ORDER COMATULIDA Feather stars and some sea lilies. Stem usually lost following postlarval stage; most proximal stem element in feather stars retained at base of cup to support cirri that act as attachment appendages. (e.g., *Antedon*, *Bourgeticrinus*, *Comatula*, *Mariametra*, *Tropiometra*)

ORDER CYRTOCRINIDA Aberrant, stemless sea lilies. Calyx sometimes elongate to resemble a stem; no cirri; calyx directly attached to bottom, or attached by a disk. (e.g., *Pilocrinus*, *Neogymnocrinus*, *Cyathidium*, *Holopus*)

ORDER HYOCRINIDA Sea lilies with well-developed stem attached to bottom by expanded terminal disk (holdfast); stem lacking cirri and without nodals and internodals, i.e., elements making up stem are identical. (e.g., *Hyocrinus*, *Calamocrinus*, *Ptilocrinus*, *Laubiericrinus*, *Thalassocrinus*)

ORDER ISOCRINIDA Sea lilies with calyx of very thick stereom elements; with well-developed stem composed of internodals (without cirri) and nodals (with cirri). (e.g., *Isocrinus*, *Hypalocrinus*, *Neocrinus*, *Teliocrinus*, *Endoxocrinus*, *Metacrinus*, *Saracrinus*)

SUBPHYLUM ASTEROZOA Contains the stellate forms, Asteroidea and Ophiuroidea, in which the mouth (oral surface) faces the substratum.

CLASS ASTEROIDEA Starfish (Figures 26.1B–G and 26.2C). Body stellate with five or more arms; arms not sharply demarcated from central disk by distinct articulations; arms have coelomic extensions enclosed by both axial and extraxial body wall; anus (when present) on aboral surface; ambulacral grooves with external radial water vessel; tube feet with internal ampullae, with or without suckers; madreporite aboral on CD interambulacrum. About 1,900 extant species.

ORDER PERIPODIDA Circular, lacking arms; tube feet with suckers; anus absent; mouth very large; young retained in brood chambers on oral surface. Deep-sea wood-dwelling starfish. Three species in a single genus, *Xyloplax*. (Formerly regarded as a separate echinoderm class or sometimes treated as an infraclass of Asteroidea.)

ORDER FORCIPULATIDA With 5–50 arms; tube feet with suckers; anus present; with pincerlike pedicellariae. Widely distributed, including most familiar intertidal species; several hundred species. (e.g., *Asterias*, *Pisaster*, *Heliaster*, *Labidiaster*, *Pedicellaster*, *Pycnopodia*, *Stichaster*, *Zoroaster, Stylasterias*)

ORDER BRISINGIDA With 6–20 long, attenuated arms; fused ring of disk plates; crossed, pincer-like pedicellariae. Most are deep-sea suspension feeders. (e.g., *Brisinga*, *Odinia*, *Freyella*, *Astrocles, Novodinia*)

ORDER SPINULOSIDA With 5–18 arms; tube feet with suckers; anus present; generally lacking pedicellariae. With a few hundred species. (e.g., *Echinaster*, *Henricia*, *Acanthaster*, *Mithrodia*)

ORDER NOTOMYOTIDA Usually five long, straight-sided arms; small disk; prominent muscle bands running inside arm coeloms from disk to arm tip. (e.g., *Benthopecten, Cheiraster*)

ORDER PAXILLOSIDA Upper surface with umbrella-like clusters of ossicles (paxillae); tube feet without suckers; anus present or absent. Epibenthic or shallow burrowers. (e.g., *Astropecten*, *Luidia*, *Platasterias*, *Ctenodiscus*)

ORDER VALVATIDA Tube feet with suckers; anus present; some possess paxillae; some possess clamplike pedicellariae recessed into plates. Widely distributed, with several hundred species. (e.g., *Archaster*, *Asterina*, *Patiria*, *Goniaster*, *Fromia*, *Linckia*, *Solaster*, *Ophidiaster*, *Odontaster*, *Oreaster, Valvaster, Culcita, Dermasterias, and Porania*)

ORDER VELATIDA Usually 5–15 arms; body relatively thick; disk large; stereom ossicles sometimes poorly developed, particularly aborally. Primarily cold-water, deep-sea forms. (e.g., *Pteraster*, *Hymenaster*, *Korethraster*, *Myxaster*, *Caymanostella*)

CLASS OPHIUROIDEA Brittle stars and basket stars (Figures 26.1H,I and 26.2D). Body with five unbranched or branched, thin, articulated arms, clearly demarcated from a central disk; oral arm plates cover ambulacral groove; coelom in arms greatly reduced; tube feet without internal ampullae or suckers; anus lacking; madreporite on CD interambulacral plate on oral surface, often reduced. About 2,000 extant species in six orders.

ORDER EURYALIDA Arms often highly branched (branching extensively in basket stars) and capable of coiling vertically (in the oral-aboral plane) as well as horizontally; "dorsal" arm plates absent; central disk often covered with thick dermis. Many use outstretched arms to form basketlike filter for suspension feeding; others live with arms tightly coiled around coral branches. (e.g., *Asteronyx*, *Gorgonocephalus*, *Euryale*, *Asteroschema*)

The following five orders contain similar forms: Unbranched arms capable of horizontal coiling, but only limited vertical movement; aboral and oral arm plates present and usually well developed.

ORDER OPHIURIDA (e.g., *Ophiura, Ophiomusium, Ophiosphalma*)

for more ebook/ testBank/ solution manuals requests: email 960126734@qq.com

ORDER AMPHILEPIDIDA The most speciose group of brittle stars. (e.g., *Amphilepis, Amphiura, Ophiactis, Ophiolepis, Ophiothrix, Ophiophragmus*)

ORDER OPHIACANTHIDA (e.g., *Ophiacantha, Ophiocanops, Ophiopteris, Ophiocoma, Ophioderma*)

ORDER OPHIOLEUCIDA (e.g., *Ophioleuce, Ophiernus, Ophiopallas*)

ORDER OPHIOSCOLECIDA (e.g., *Ophiomyces, Ophiotholia, Ophioscolex, Ophiolycus, Ophiogeron*)

SUBPHYLUM ECHINOZOA The Echinoidea and Holothuroidea. Species in this subphylum lack distinct arms but possess a specialized subdivision of the left somatocoel, which in echinoids develops into a jaw apparatus.

CLASS ECHINOIDEA Sea urchins, pencil urchins, heart urchins, and sand dollars (Figures 26.1J–L and 26.2E–G,J). Body globose to flattened and discoidal, often secondarily bilateral; stereom plates sutured together by connective tissue and calcite interdigitations to form a usually rigid test; pedicellariae of varying types always present; movable spines mounted on tubercles; radial water vessels wholly enclosed within test; internal jaw apparatus (Aristotle's lantern) present in most groups. About 1,000 extant species in two subclasses.

SUBCLASS CIDAROIDEA Pencil urchins. Test high and globular, ambulacral plates not compound, each with a pore pair supporting a single tube foot; primary spines large, pencil-like, without epidermal covering; anus at aboral pole; ambulacral plates continuing onto peristomial membrane. About 150 living species in one order (Cidaroida). (e.g., *Cidaris*, *Histocidaris*, *Stylocidaris*, *Eucidaris*, *Phyllacanthus*, *Psychocidaris*)

SUBCLASS EUECHINOIDEA Sea urchins, heart urchins, lamp urchins, sea biscuits, sand dollars. Test globular to discoidal, with pronounced bilateral symmetry in some forms (the Irregularia); numbers of tube feet and spines per plate vary; anal position varies from aboral to "posterior." Aristotle's lantern absent in heart and lamp urchins. About 850 living species.

INFRACLASS AULODONTA Includes five orders. Echinothurioida are among largest of echinoids, with test up to 30 cm in diameter, flexible, collapsing upon removal from water; plates usually small and thin, joined with large amounts of collagen; anus aboral; subset of spines with poison glands; usually deep-water (1,000–4,000 m); some species with club-shaped spines for walking on ooze (e.g., *Araeosoma*, *Asthenosoma*, *Phormosoma*, *Sperosoma*). Pedinoida are a less well known deep-water group (e.g., *Caenopedina*). Diadematoida have thin poison-tipped spines below a canopy of longer nonpoisonous spines, and a rigid test; shallow or deep-water (e.g., *Diadema*, *Astropyga*, *Echinothrix*). Aspidodiadematoida are deep-water with a small, almost spherical rigid body held up above the sea bottom by extremely long curved spines (e.g., *Aspidodiadema*, *Plesiodiadema*). Micropygoida are similar to diadematoids but with greatly enlarged aboral tube feet ending in umbrella-shaped, sticky expansions (e.g., *Micropyga*).

INFRACLASS ECHINACEA Globose sea urchins with keeled teeth and large spines. Includes the orders Salenioida (e.g., *Salenia*, *Bathysalenia*), Arbacioida (e.g., *Arbacia*, *Coelopleurus*, *Podocidaris*), Stomopneustoida (e.g., *Stomopneustes*), and Camarodonta (e.g., *Echinometra*, *Echinus*, *Heterocentrotus*, *Paracentrotus*, *Strongylocentrotus*, *Toxopneustes*, *Tripneustes, Lytechinus*).

INFRACLASS IRREGULARIA Heart urchins, lamp urchins, sea biscuits, sand dollars. Body globular or discoidal, always with some bilateral symmetry; anus never wholly within apical system and shifted to "posterior" (even oral) position; spines small, forming dense covering; Aristotle's lantern absent or present. Seven extant orders: Echinoneoida, lantern absent in adults (e.g., *Echinoneus*, *Koehleraster*); Holasteroida, deep-sea heart urchins, lantern always absent (e.g., *Urechinus*, *Pourtalesia*); Spatangoida, "true" heart urchins, lantern always absent (e.g., *Spatangus*, *Echinocardium*, *Maretia*, *Meoma*, *Metalia*, *Lovenia*); Cassiduloida, lamp urchins, lantern absent in adults (e.g., *Cassidulus, Rhyncholampas, Oligopodia*); Clypeasteroida, sea biscuits, lantern always present (e.g., *Clypeaster*, *Arachnoides*); Echinolampadoida, lamp urchins that form a sister group to Scutelloida, lantern absent in adults (e.g., *Echinolampas*, *Conolampas*); Scutelloida, "true" sand dollars, lantern always present (e.g., *Laganum*, *Echinocyamus*, *Echinarachnius*, *Dendraster*, *Mellita*).

CLASS HOLOTHUROIDEA Sea cucumbers, or holothuroids (Figures 26.1M–Q and 26.2H,I). Body fleshy and elongated along oral-aboral axis, even wormlike; skeleton usually reduced to isolated ossicles embedded in body wall; pentaradial symmetry manifested in circumoral feeding tentacles, which are derived directly from radial vessel; feeding tentacles can be highly branched; tube feet along body variably expressed, derived from embryologically interradial longitudinal canals that are not homologous with radial canals of other echinoderms (Figure 26.3A); madreporite suspended from stone canal within coelom; with circle of feeding tentacles around mouth. About 1,700 extant species in five orders.

ORDER APODIDA Body wormlike or snake-like, often very elongate, contractile; lacking tube feet along body; distinctive and abundant wheel or anchor ossicles in body wall; 10–25 branched

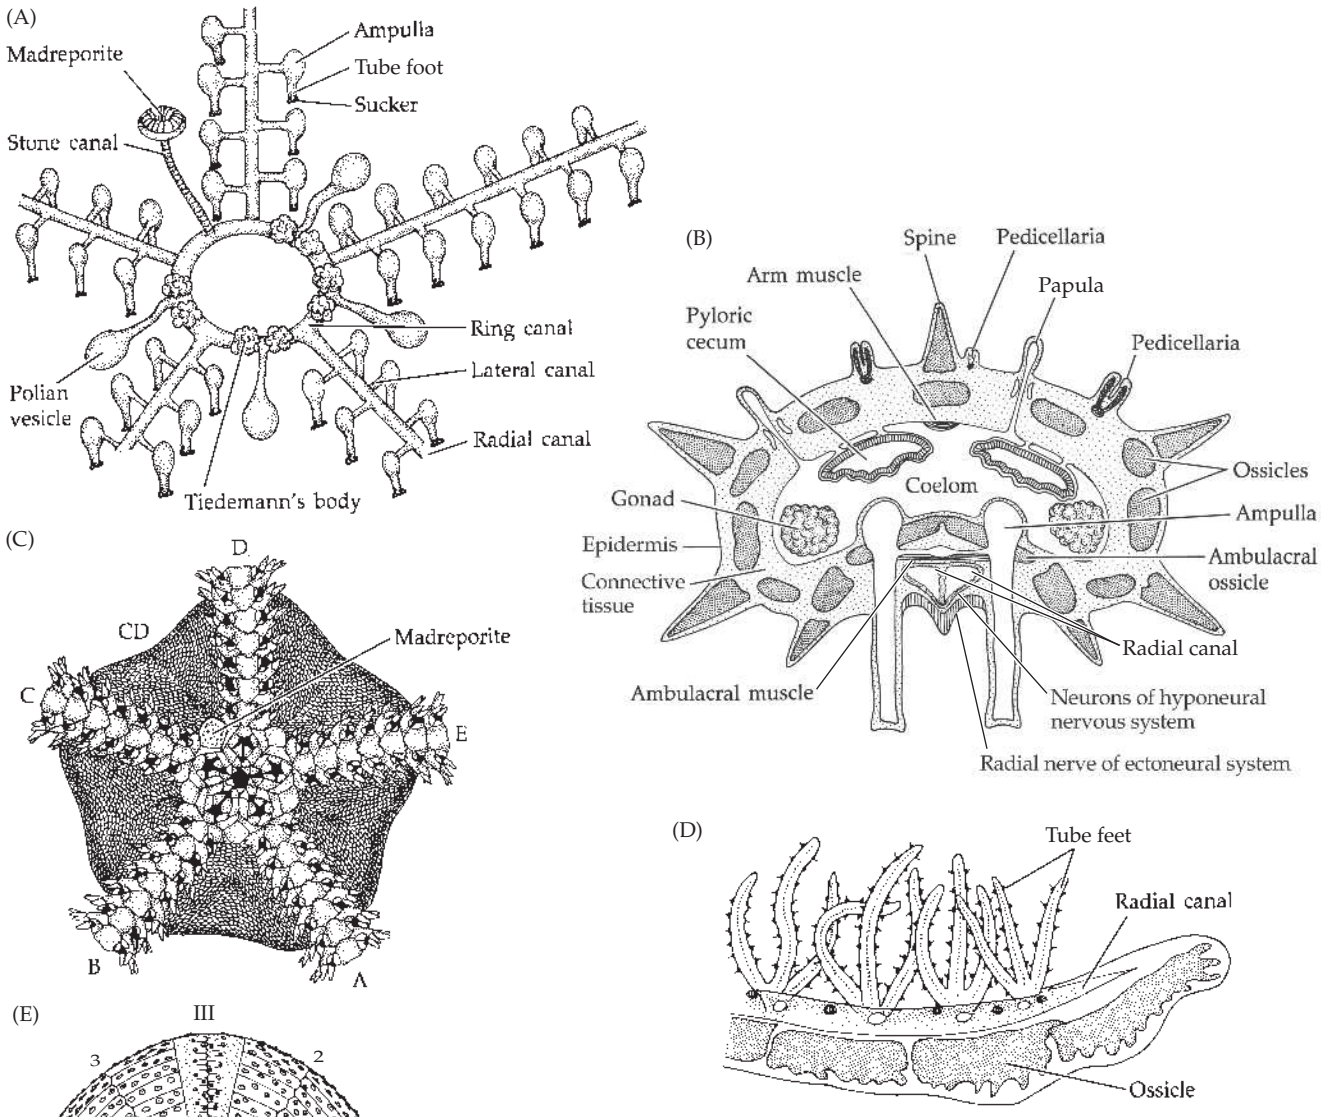

FIGURE 26.3 The water vascular system and related structures. (A) General structure of the water vascular system in a starfish (Asteroidea). (B) A starfish arm (cross section). (C) The central disk (oral view) of a brittle star, *Amphiura* (Ophiuroidea). The madreporite is on the CD interambulacrum. (D) The end of a crinoid pinnule (longitudinal section). feeding tentacles; respiratory trees absent. Some burrow through peristaltic action of body wall muscles, others are epifaunal at varying depths. (e.g., *Chirodota*, *Myriotrochus*, *Synapta*, *Euapta*, *Leptosynapta*)

ORDER ASPIDOCHIROTIDA Body sausage-like; tube feet present along body, often arranged to make solelike flattened area on lower surface; oral tentacles flattened, even leaflike; oral region lacks retractor muscles; respiratory trees present. Includes the largest holothuroids and many familiar, shallow-water forms. (e.g., *Holothuria*, *Stichopus*, *Parastichopus*, *Thelenota*, *Actinopyga*, *Bohadschia*, *Mesothuria*, *Bathyplotes*, *Synallactes*, *Apostichopus*)

ORDER DENDROCHIROTIDA Body sausage-like, sometimes U-shaped; body wall with small ossicles but partially enclosed in plates in certain genera (e.g., *Psolus*); feeding tentacles typically branched; retractor muscles present in tentacles

for more ebook/ testBank/solution manuals requests: email:960126734@qq.com

and oral region; tube feet present along body. Includes many common intertidal sea cucumbers; most are suspension feeders. (e.g., *Cucumaria*, *Eupentacta*, *Phyllophorus*, *Psolus*, *Thyone*, *Ypsilothuria*, *Vaneyella*)

ORDER ELASIPODIDA Body wall often thin with elongated papillae, sails or fins; respiratory trees absent. Typically deep-sea cucumbers, some with strange body forms adapted for swimming (some are benthopelagic, and at least one species is fully pelagic). (e.g., *Deima*, *Elpidia*, *Peniagone*, *Scotoplanes*, *Laetmogone*, *Enypniastes*, *Pelagothuria*, *Benthodytes*)

ORDER MOLPADIDA Body stout, narrowed posteriorly to a distinct tail; with 10 or 15 digitate tentacles; lacking tube feet along body. Found from shallow water to over 5,000 m. (e.g., *Caudina*, *Molpadia*, *Gephyrothuria*)

The Echinoderm Body Plan

Radial symmetry is usually linked to sessile or planktonic habits of animals that face their environments on all sides as suspension feeders (e.g., feeding structures of tube-dwelling polychaetes, bryozoans, phoronids, and others) or as passive predators (e.g., cnidarians). However, echinoderms have managed to combine motility with radial symmetry in their adult form, and they display many different feeding strategies and lifestyles. Much of the biology of echinoderms is associated with their unique **water vascular system** (Figure 26.3A), a complex of fluid-filled canals and reservoirs that supports the function of the tube feet (or podia). These are hydraulically operated, fleshy projections that serve in locomotion, gas exchange, feeding, attachment, and sensory perception. Much of the evolution of echinoderms is associated with elaboration of the **ambulacra**, that is, the region along the rays in which the water vascular system and skeletal plates that support the tube feet are situated.

The water vascular system is derived relatively late in development, in the bilaterally symmetrical larva. The coelomic cavities of adult echinoderms are not expressed in the typical three body regions usually associated with deuterostomes. All the elements of the water vascular system come from a specialized part of the left mesocoelic portion of the embryonic tripartite coelom, called the **hydrocoel** (see below). The interaction of the hydrocoel with the left somatocoel leads to formation of a region on the left side of the echinoderm larva called the **rudiment**—and the rudiment represents the first glimmerings of pentaradial symmetry. In fact, it represents the first glimmerings of the adult animal itself because the adult form is produced by elaboration of the rudiment, with accompanying loss or incorporation of the bilateral parts of the old larva into the newly emerging adult. This patterning, an extreme case of maximal indirect development, is the key to understanding the uniqueness of echinoderm anatomy and almost all the morphologies seen throughout the phylum—even the most bizarre of the Paleozoic forms.

Developmental Roots of the Echinoderm Body Plan

Axial and extraxial body regions Echinoderms look like nothing else in the animal kingdom. What is more, the echinoderm classes look nothing like one another. How has this strange anatomy come about? Part of the explanation lies in the unique transformation of the echinoderm's bilaterally symmetrical larva into a pentaradial adult. A theory that describes this complex process and body plan is called the **extraxial/axial theory**, or **EAT**. The theory draws from embryology, larval development and metamorphosis, and body wall morphology. The EAT describes adult body regions and homologies in the various echinoderm lineages based on how different larval regions develop into adult body regions.

There are two main body wall regions in larval echinoderms, called the **axial** and the **extraxial regions** (Figure 26.4A). These two regions produce very different parts of the adult echinoderm, which is thus also composed of axial and extraxial regions. Each region produces skeletal material but develops following different patterns.

During the gastrula stage, echinoderms form the three right and left pairs of coelomic compartments that characterize archimeric deuterostomes—protocoel, mesocoel, and metacoel. However, the mesocoel comes to be dominated by the left compartment, called the **hydrocoel**. The compartments of the metacoel are called the **left and right somatocoels**. One of the most unusual features of echinoderms is the expansion of the left side of the larva as the adult begins to form. During larval development, the hydrocoel and left somatocoel become a single functional unit called the **rudiment**. The rudiment contains the axial region, and it develops a ring around the larval esophagus. From this ring are sent out the five radial canals that characterize adult echinoderms. The adult axial region thus includes the mouth, water vascular system, tube feet, and ambulacral skeleton (which grows according to the ocular plate rule, described below).

In contrast, the extraxial region derives from the non-rudiment part of the larva, and it makes up most of the central body of adult echinoderms (except in echinoids, in which the extraxial region is almost entirely lost). The extraxial region consists of two parts, known as the **perforate** and **imperforate extraxial regions**. In adult echinoderms, the skeletal components of the perforate extraxial region are pierced by various orifices (hence the name), such as the anus, genital pores,

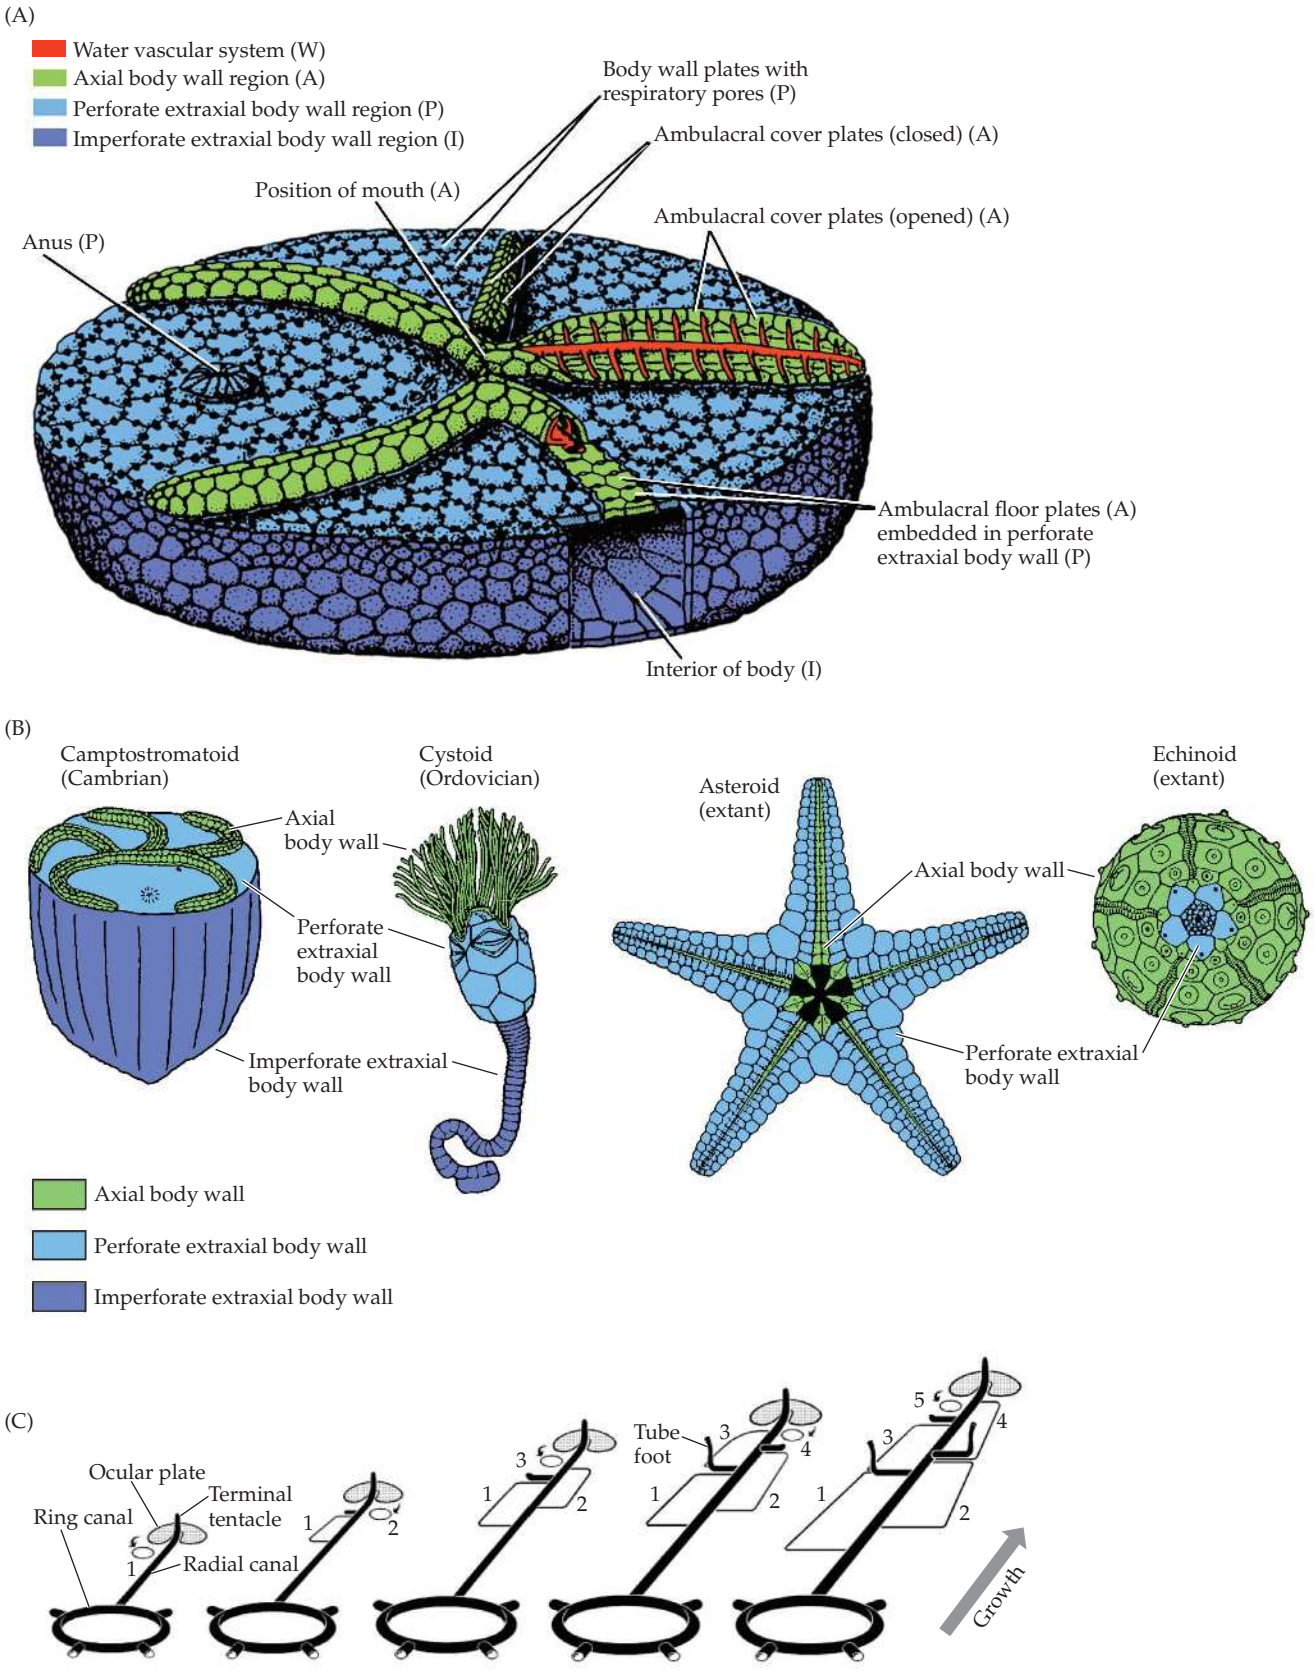

FIGURE 26.4 Body wall regions in echinoderms. (A) Axial and extraxial body wall regions mapped onto a generalized reconstruction of an early echinoderm, such as the disk-shaped *Stromatocystites*. for more ebook/ testbank/ solution manuals requests email:960126734@qq.com

and specialized openings to the water vascular system. Skeletal components of the extraxial region are not added by any organized "law," but can be generated anywhere needed in the body wall.

During evolution in the Echinodermata, alterations in relative amounts of each of the major body regions (axial and extraxial) gave rise to the diverse forms seen throughout the phylum's half-billion year history (Figure 26.4B). Most significantly, in the living classes Asteroidea, Ophiuroidea, Echinoidea, and Holothuroidea, the imperforate body wall region is greatly reduced and contributes very little to the adult body wall (Figure 26.4B). In crinoids, on the other hand, much of the main body wall below the arms and the stem is made up of imperforate extraxial body wall. Regulatory genes that help control timing and rate of development of major regions of echinoderms, and their associated coelomic structures also have distinctive expression patterns in these regions. From these patterns, researchers are starting to gain insights into the mechanisms by which the unique pentaradial symmetry of echinoderms evolved.

During development, as the axial region gives rise to the ambulacral plates and their accompanying tube feet, growth tightly adheres to a set of empirical "rules." Within the axial region, the tip of the growing hydrocoel farthest from the mouth is expressed as a terminal "tentacle" (similar to a tube foot) in starfish. In sea urchins, for which the dynamics of this system were first understood, this small terminal extension protrudes through a distinctive plate known as the **ocular plate**. The term "ocular" derives from an old idea that the pore through which the terminal tentacle pierces the plate in echinoids was a kind of eye. Although light sensitive tissues can be associated with the terminal tentacle itself, there are no known true eyes among echinoderms. The ontogenetic pattern by which new tube feet are laid down in the axial region is known as the **ocular plate rule (OPR)**, whether or not the ocular plate itself (Figure 26.4C) is actually calcified. In all echinoderms, as the **radial canals** (hydrocoelar extensions) of the developing rudiment expand outward along the rays from the **ring canal** (the hydrocoelar ring that encircles the esophagus), new tube feet appear just proximal to the ocular tentacle (the **terminal tentacle**). A new tube foot appears first on one side of the radial canal, and then on the other, to form a zigzag pattern of tube foot additions along the growing biserial ambulacrum (Figure 26.4C). In most echinoderms, as each new tube foot appears, so does a new ambulacral plate. Therefore, a basic property of the OPR is that the oldest plates and tube feet in the ambulacrum are near the mouth, and the youngest are at the tip of the ambulacrum, just proximal to the terminal tentacle.

Ray homologies Although it is not always obvious, each ray of an echinoderm can be homologized to those of any other in terms of reference to particular radii. For example, the position of the opening to the water vascular system is marked by one or more **hydropores**. These minute pores, which are often borne on a special plate called the **madreporite**, lead via an internal canal to the water vascular system (Figure 26.3A). The madreporite gives a clue to body orientation because it lies between specific rays. A system of lettering has been developed in which the ambulacrum opposite the madreporite is coded A; the others are then coded B through E in a counterclockwise fashion as viewed from the aboral surface (Figure 26.2C). The madreporite (or hydropore, in forms lacking a madreporite) always lies between ambulacra C and D (i.e., on the CD interradius). Ambulacra C and D comprise the **bivium**, while radii A, B, and E comprise the **trivium**.

Body Wall and Coelom

An epidermis covers the body of all echinoderms and overlies a mesodermally derived dermis that contains stereom skeletal elements referred to as **ossicles** and **plates**, as noted earlier (Figure 26.5A–D). Internal to the dermis and ossicles are muscle fibers and the peritoneum of the coelom. The degree of development of the skeleton and muscles varies greatly among groups. In echinoids, the ossicles are firmly attached to one another to form a rigid test, and body wall musculature is weakly developed. In sea cucumbers, ossicles are seldom contiguous and are usually scattered within the fleshy dermis (Figure 26.5D), in which distinct muscle layers are present. Between these two extremes are cases in which adjacent skeletal plates articulate to varying degrees. In the arms of starfish and brittle stars, the body wall muscles are arranged in bands between the plates, providing various degrees of arm motion. In some groups, skeletal plates are developed to such a degree that they nearly obliterate internal cavities. In brittle stars, for example, each arm is made up of a column of tightly interlocked pairs of ambulacral plates called **vertebrae** (see Figure 26.9A,B), and the arm coeloms are reduced to small channels. Similarly, the arm coeloms in crinoids are relatively small canals within skeletal plates.

The endoskeleton is calcareous, mostly $CaCO_3$ in the form of calcite, with small amounts of $MgCO_3$ added to increase hardness through "dolomitization." Each ossicle begins as a separate spicule-like element to which additional material is added in precise patterns to make specific elements in the skeleton. Within each ossicle, an anastomosing network of minute struts (the trabeculae) forms, creating labyrinth-like spaces (Figure 26.5D) so that the ossicle is made of porous, spongelike stereom. The spaces contain dermal cells and fibers (the stroma). Although each plate behaves as a single crystal, the stereom is polycrystalline, with aligned microcrystals intermixed with small amounts of organic matrix.

Note the position of muscles relative to the body wall layers.

Plates can remain single (simple plates) or, more rarely, fuse to form compound plates. External plates can have bumps and knobs called tubercles, some of which support a variety of articulated, external projections such as spines (Figure 26.5A,E). In asteroids, echinoids, and euryalid ophiuroids, unique pincerlike structures called **pedicellariae** (Figure 26.5E–I) can also be mounted on these tubercles. Movable spines and pedicellariae respond to external stimuli independently of the main nervous system, and they possess their own neuromuscular reflex components. Pedicellariae were discovered in 1778 by O. F. Müller, who described them as parasitic polyps and gave them the genus name "*Pedicellaria*." He recorded three species of these "parasites" (*P. globifera*, *P. triphylla*, and *P. tridens*); variations on these names are still used to describe different types of pedicellariae. Nearly a century later, it was realized that pedicellariae are produced by the echinoderms themselves, but their exact nature remained elusive. Louis Agassiz even believed they were attached young! It is now known that pedicellariae are functional appendages of the animals that produce them. Pedicellariae vary in morphology, size, and distribution on the body. In echinoids, most are elevated on stalks, but on asteroids, they usually lie nestled directly on the body surface, sometimes in clusters. Some help keep debris and settling larvae of other invertebrates off the body, and others are used in defense. Some echinoid pedicellariae are venomous to discourage predators, and others are pincers that grasp and hold objects for camouflage and protection. A few starfish even use their pedicellariae to capture prey (Figure 26.5F,G).

Spines, pedicellariae, and the epidermis contain tissues isolated from the coelom and digestive system because they are external to the main body wall (Figure 26.5H–J). Being isolated from the gut and coelom, in which nutrient supply is aided by circulation and hemal systems, external appendages and epidermal structures have their nutritional needs met by nutrients absorbed directly from the water or by small trapped organic particulates or organisms that are absorbed.

As in all deuterostomes (except Chordata), the coelomic system of echinoderms typically develops as a tripartite series, originating as paired **proto-**, **meso-**, and **somatocoels** that are thought to be homologous to the tripartite coeloms seen in other deuterostomes. As noted above, in adult echinoderms, these coelomic cavities do not form the usual three body regions typically associated with deuterostomes. Recall that the main body coeloms of adult echinoderms are derived from the left and right somatocoels, and they are usually well developed. However, the water vascular system forms from the left mesocoel—called the hydrocoel (as described earlier). Other coelom derivatives include gonadal linings and certain neural sinuses. The main body cavities, or **perivisceral coeloms**, are lined with ciliated peritoneum, and their coelomic fluid plays major circulatory roles. A variety of coelomocytes, many phagocytic, are present in the body fluid and water vascular system. Hemoglobins occur in the coelomocytes of certain holothuroids and brittle stars. Echinoderm coelomic fluid is isotonic with ambient seawater, and no mechanisms have evolved to control osmolarity of these fluids—a major reason that there are no terrestrial or freshwater echinoderms.

Mutable Collagenous Tissue

Between many of their skeletal ossicles, and in the body wall itself, echinoderms have a uniquely elaborated system of connective tissue. The material properties of this tissue are mutable on short time scales and are under neuronal control. This **mutable collagenous tissue (MCT)** is normally rigid, but it can be temporarily softened, allowing echinoderms to maintain fixed postures with zero muscular effort and energy expenditure. Long viewed as a curiosity, MCT is crucial to understanding how echinoderms maintain relatively low metabolic budgets in situations causing nutritional challenges to other phyla. In holothuroids, much of the body wall is constructed of MCT, allowing them to quickly change turgidity. In echinoids, muscular rings around the bases of the spines position them within a rocky crevice, then a similarly positioned ring of MCT (so-called "catch collagen") "freezes" the spine into position to wedge the animal into place. During crawling, starfish soften their body, then use MCT in their body wall to adopt a new posture, securing their position over uneven substrata, making them virtually impossible to dislodge by predators or wave action.

Water Vascular System

The water vascular system is so critical to all aspects of echinoderm biology that a discussion of its anatomy is a necessary preface to other considerations, starting with starfish and then comparing their system to other echinoderms.

Asteroidea Figure 26.3A is a schematic representation of the starfish water vascular system. The system opens to the exterior through a skeletal plate, the madreporite (or sieve plate) located off-center on the aboral surface on the CD interambulacrum (Figure 26.2C). The madreporite is perforated by hydropores set in deep furrows. The overlying epidermis is ciliated, even where it lines the pores. The traditional view of madreporite function is that it permits seawater to enter the system to replace water lost through the thin walls of the tube feet, as demonstrated by using radioactive tracers.

Internally, the madreporite forms a cuplike lumen called the ampulla (distinct from the tube foot ampulla) that communicates with other coelomic derivatives of the water vascular and hemal systems. The lower end of the ampulla connects with the **stone canal**, so named because of hard skeletal deposits in its wall. A portion of the hemal system called the **axial sinus** is often intimately associated with the stone canal. The stone canal proceeds orally to join with a circular ring canal encircling the esophagus. The ring canal gives rise to radial canals extending into each arm. Interradial blind pouches called **Tiedemann's bodies** and **Polian vesicles** are attached to the ring canal (Figure 26.3A,B). There is uncertainty about the function of these pouches, but the former are suspected to produce certain coelomocytes, and the latter to help regulate internal pressure within the water vascular system.

The liquid in the water vascular system consists of ambient seawater to which the animal adds specific components such as coelomocytes, organic compounds such as proteins, and a relatively high concentration of potassium ions. The fluid is moved through the system largely by cilia that line the internal epithelia of the canals, some of which, especially the stone and ring canals, contain partition-like inner extensions that could help direct the flow. The stone canal, at least in some starfish, has been described as a "ciliary pump" that draws fluid into the water vascular system from both the madreporite and the axial sinus of the hemal system.

In each arm, the radial canal gives rise to numerous **lateral canals**, each of which terminates in a tube foot–ampulla system. All tube feet form according to the ocular plate rule (Figure 26.4C), with oldest ones near the mouth, and youngest at the arm tips. The tube foot is a contractile, muscular tube typically ending in a sucker; it extends externally from a bulblike, internal ampulla (Figure 26.3B). Longitudinal and circular muscles attach to a collagenous sheath surrounding a coelomic lumen, and the tip and shaft are well supplied with nerves. Tube feet function as primary tactile, locomotory, attachment, and food-manipulating organs. Each radial canal ends in an unsuckered, tentacle-like, terminal tube foot that is most likely photoreceptive.

The system of tube feet and ampullae comprise a sophisticated hydrostatic system. Two sets of muscles operate around the fluid in the lumens of tube feet and ampullae. A valve in the lateral canal can effectively isolate the tube foot and ampulla from the rest of the canal. With the valve closed, muscles in the ampullar wall contract, forcing fluid into the lumen of the extending tube foot, in which the longitudinal muscles are relaxed. The sucker is then pressed against the substratum and held there by adhesive secretions of the epidermis and by the contraction of tip muscles that raise the center of the sucker and create a suction-cup-like vacuum. When the longitudinal muscles of the tube foot contract, it shortens, decreasing the lumen volume and forcing fluid back into the now relaxed ampulla. When the tip muscles relax, the suction is broken. Chemicals secreted by cells in the sucker reverse the adhesive action of substances secreted by the tube foot. Tube feet bend by differential contraction of the longitudinal muscles.

Ophiuroidea The water vascular system of brittle stars is similar to that of asteroids. However, the madreporite is on the oral surface of the central disk (Figure 26.3C), and the internal plumbing is modified accordingly. In some ophiuroids the madreporite is reduced to just two hydropores.

The ring canal bears Polian vesicles, but apparently lacks Tiedemann's bodies. The ring canal gives off the usual five radial canals and also bears a wreath of buccal tube feet around the mouth. In basket stars (order Euryalida) the arms and the radial canals are branched. The suckerless tube feet are highly flexible, being fingerlike structures that can secrete copious amounts of sticky mucus. They function in feeding, digging, locomotion, and sensation.

Crinoidea The water vascular system of crinoids operates entirely on coelomic fluid. There is no centralized madreporite in modern forms. Multiple stone canals arise from the ring canal and open to coelomic channels. There can be hundreds of such canals. The main perivisceral coeloms bear ciliated funnels to the exterior through which water enters the body cavities, perhaps to regulate hydraulic pressure in the water vascular system.

From the ring canal, radial canals bifurcate into all the branches of each arm, which can have as many as 200 termini. Crinoid arms also bear side branches called **pinnules** (Figure 26.2B), into which extensions of the radial canals also reach. Topologically with respect to the coeloms, radial canals are positioned just as they are in starfish. However, ambulacral ossicles are lacking, and the canals are embedded in a soft tissue shelf, reducing weight and metabolic expense otherwise needed to produce a skeleton in the long arms. The arms are well supported by brachial ossicles, relatively large, articulated stereom elements that form the aboral surface of all arms and pinnules (see Figure 26.7A,B). Suckerless tube feet

for more ebook/ testbank/solution manuals requests email:960126734@qq.com

occur along pinnules, often in clusters of three (Figure 26.3D), and each cluster is served by a branch from the radial canal. Equipped with adhesive papillae, the tube feet are highly mobile, functioning primarily as feeding and sensory organs.

Echinoidea Echinoids bear a special set of skeletal plates, called the **apical system**, around the aboral pole, one of these plates being a madreporite (Figure 26.3E,F) that leads to an ampulla–axial gland complex. A stone canal extends to a ring canal atop the jaw apparatus (Aristotle's lantern, see below). The ring canal gives rise to a radial canal beneath each ambulacrum, as well as to Tiedemann's bodies and Polian vesicles. Each radial canal gives off lateral canals leading to tube feet and ends with a terminal tentacle protruding through an ocular plate in the apical system. The tube feet of echinoids may be suckered or unsuckered. They serve a variety of functions including attachment, locomotion, feeding, and gas exchange.

To understand the water vascular system of sea urchins, picture a starfish in which the aboral region (the perforate extraxial region) has been reduced to a tiny button (the apical system). The result is a "pulling" of the tips of the radial canals together to converge on the apical system, leaving the rows of tube feet extending around the sides of the body like five lines of longitude on a globe (Figures 26.3E and 26.4B). However, unlike any other echinoderm, stereom plates of the test are laid down external to the water vascular components, rendering the radial canals truly internal. Pores through the plates forming the ambulacra allow communication between the tube feet and ampullae. This is very different from ophiuroids, in which the radial canal is usually covered by ventral arm plates and not truly internal, and from the holothuroids in which the longitudinal canals are not homologous to radial canals of other echinoderms (see below).

Holothuroidea The story of the holothuroid water vascular system is one of reduction, or truncation of growth probably through pronounced paedomorphosis. In a sense, holothuroids can be viewed as "giant larvae"—metamorphosis is suppressed, producing an adult animal in whose construction the rudiment plays only a small part.

In the Holothuroidea, the stone canal usually extends from beneath the pharynx in an interradial position, giving rise to a madreporite opening to the coelom. A ring canal encircles the esophagus and bears from 1 to 50 Polian vesicles. Five radial canals arise from the ring canal to give off extensions to the **oral tentacles**, which are actually highly modified terminal tentacles and the first few tube feet. These represent the only elaborations of that part of the radial canal homologous to the radial canal in other echinoderms. In the least derived holothuroids, such as the Apodida, these tentacles, restricted to the circumoral region, are all that exists of the water vascular system, there being no canals or tube feet along the vermiform body. Early in postlarval growth of more derived forms, thin interradial extensions from the ring canal form to produce interradial, **longitudinal canals** that are later twisted in a kind of "torsion" that pulls them into alignment with the radial canals leading to the feeding tentacles. The longitudinal canals lie along the inside of the larval body wall, inducing formation of tube-foot-like structures without respect for the ocular plate rule. These tube-foot-like extensions can be scattered over the body wall, restricted to ambulacrum-like lines, or missing in certain radii entirely, usually along the "dorsal" or upper surface. The tube feet around the mouth serve in food gathering, whereas the tube-foot-like appendages along the body assist in locomotion, attachment, and touch.

Support and Locomotion

Except in holothuroids, structural support in echinoderms is maintained primarily by skeletal elements and the mutable collagenous tissue. Tube feet and gill-like extensions of the body wall (such as papulae) are supported mostly by hydrostatic pressure. Most sea cucumbers lack skeletal plates, which are reduced to minute, separated ossicles, but body wall muscles form thick sheets, adding integrity to the body and working antagonistically on coelomic fluids to function in a hydrostatic skeleton. The mutable collagenous tissue of echinoderms also contributes to overall support and aspects of locomotion.

Apart from sessile sea lilies (e.g., *Ptilocrinus*), most extant crinoids are capable of crawling and even swimming. Aboral cirri of feather stars (and along the stem of isocrinids) are used for temporary attachment (Figure 26.6A). During isocrinid crawling, the animal lies prone and with the stem trailing, and the arms pull the main body region, the **calyx** or **theca** (the central cup at which the arms converge), along the bottom (Figure 26.6B) to reposition the animal. Isocrinids also "run away" from deep-sea cidaroid echinoids while casting off a piece of the stem to preoccupy the echinoid predator. Swimming among the Crinoidea is accomplished by up-and-down sweeps of the arms, which are divided into functional sets that can move alternately.

Asteroids exemplify locomotion using suckered tube feet. Starfish arms are held more or less stationary relative to the central disk, even in species with a flexible skeletal framework (e.g., *Pycnopodia*). Movement is accomplished by upwards of thousands of tube feet on the oral surface. The starfish appears to glide smoothly because of the large number of tube feet, though at any given instant they are in different phases of the power and recovery strokes (Figure 26.6C). Although control of tube foot action is

FIGURE 26.6 Locomotion in echinoderms. (A) A feather star, *Antedon* (Crinoidea), at rest. (B) Depiction of an isocrinid sea lily (Crinoidea) escaping from a cidaroid sea urchin (Echinoidea) predator by crawling on its arms, dragging the stem. Note numerous other, erect sea lilies in the background, living in groups sometimes referred to as "gardens" of crinoids. (C) Starfish arm (side view) with tube feet in motion. (D) Tube foot movements as a starfish moves in the direction of the arrow. Power stroke occurs with sucker in contact with the substratum (x), recovery stroke while lifting. Note changes in tube foot length and corresponding changes in volume of the ampulla. (E) Tube feet of a crawling starfish *Dermasterias imbricata*.

not fully understood (even isolated arms crawl about normally), tube feet are coordinated to produce movement in a particular direction. There are no metachronal waves of motion as seen in many other multi-legged creatures. Most starfish move slowly, but a few (e.g., *Pycnopodia*) are relative speedsters, and otherwise sedentary asteroids become rapid "runners" upon encountering a potential predator. Species that cannot "run" have other defense mechanisms. The slow-moving Pacific cushion star, *Pteraster tesselatus* (Figure 26.1D), secretes copious amounts of mucus that discourages predators such as *Solaster* and *Pycnopodia*. Starfish on sandy bottoms (e.g., *Astropecten*) can burrow rapidly by using tube feet to move sand from below to on top of themselves.

Following the action of a single tube foot during movement reveals the sources of the locomotory forces (Figure 26.6D). At the end of a recovery stroke, the tube foot extends in the direction of movement and attaches to the substratum. The sucker remains attached during the power stroke as the longitudinal muscles in the wall of the tube foot shaft contract, shortening the tube foot and pulling the body forward. At the end of the power stroke, the tube foot detaches and swings forward again. The great number of tube feet and the general flexibility of the body allow starfish to move easily over even the most irregular surfaces (Figure 26.6E).

Ophiuroids primarily use their flexible, articulated arms for crawling or clinging (Figure 26.2D). In most forms, the skeletal arrangement within the arms allows for rapid lateral, snakelike movements on a plane parallel to the disk (hence the Greek prefix *ophio*, "snake"). Only in taxa such as basket stars do the arms have full range of movement in all planes. In most species, the articulated arms are fragile and break easily when seized (hence "brittle stars"). The tube feet lack suckers and ampullae, but a well-developed lattice of muscles in their wall allows protraction, retraction, and swinging motions. Combined action of arms and tube feet allows some ophiuroids to burrow into sediments, or move swiftly when escaping from predators or chasing prey.

Sea urchins move by the use of tube feet and movable spines. Strong, suckered podia are capable of a wide range of extension and motion, while spines provide stiltlike support and movement. Some urchins can excavate stone by scraping with their spines and

for more ebook/ testbank/solution manuals requests email:960126734@qq.com

chewing with their teeth. Some populations of *Strongylocentrotus purpuratus*, a common northeast Pacific urchin, form pockets in intertidal rocks, and *Echinometra vanbrunti* also does this on tropical eastern Pacific shores. Individuals are sometimes trapped in their self-made homes, but they are protected from predation and wave action. The common Indo-Pacific reef urchin, *Echinometra mathaei*, excavates elongate channels in rock largely by the action of teeth in the jaw apparatus; in these species the test is slightly elongated to allow movement of the urchin along the channel as it harvests a "garden" of algae growing there. Some irregular urchins burrow below the sediment surface. Sedentary species (e.g., *Echinocardium*) maintain an open chimney to the overlying water (see Figure 26.11G). Soft-sediment burrowers often have specialized spatulate spines along the body that aid in locomotion and digging. Clypeasteroid sand dollars live on sandy bottoms, and all species lie flat with the oral surface toward the bottom except *Dendraster excentricus*, an abundant North American west coast species that lives embedded upright in the substratum (see Figure 26.11F). Clypeasteroid burrowing and crawling are accomplished by the action of spines that move in metachronal waves. Sand dollar morphology is strongly tied to hydrodynamic forces. Deep marginal notches and holes (**lunules**) in the tests of some sand dollars (Figure 26.2F) are not for feeding, but act as lift spoilers to help the animals maintain stability in strong currents characterizing their coastal environments. Lift forces are also mitigated by flow along **pressure drainage channels** from the center of the body to the lunules.

Holothuroids inhabit various substrata, coral crevices, spaces under rocks, or soft sediments. They crawl or burrow in sand or mud using tube feet or peristaltic actions of body wall muscles. In epibenthic species that lodge themselves in rock crevices, the tube feet can be used for anchorage and to hold bits of shell and stone for camouflage and protection. In deep-sea forms such as *Scotoplanes* (Figure 26.1N), some tube feet are elongated for walking like small mammals, hence the nickname "sea pig." In psolids, the lower surface is modified into a footlike sole upon which the animal creeps. Among the apodids are the bizarre synaptids, with unique anchor ossicles in densities up to 1,500 per cm^2 of body wall. In lieu of tube feet, these provide a grip akin to Velcro by protruding and retracting into the skin in peristaltic waves along the body wall. Some holothuroids live completely buried, whereas others form U-shaped burrows. A few holothuroids are truly pelagic and capable of swimming (Figure 26.1P,Q).

Feeding and Digestion

Crinoidea Sea lilies and feather stars sit with their oral sides up and suspension feed, usually clinging to elevated areas exposed to currents (see the yellow feather star *Comaster* at the chapter opener). The arms and pinnules are held outstretched into ambient water flow, presenting a large food-trapping surface. Some forms emerge from concealment to feed only at night. Deep-water species hold their arms upward and outward, forming a funnel with which they capture detrital rain, and stalked forms raise a crown of arms like an umbrella into the current; the stalk is bent with the current flowing into the underside of the umbrella, and particle capture occurs downstream, on the oral surfaces of the arms.

Food particles, including plankton and organic particulates, contact tube feet along the ambulacral grooves in arms and pinnules (Figure 26.7B). These tube feet flick the food into the grooves, which are lined with cilia that beat toward the calyx, driving food to the mouth, where it is ingested. This use of the tube feet and ambulacral grooves for feeding likely represents an original function of the early water vascular system in Echinodermata.

The mouth opens to a short esophagus leading to a long intestine (Figure 26.7A,C) that loops inside the calyx, then straightens to a short rectum terminating at the anus, which is borne on an anal cone near the arm bases. The intestine can bear diverticula, some of which are branched. The histology of the crinoid gut has been described, but little is known about the digestive physiology of these animals.

Asteroidea Most starfish are opportunistic deposit feeders, scavengers, or predators, feeding on nearly any organic matter or small prey. Many species are generalists in terms of food preference and play important roles as high-level benthic predators in intertidal and subtidal communities. Others, such as *Solaster stimpsoni* from the northeastern Pacific, are specialists feeding on holothuroids, while a related species (*S. dawsoni*) preys almost exclusively on *S. stimpsoni*! Tropical crown-of-thorns starfish (species of *Acanthaster*) feed on coral polyps, receiving great notoriety because of their implied destruction of coral reefs. There remains disagreement concerning causes for increases in *Acanthaster* populations, and even the level of harm they actually perpetrate on the reefs, but most agree that human interference in predator-prey balance in reef communities is more to blame than *Acanthaster* itself. A major predator of *Acanthaster* is the giant triton snail *Charonia tritonis*, which is collected in high numbers for its handsome shell. In undisturbed environments, *Acanthaster* likely plays a role in maintaining coral diversity by acting as forest fires often do, opening new habitats in climax ecosystems for the establishment of other species.

Except for a few suspension feeders, starfish use an eversible portion of the stomach to obtain food. Some forms, including *Culcita* (a cushion star, Figure 26.1E), *Acanthaster* (Figure 26.1F), and *Patiria* (a bat star; see Figure 26.8D), spread their stomach over the surface of a food source, secrete digestive enzymes, and suck in the partially digested soup.

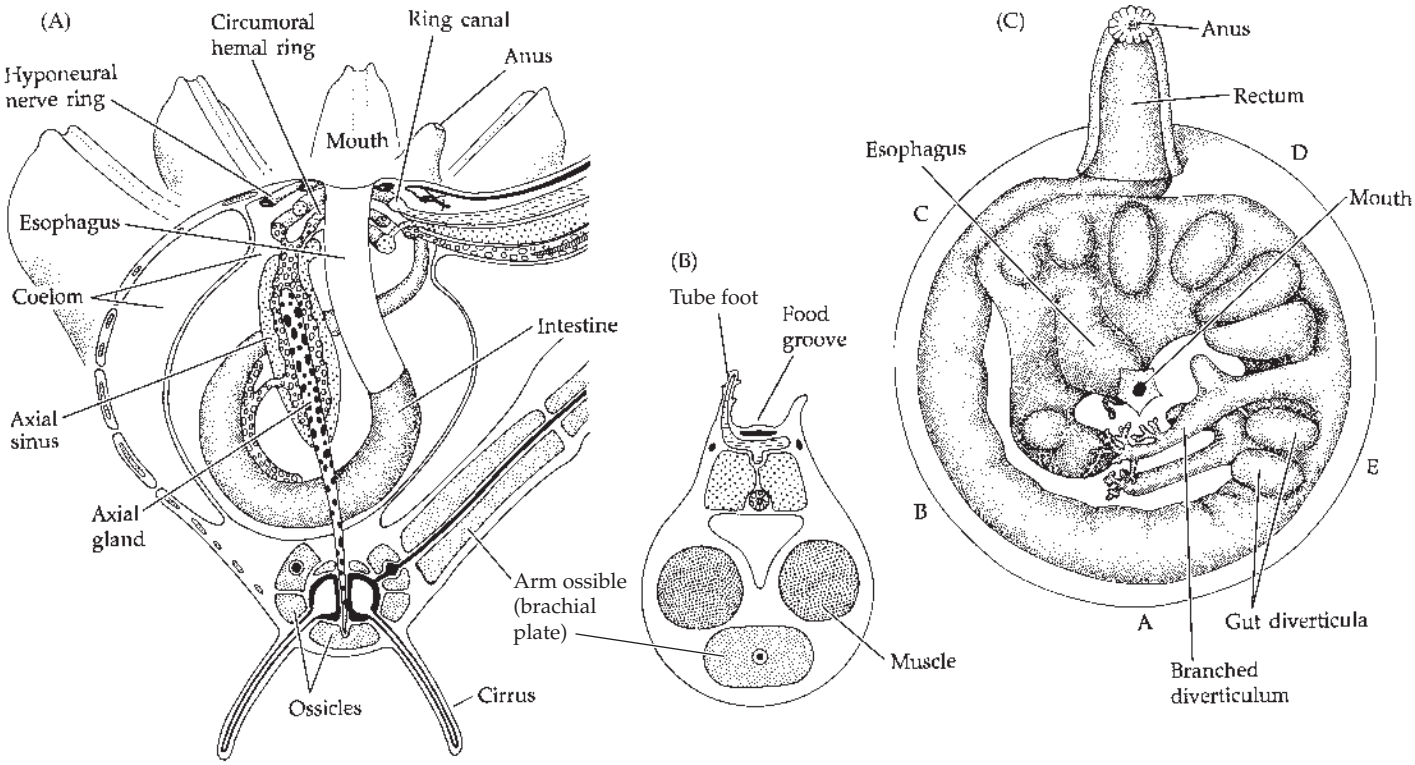

FIGURE 26.7 Internal anatomy of sea lilies and feather stars (Crinoidea). (A) Central disk and base of one arm (vertical section). (B) Arm with open ambulacral groove (cross section). (C) Oral surface of the feather star *Antedon* (cutaway view). Positions of radii indicated by letters.

For *Culcita* and *Patiria*, food can include encrusting sponges, algal mats, or accumulated organic detritus over which the starfish crawls. *Oreaster*, also a cushion star, feeds similarly but switches to a predatory or scavenging mode when appropriate food sources are encountered. Sedentary or sessile prey, such as gastropods, bivalves, and barnacles, are eaten by asteroid predators, especially members of the Forcipulatida. The voracious Pacific ochre star *Pisaster ochraceus* hunches over its prey with the oral area pressed against the potential victim, holding itself in position with its tube feet. The stomach is very thin and flexible and can be slid between even the tightly clamped valves of mussels and clams to liquefy the prey's body inside its own shell so that nutrients are drawn in with the retracting stomach.

Some starfish are suspension feeders, consuming plankton and organic detritus. *Henricia*, *Porania*, and a few others are typically full-time suspension feeders, and some predators, such as *Astropecten*, are facultative suspension feeders to supplement their usual diet. Usually, particulate food material that contacts the body surface is trapped by mucus and moved by ciliary action to the ambulacral grooves and ultimately to the mouth. *Novodinia* extends its arms upward into water currents. The dozen or so arms form a large feeding surface used to capture planktonic crustaceans; the prey are grasped by clusters of pincerlike pedicellariae. A few forms, including *Stylasterias*, *Pycnopodia*, and *Labidiaster*, possess wreathlike circlets of pedicellariae (Figure 26.5F,G) used to capture a variety of animals, even fishes.

The starfish gut typically extends from the mouth at the junction of the arms to the aboral anus (Figure 26.8A). The mouth is surrounded by a leathery **peristomial membrane**, which is flexible to allow eversion of the stomach, and contains a sphincter muscle that closes the mouth orifice. Internal to the mouth is a very short esophagus leading to the **cardiac stomach**—the portion that is everted during feeding. Radially arranged retractor muscles retract the stomach. Aboral to the cardiac stomach is a flat **pyloric stomach**, from which arises a pair of pyloric ducts extending into each arm and leading to paired digestive glands (**pyloric ceca**) (Figure 26.8A,C). A short intestine, often bearing outpocketings (rectal glands or rectal sacs) leads from the pyloric stomach to the anus. The pyloric ceca and cardiac stomach are the main producers of enzymes (mostly proteases) carried by ciliary action through the everted stomach and released onto the food material. Digestion is completed internally, but extracellularly, after ingestion of the liquefied food. Digested products are moved through the pyloric ducts to the pyloric ceca, where they are absorbed and stored. The intestine does not seem to function in actual digestion, but the rectal sacs are known to absorb nutrients.

Many starfish harbor commensals that derive nutrition from their host's leftovers. A polynoid scale worm, *Arctonoe vittata*, is an obligate symbiont living

with several species of asteroids, including the Pacific leather star, *Dermasterias*. The worm spends most of its life cruising and feeding in the host's ambulacral grooves. Not only is the polychaete chemically attracted to its host, but studies indicate that *Dermasterias* is also attracted to *A. vittata*, suggesting that the starfish might also derive benefit from the association. Another polynoid from the northeast Pacific coast, *Arctonoe pulchra*, is commensal on several echinoderm species, including the sea cucumber *Apostichopus parvimensis*. Forms such as *Xyloplax* and caymanostellid "wood stars" (Figure 26.1G) that live only on sunken wood seem to be **xylophagous**, harboring cellulose-digesting gut bacteria that help the starfish derive nutrients from wood that starfish are otherwise incapable of digesting.

Ophiuroidea Brittle stars exhibit predation, deposit feeding, scavenging, and suspension feeding, and some species are capable of more than one feeding method. Basket stars (Figure 26.1I) are actually predators that utilize suspension-feeding behaviors to capture relatively large swimming prey (up to about 3 cm long).

Selective deposit feeding is accomplished in ophiuroids by tube feet and sometimes by spines along the arms. The arm spines and tube feet produce mucus to which organic material adheres. The tube feet roll the mucus and food into a bolus. Near the base of each tube foot is a flaplike projection called a **tentacle scale** (Figure 26.9B,D). The bolus is transferred from a tube foot

onto its adjacent scale, picked up by the next tube foot, and so on, transporting the food along the arm to the mouth. Suspension feeding usually involves a similar method of transport once food is trapped. Food capture is sometimes aided by secretion of mucous threads among the arm spines and holding the arms within currents to trap plankton and organic detritus. Brittle stars using this technique typically have very long arm spines (e.g., *Ophiocoma*, *Ophiothrix*). *Astrotoma* (a euryalid with unbranched arms) extends its arms (each up to 70 cm long) into the overlying water to capture planktonic copepods. Other brittle stars suspension feed by using extended tube feet to form a trap, passing clumps of food to the mouth (Figure 26.9E). Several species burrow to form semipermanent, mucus-lined burrows. The arms extend to the surface and help maintain ventilation currents within the burrows. Such species are able to extract food from the sediment, the substratum surface, and the overlying water. The commensal brittle star *Ophiothrix lineata* lives in the atrium of the large sponge *Callyspongia aculeata*, emerging to feed on detritus adhering to its host's outer surface. While keeping the sponge clean, the ophiuroid is supplied with food and afforded protection from predators.

Predatory suspension feeding by basket stars occurs mostly at night. At dusk the animals emerge from their hiding places and unfold and hold their branched arms fanlike, in a manner similar to that of feeding crinoids. *Astrophyton* changes position with the tidal direction, always orienting its arms into the current; it stops feeding at slack tide. When a small animal contacts an arm, the appendage curls to capture it by impaling it on microscopic hooks along the arm. Ingestion is often postponed until darkness has passed; the prey is then transferred to the mouth by the flexible arm. Basket stars feed on a variety of small invertebrates, such as swimming crustaceans and demersal polychaetes.

Some brittle stars are active predators, capturing benthic organisms by curling an arm into a loop around the prey, then pulling it to the mouth. Species that feed this way usually have short arm spines that lie flat against the arm (e.g., *Ophioderma*). *Ophiura sarsii*, an ophiuroid from northern temperate seas, acts in groups to subdue and tear apart active swimming prey, such as fishes and crustaceans.

In ophiuroids, the intestine and anus have been lost, and the digestive system is confined entirely to the central disk (Figure 26.9A). The mouth, surrounded by a jawlike set of modified ambulacral ossicles, leads to a short esophagus and large stomach in which digestion and absorption occur. Digested waste material is ejected back through the mouth. The stomach fills most of the interior of the disk, reducing the coelom to a thin chamber.

Echinoidea Echinoids engage in various kinds of herbivory, suspension feeding, detritivory, and rarely, predation and xylophagy. In typical globose urchins, feeding is facilitated by an intricate masticatory apparatus, the **Aristotle's lantern**, that lies just inside the mouth and bears five calcareous protractible teeth (Figure 26.10). It is an impressive example of evolutionary engineering: a complex of hard stereom elements and muscles that control protraction, retraction, and grasping movements of the teeth. Usually, the entire apparatus can be rocked so that the teeth protrude at different angles. There is great variation in lantern structure among echinoids, but the following applies to most conditions in which it is well developed.

The main structural part of the lantern (Figure 26.10) consists of five pairs of vertically oriented, calcareous, trapezoidal elements connected to form five triangular pyramids, each of which supports a single tooth in a groove called the tooth slide. The interambulacrally positioned pyramids are attached to one another by muscles that pull the pyramids (and the teeth) together to close the jaws. Along the aboral edge of each pyramid is a thickened bar, the epiphysis. Tooth honing occurs by the manner in which small platelets that make up the tooth are worn off, like a self-sharpening chisel. The tooth grows at the proximal end through the constant addition of new platelets where the tooth emerges from the top of the pyramid. This region is covered by a soft dental sac of coelomic origin that encloses the unhardened proximal end of each tooth. With normal wear, the teeth usually grow about 1 mm each week. Atop the main structure of the lantern are five, small, Y-shaped skeletal ossicles known as **compasses**, one along each ambulacral radius. The compasses and associated muscles appear to regulate hydrostatic pressure within the peripharyngeal coelom.

Protractor muscles originate from an interambulacral "lantern girdle" around the mouth and insert small skeletal elements (**rotules**) on the **epiphyses** that are attached to the proximal (upper) end of each pyramid. Contraction of these protractors pulls the entire lantern orally through the mouth, spreading the teeth apart (Figure 26.10A). Retractor muscles originate on thick ambulacral girdle extensions (auricles), inserting on the distal end of the lantern. Additional muscles associated with the pyramids and the rotules produce a variety of tooth movements.

Most urchins with well-developed lanterns use their teeth to scrape algae from the substratum and to bite off chunks of macroalgae. Some species feed on animal matter by similar actions. Some tiny, deep-water urchins nip pieces from sunken wood so that symbiotic microbes in their gut can digest the cellulose and release nutrients into the urchin's gut. Urchins that excavate burrows in hard substrata feed on the algal film that develops on the burrow wall. Others ingest suspended particles or drift algae that enter the chamber, or organic material trapped by spines, tube feet, and pedicellariae. Some irregular urchins

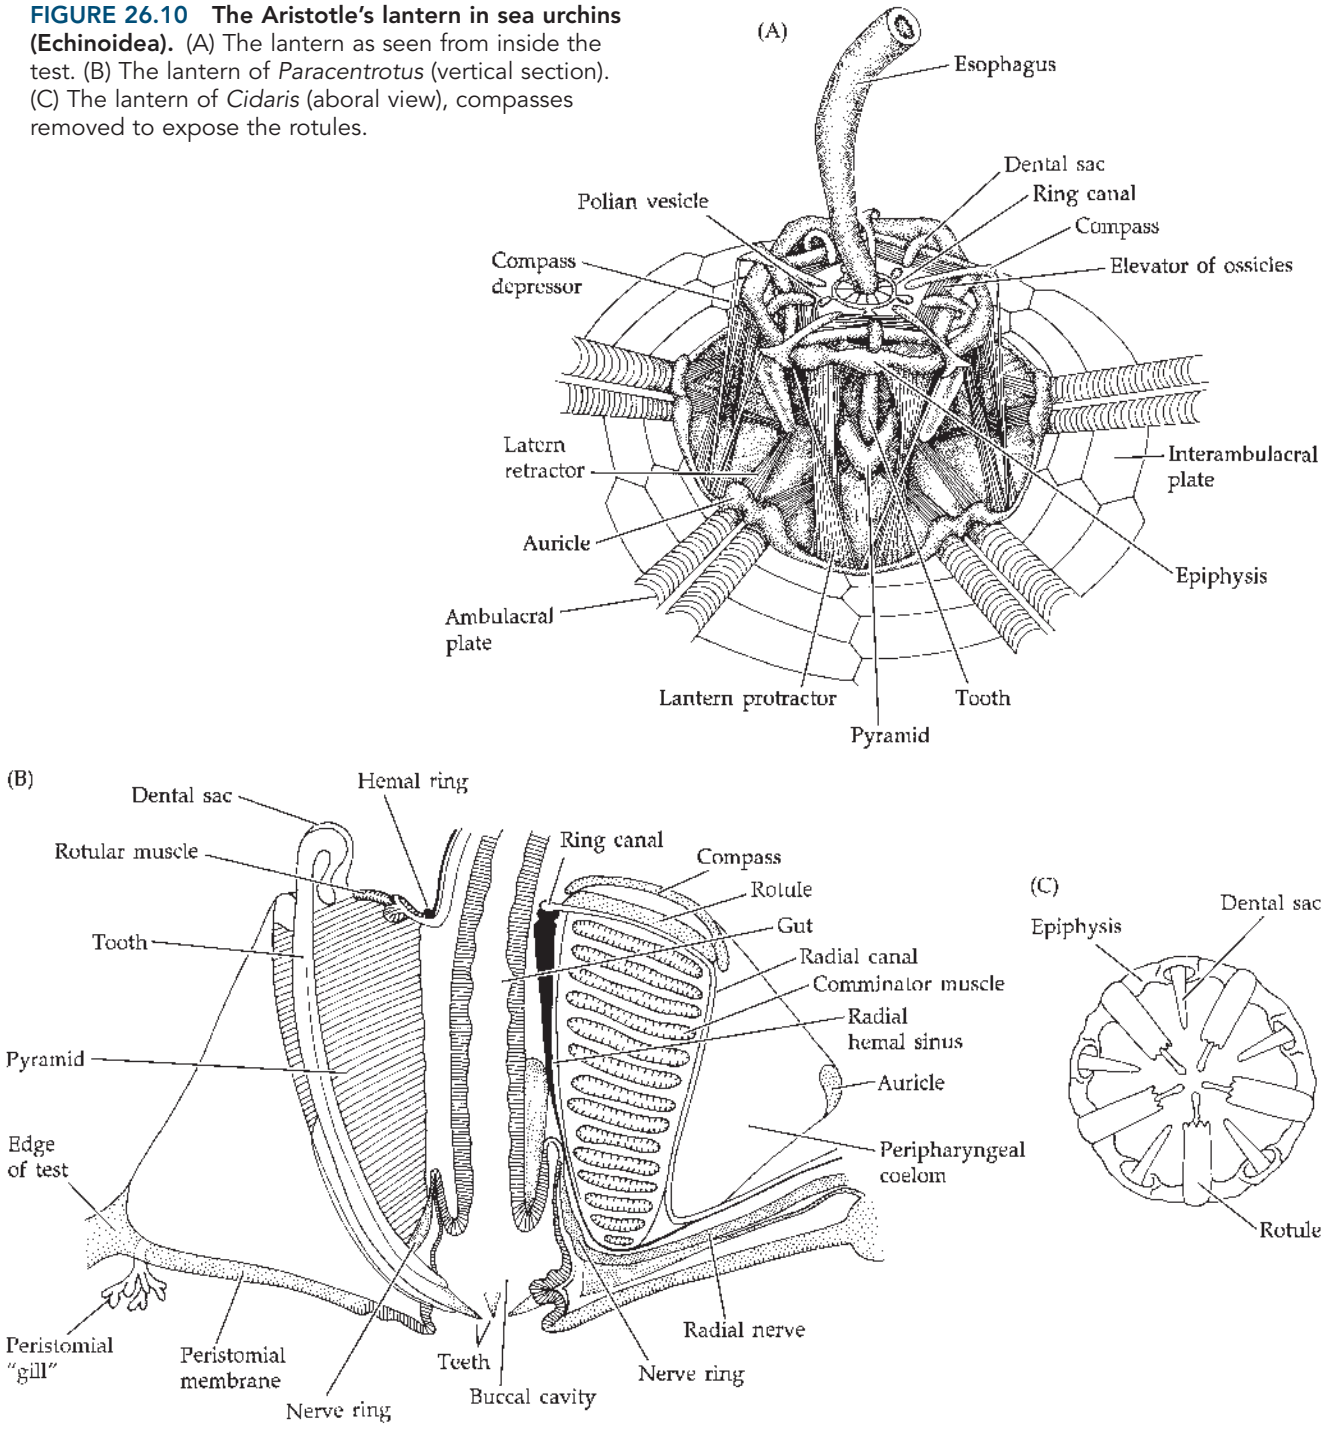

FIGURE 26.10 The Aristotle's lantern in sea urchins (Echinoidea). (A) The lantern as seen from inside the test. (B) The lantern of *Paracentrotus* (vertical section). (C) The lantern of *Cidaris* (aboral view), compasses removed to expose the rotules.

(e.g., cassiduloids and echinoneoids) lose the lantern before adulthood, and spatangoid heart urchins never develop one. Spatangoids burrow and swallow the sediment to digest the contained organic material (Figure 26.11G). Tube feet can be used to sort food material from the mud or sand and pass it to the mouth. The superimposed bilateral symmetry derived from evolutionary movement of the anus from the apical system to a functional "posterior" in irregular echinoids is an adaptation to sediment-swallowing habits, much as in an earthworm.

Most sand dollars are "podial particle pickers," possessing a highly modified lantern with nonprotractable teeth that act as a crushing mill. As they move over the sediment, sand dollars select organic-rich material using thousands of miniaturized tube feet distributed in fields over the oral surface, add mucus to the particles, and pass them into food grooves. Specialized tube feet act as a "bucket brigade" to shunt mucus-coated particle trains to the mouth (Figure 26.11E). Related to the sand dollars, sea biscuits feed on larger particles, including bits of seagrass.

(D) Digestive system of the sand dollar *Echinarachnius parma* (aboral view, test dissected away). (E) Food groove on oral surface of a sand dollar (cutaway view), tube feet moving food toward the mouth. (F) *Dendraster excentricus* in feeding position, half-buried in substratum. (G) A heart urchin, *Echinocardium cordatum*, in its burrow. (A,C after W. M. Reid. 1950. In F. A. Brown [Ed.], *Selected Invertebrate Types*. John Wiley and Sons, New York.)

Dendraster excentricus buries the anterior portion of its body in the sand so that the posterior part extends upwards above the sediment (Figure 26.11F), trapping diatoms and other particulate food in the water with its tube feet and ingesting it as described above. Tiny crustaceans can be captured by the pedicellariae. Members of most populations of *Dendraster* position themselves in groups oriented edgewise into the current, exploiting hydrodynamic properties of ambient flow to enhance each other's food collection process. Some sand dollars have high-density sand grains (especially those containing iron oxides) stored in a diverticulum of the gut as ballast to help stabilize their position on the sea bottom. Microechinoids (e.g., *Echinocyamus*) nestle among coarse sand grains, which are brought to the mouth by tube feet, then rotated by the peristomial membrane and tube feet as the teeth scrape off attached diatoms and organic detritus.

The digestive system of echinoids is essentially a simple tube from mouth to anus. The mouth is at the center of the oral surface, or it is shifted slightly anteriorly in some irregular urchins; the anus is on the aboral surface, located centrally or shifted posteriorly. An esophagus extends through the vertical axis of the lantern (when present) to join an elongate stomach-intestine (Figure 26.11A,B,D). In most echinoids, a narrow duct (the **siphon**) parallels the intestinal tract for part of its length. Both ends of this siphon open to the intestine, possibly providing a shunt for excess water taken in with the food. In many species, blind ceca of uncertain function arise from the gut near the junction of the esophagus and stomach-intestine. The intestine narrows into a short rectum leading to the anus, located either centrally in the apical system or at various points along the posterior interambulacrum. Digestive enzymes are produced by the intestinal and cecal walls, and breakdown is largely extracellular.

Holothuroidea Most sea cucumbers are suspension or deposit feeders. Many of the sedentary epibenthic or nestling forms (e.g., *Eupentacta, Psolus, Cucumaria*) extend their branched, mucus-covered tentacles (Figure 26.12D,E) into the water to trap suspended material, including live plankton and organic detritus. The tentacles are then pushed into the mouth one at a time and the food ingested (Figure 26.12F). A supply of mucus is provided by secretory cells in papillae on the tentacles and gland cells of the foregut.

More active epibenthic types (e.g., *Stichopus*) crawl across the substratum and use their tentacles to collect and ingest sediment and organic detritus (Figure 26.12C). Studies indicate that some holothuroids (e.g., *Stichopus*, *Holothuria*) are highly selective deposit feeders, preferentially collecting sediments rich in organic content. Many apodid holothuroids ingest sediment as they burrow through the substratum by peristaltic movements.

The anterior mouth is surrounded by a whorl of buccal tentacles. The esophagus (or pharynx) leads inward and passes through a ring of calcareous plates supporting the foregut and ring canal of the water vascular system. The esophagus joins an elongate intestine, the anterior of which is often enlarged as a stomach. The intestine, along which digestion and nutrient absorption occurs, extends posteriorly, loops forward, and then posteriorly again, sometimes in coils (Figure 26.12A,B). The intestine terminates in an expanded rectum leading to the posterior anus. The rectal area is attached to the body wall by a series of suspensor muscles and often bears highly branched outgrowths, the **respiratory trees**, that extend anteriorly within the body cavity. Water is pumped via the anus into the trees for gas exchange (Figure 26.12A,B,H).

The digestive system of sea cucumbers exhibits two fascinating phenomena: (1) auto-evisceration and (2) the discharge of structures called Cuvierian tubules (Figure 26.12H,I). Evisceration is the expulsion by autotomy and muscular action of part or all of the muscles, digestive tract, and sometimes other organs, including the respiratory trees and gonads. These lost parts are usually regenerated. In some forms, these structures are expelled following rupture of the hindgut region. In others, rupture occurs anteriorly and the feeding tentacles and foregut are lost. Evisceration can be induced in the lab by chemical stress, physical manipulation, and crowding, but it also occurs in nature in some species, although its significance remains unclear. It is viewed by some as a seasonal event associated with adverse conditions, and by others as a defense mechanism wherein eviscerated parts serve as sacrificed decoys.

Cuvierian tubules are clusters of sticky, blind tubules arising from the base of the respiratory trees in certain genera (e.g., *Actinopyga*, *Holothuria*) (Figure 26.12A,H,I). When threatened, these holothuroids aim the anus at the potential predator and contract the body wall to discharge the tubules by rupturing the hindgut, everting the tubules onto the predator and entangling it in a mass made extremely sticky by secretions from the tubules. The Cuvierian tubules are regenerated. Such elaborate defense mechanisms are important, since holothuroids can fall prey to various fishes, starfish, gastropods, crustaceans, and even humans.

Circulation and Gas Exchange

Circulation Internal transport in echinoderms is accomplished largely by the main perivisceral coeloms, variously augmented by hemal and water vascular systems (Figure 26.13), both of which are derived from the coelom. Fluids move through these systems primarily by ciliary action and in some cases by muscular pumping. In at least one species of sea urchin (*Lytechinus variegatus*), coelomic fluid is known to be driven by movements of Aristotle's lantern.

(I) Release of Cuvierian tubules by *Holothuria*.

The hemal system is a complex array of canals and spaces, mostly enclosed within coelomic channels called **perihemal sinuses**. The system is best developed in holothuroids, in which it is bilaterally arranged, and in crinoids, in which the channels can form netlike plexi. In other groups the system is radially arranged and generally parallels the elements of the water vascular system consisting of oral and aboral **hemal rings**, each with radial extensions. The two rings are connected by an axial sinus (Figure 26.13A) that lies against the stone canal. Within the axial sinus there is a core of spongy tissue called the **axial gland**, thought to be responsible for producing certain coelomocytes. Radial hemal channels extend from the aboral ring to the gonads. Other radial channels arise from the oral hemal ring and are associated with the rows of tube feet; these channels are housed within a perihemal space called the hyponeural sinus (Figures 26.3B and 26.13A). A third hemal ring, the gastric ring, occurs in many echinoderms, including most asteroids, and is associated with the digestive system.

Cilia move fluid through the hemal system. In asteroids and most echinoids the axial sinus bears a **dorsal sac** near its junction with the aboral hemal ring. This sac pulsates, likely to aid fluid movement within hemal spaces. The hemal system of holothuroids includes an elaborate set of vessels intimately associated with the digestive tract (Figure 26.13B) and, when present, the respiratory trees. In many holothuroids the hemal system can include a multitude of "hearts" or circulatory pumps.

The function of the hemal system is not fully understood, but it probably helps distribute nutrients absorbed from the digestive tract. Experiments on the starfish *Echinaster graminicola* show that absorbed nutrients appear in the hemal system within a few hours after feeding and eventually concentrate in gonads and tube feet. In sea cucumbers the hemal system probably also plays a role in gas exchange because some of the vessels are in contact with the respiratory trees.

Gas exchange Most echinoderms rely on thin-walled external processes as gas exchange surfaces. Crinoids apparently exchange oxygen and carbon dioxide between the coeloms and the ambient seawater across all exposed thin parts of the body wall, especially the tube feet. Only ophiuroids and holothuroids have specific internal organs for respiration. Given the relatively large coelomic volumes of many echinoderms, and the lack of circulatory connections from the inside to the outside of the body wall, coelomic fluid transport mechanisms figure prominently in internal gas exchange, whereas external tissues exchange directly with the ambient seawater.

Gas exchange in asteroids occurs across tube feet and special outpocketings of the body wall called **papulae** (Figure 26.14A,B), which are evaginations of the epidermis and peritoneum. Both tissues are ciliated to produce currents in both the coelomic fluid and the overlying water. The two currents move in opposite directions, setting up countercurrents that maximize concentration gradients across the surfaces of papulae.

Ophiuroids possess ten invaginations of the body wall, called **bursae**, that open to the outside via ciliated slits (Figure 26.9A,C). Water circulates through the bursae by cilia and, in some species, by muscular pumping of the bursal walls. Gases are exchanged between flowing water and body fluids. Hemoglobin occurs in the coelomocytes of a few species of ophiuroids.

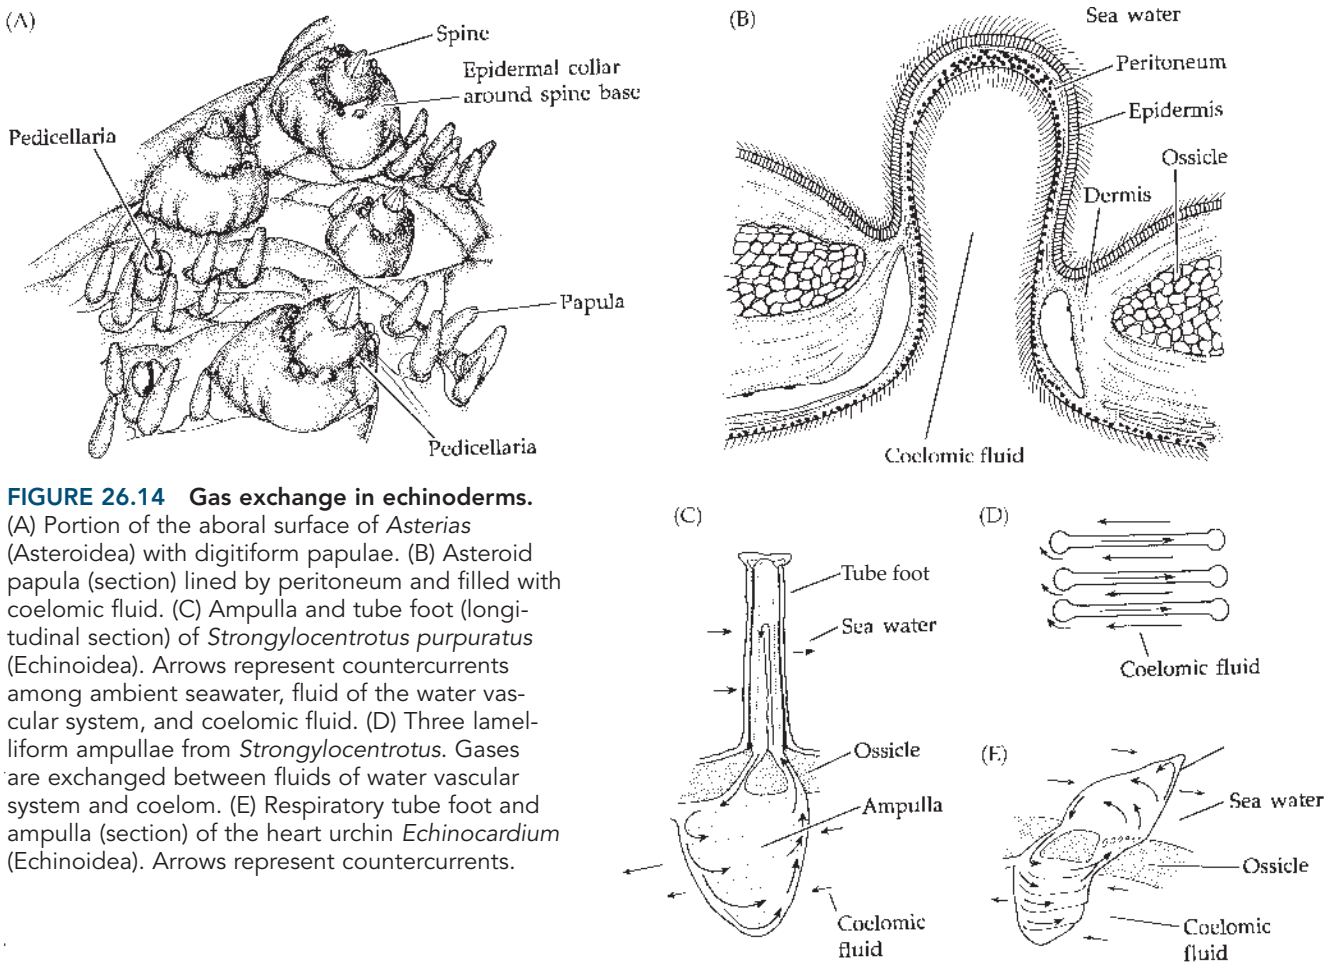

FIGURE 26.14 Gas exchange in echinoderms. (A) Portion of the aboral surface of *Asterias* (Asteroidea) with digitiform papulae. (B) Asteroid papula (section) lined by peritoneum and filled with coelomic fluid. (C) Ampulla and tube foot (longitudinal section) of *Strongylocentrotus purpuratus* (Echinoidea). Arrows represent countercurrents among ambient seawater, fluid of the water vascular system, and coelomic fluid. (D) Three lamelliform ampullae from *Strongylocentrotus*. Gases are exchanged between fluids of water vascular system and coelom. (E) Respiratory tube foot and ampulla (section) of the heart urchin *Echinocardium* (Echinoidea). Arrows represent countercurrents.

Typical sea urchins possess five pairs of lobate gills around the **peristome**, or the opening in an echinoid test surrounding the mouth (Figure 26.11B,C). These were long viewed as important gas exchange organs. However, various authors have provided evidence of a different function. The pressure within these gills changes by manipulation of the compasses of Aristotle's lantern, so gills probably function to accommodate pressure changes in the peripharyngeal coelom during movements of the lantern and perhaps to enhance oxygen supply to associated muscles. The main gas exchange structures in urchins are thin-walled tube feet that operate on a countercurrent system similar to that associated with the papulae of asteroids (Figure 26.14C,D). Irregular urchins such as heart urchins and sand dollars bear highly modified respiratory tube feet arranged in modified aboral ambulacral regions of the test called **petaloids** (Figure 26.2E,J). Respiratory tube feet are leaflike and thin walled to serve as gas exchange surfaces. A countercurrent flow occurs between water vascular system fluid in the tube foot and seawater, and between water vascular system fluid in the internal ampullae and coelomic fluid.

In the respiratory trees of certain holothuroids, water is pumped in and out of the hindgut and branches of the respiratory trees, and gases are exchanged between the water and the coelomic and hemal systems. This process is augmented by exchange across the tube feet, which is facilitated by a countercurrent system. Hemoglobin occurs in the coelomocytes of many holothuroids.

Excretion and Osmoregulation

Excretion In most echinoderms, dissolved nitrogenous wastes (ammonia) diffuse across body surfaces to the outside. This type of excretion occurs across the tube feet and papulae in asteroids and is suspected to occur across the paired respiratory trees in holothuroids.

Precipitated nitrogenous material and other particulate wastes are phagocytized by specialized coelomocytes in body fluids and then discharged by various methods. In asteroids, waste-laden coelomocytes can accumulate in papulae, which then pinch off their distal ends, expelling the cells and waste material. Some studies suggest that rectal glands might also be involved in excretion. In ophiuroids it is suspected that coelomocytes deliver wastes to the bursae, where they are released. Phagocytic coelomocytes in echinoids accumulate wastes and transport them to the tube feet and gills for release. In holothuroids, particulate wastes are carried by coelomocytes to the respiratory trees,

gut, and even the gonads, and released to the outside. Crinoid coelomocytes deposit wastes in tiny pockets along the sides of the ambulacral grooves.

Osmoregulation Echinoderms are generally strictly marine stenohaline creatures that do not have to deal with severe osmotic and ionic regulation. However, some species have been reported from brackish water. For example, *Asterias rubens* (Asteroidea) has been collected from the Baltic Sea (8% salinity), *Ophiophragmus filograneus* (Ophiuroidea) from Cedar Key, Florida (7.7% salinity), and various holothuroids from the Black Sea (18% salinity). Some mechanism must allow these taxa to survive in such low salinities, but it is, as yet, unknown. Evidence suggests that echinoderms are osmoconformers. Both water and ions pass relatively freely across thin body surfaces, and the tonicity of the body fluids varies with environmental fluctuations. There appears to be some ionic regulation through active transport, but it is minimal.

Nervous System and Sense Organs

The derived pentaradiality of echinoderms is clearly reflected in the anatomy of their nervous systems and the distribution of their sense organs. The nervous system is decentralized, somewhat diffuse, and without significant ganglia. There are three main neuronal "systems," integrated with one another and developed to varying degrees among the clades: ectoneural (oral), hyponeural (deep oral), and entoneural (aboral). The **ectoneural system** is predominately sensory, although motor fibers do occur; the **hyponeural system** is largely motor in function. The **entoneural system** is absent from holothuroids and reduced to different degrees in other groups—except the crinoids, in which it is the primary nervous system, serving both motor and sensory functions. Note that these terms refer only to the *position* of the neuronal systems, not to their embryological origins.

The three systems are interconnected by a nerve net derived primarily from ectoneural and entoneural components. The net is described as a subepidermal plexus, but it gives rise to intraepidermal neurons and clearly has an intimate association with the epithelium both internal and external to the body wall. Except for crinoids, in which the entoneural component predominates, the most obvious nerves in echinoderms are derived from the ectoneural system. A circumoral nerve ring just beneath the oral epithelium encircles the esophagus. From this ring arise radial nerves extending along each ambulacrum. In starfish, these radial nerves appear as a distinct V-shaped, epidermal thickening in each ambulacral groove (Figure 26.3B). The entoneural nerve plexus also produces radial cords, such as those along the margins of asteroid arms. The hyponeural system generally parallels the nerves of the ectoneural system. Hyponeural neurons are subepidermal and lie near the hyponeural sinus of each ambulacral area (Figure 26.3B), giving rise to motor fibers and ganglia in the tube feet.

Sensory receptors are largely restricted to relatively simple epithelial structures innervated by a plexus of the ectoneural system. Frequently associated with outgrowths of the body wall, such as spines and pedicellariae, sensory neurons in the epidermis respond to touch, dissolved chemicals, water currents, and light. Photoreceptors occur in asteroids as light-sensitive regions comprising pigment-cup ocelli at the tips of the arms. Some brittle stars (e.g., *Ophiocoma*) have a comprehensive network connecting opsin-containing cells across the body surface. Statocysts are known in some holothuroids, while in certain echinoids there are structures called **sphaeridia** that are thought to function in georeception. Chemoreception is understudied in echinoderms, but some evidence suggests that buccal tentacles of holothuroids and oral tube feet of echinoids are sensitive to dissolved chemicals. Chemoreception in asteroids appears to depend largely on direct contact, although distance chemoreception is reported in some species. Larvae are reported to respond to pheromones in the water column in order to metamorphose.

In spite of their rather simple nervous system and lack of specialized sense organs, many echinoderms engage in complex behaviors. Time-lapse videos of echinoderms reveal that they have complex interactions similar to any invertebrate—they just do nearly everything at such a slow pace that it is difficult to notice. There is still much to be learned about functional mediation between circuitry of the nervous system and observed behavioral responses, as in coordination of tube feet and spines during locomotion. Most echinoderms exhibit distinct righting behaviors when overturned—actions involving touch, georeception, and perhaps photoreception. Orientation to currents is known in some sand dollars and in many ophiuroids and crinoids, and responses to potential predators often include coordination of spine movements, pedicellariae, and locomotion.

Reproduction and Development

Regeneration and asexual reproduction Echinoderms have remarkable powers of regeneration. Tide pool observers often encounter starfish regenerating a new arm, or notice tube foot suckers left on a rock from which a starfish or urchin has been pulled free. Lost suckers are quickly replaced by regeneration. During the processes of evisceration and expulsion of Cuvierian tubules, multiple lost organs are replaced. Damage to the test of echinoids, even perforation and loss of plates, is usually followed by healing and regeneration of the plates and associated appendages. Studies have put to rest tales of oystermen claiming

for more ebook/ testbank/solution manuals requests email:960126734@qq.com

that chopping starfish into small pieces resulted in regeneration of an entire new animal from each part. Although a damaged animal can grow new arms if a substantial portion of the central disk remains intact, an isolated arm soon dies. However, an exception to this is *Linckia*, which can regenerate an entire individual from a single arm, the regenerating stage being appropriately called a **comet** (Figure 26.15). Ophiuroids and crinoids frequently cast off arms or arm fragments when disturbed, then regenerate the lost part. Such autotomy is also documented for certain asteroids. The Pacific coast ochre star, *Pisaster ochraceus*, autotomizes arms at their junction with the central disk when confronted by predators. Deep-sea isocrinid sea lilies autotomize distal portions of their stems to distract echinoid predators.

Asexual reproduction occurs in some asteroids, ophiuroids, and holothuroids by **fissiparity**. In the stellate forms the central disk divides in two, and each half forms a complete animal by regeneration. When forms such as certain species of the small six-rayed brittle star *Ophiactis* divide, each half retains three arms. Asexual fission also occurs in some holothuroids, but the process is not well understood.

Sexual reproduction The majority of echinoderms are gonochoristic, but hermaphroditic species are known among asteroids, holothuroids, and especially ophiuroids. The reproductive system is relatively simple and intimately associated with derivatives of the coelom. Gonads are usually housed within genital sinuses lined with peritoneum. Holothuroids are unique among extant echinoderms in possessing a single gonad, which lies "dorsally" (Figure 26.12A,B). A single gonoduct opens between the bases of two "dorsal" buccal tentacles or just posterior to the tentacular whorl, and this is why they often raise the oral end when spawning.

Crinoids lack distinct gonads. Gametes arise from the peritoneum of special coelomic extensions, called genital canals, in the pinnules extending from the proximal portion of each arm. There are no gonoducts; gametes are released by rupture of pinnule walls. Ophiuroids possess from one to many gonads attached to the peritoneal side of each bursa adjacent to the bursal slits (Figure 26.9A). Gametes are released into the bursae and expelled through the slits.

Asteroids and echinoids possess multiple gonads (Figures 26.8C and 26.11B) with gonoducts leading to interambulacral gonopores (Figure 26.8A). Typical sea urchins contain five gonads, one in each interradius. Gonopores are located on the five interambulacral genital plates of the apical system (Figures 26.3F and 26.11A). The **periproct** (the opening of an echinoid test surrounding the anus) and anus have migrated posteriorly in irregular urchins, but the genital plates remain more or less centrally located on the aboral surface. In most irregular echinoids there are only four (and sometimes fewer) gonads, one being lost along the line of migration of the anus, with corresponding reduction in number of gonopores. In urchins typically one of the genital plates is perforated and functions as a madreporite.

Echinoderm life history strategies vary, from free spawning followed by external fertilization and indirect development, to various forms of direct development and brooding. Studies indicate that spawning is mostly a nocturnal event, wherein the animals assume characteristic postures with their bodies elevated off the substratum, especially holothuroids, asteroids, and ophiuroids. In at least some asteroids and echinoids, gametogenesis is regulated by photoperiod, which ensures more or less synchronous spawning among members of the same population. In some species of free-spawning asteroids, females release pheromones that stimulate sperm release from nearby conspecific males, and many species aggregate before spawning to enhance fertilization success.

Brooding is especially common among boreal and polar species (in all groups of echinoderms) (Figure 26.16C) and in certain deep-sea asteroids, whose environments might be unfavorable for larval life. Brooding species produce fewer but larger and yolkier eggs than do their free-spawning counterparts. Among the crinoids, *Antedon* and a few others cement their eggs to the epidermis of the pinnules from which they emerge (Figure 26.16A,B); once eggs are fertilized by free sperm, embryos are held by the parent until hatching. Most brooding asteroids hold embryos on the body surface. One species from the northeastern Atlantic and Mediterranean (*Asterina gibbosa*) cements its eggs to the substratum, and another from the northwestern Atlantic (*Leptasterias tenera*) broods its early embryos in the pyloric stomach before moving them to the outer body surface. The deep-sea *Xyloplax* and caymanostellid wood stars (Figure 26.1G) seem to brood within the gonads, releasing juveniles that drift or crawl away. Brooding is common among ophiuroids. Sperm enter the bursae and fertilize the eggs, and embryos are held within these sacs during development. Some echinoids brood embryos and young urchins among clusters of spines on the body, around the peristome, in depressions caused by the sunken petaloids of females or, remarkably, in body wall invaginations at the apical system through which the urchins are "born." Brooding holothuroids usually carry their embryos externally (Figure 26.16C), but some species of *Thyone* and *Leptosynapta* brood inside the coelom.

Development The tremendous numbers of eggs produced by many echinoderms, and the ease with which they can be reared in the laboratory, have made many of these animals embryological model organisms, from studying the original characterization of the dynamic changes of transcription during embryogenesis to analyses of gene regulatory networks. Much of our information about biology of animal fertilization and early development comes from over a century of work on urchins and starfish, and early ontogeny of some echinoderms serves as a model of deuterostome development. Except in brooding species, in which development is modified by large amounts of yolk, the sequence of ontogenetic events is remarkably similar throughout the phylum.

for more ebook/ testbank/ solution manuals requests, email: 960126734@qq.com

It is impossible to completely cover the vast amount of information on this subject; what is provided here is only a brief overview of indirect development based largely on urchins and asteroids, including some comparative comments on other taxa. As you read this section, keep in mind the fact that echinoderm development produces two very different body organizations in succession: first a bilaterally symmetrical larva and later a radially symmetrical adult.

In free-spawning echinoderms, after sperm enters the vitelline layer on the egg, a fertilization membrane forms (which facilitates recognition of which eggs have been fertilized). The ova are usually isolecithal with relatively small amounts of yolk. Cleavage is radial, holoblastic, and initially equal or subequal, leading to a spacious coeloblastula. In groups such as echinoids, cleavage preceding the blastula becomes unequal, resulting in blastomere tiers of animal pole **mesomeres** underlain by slightly larger **macromeres** and a cluster of **micromeres** at the vegetal pole. (These terms refer only to the relative sizes of the cells and are not to be confused with the same terms used in describing spiral cleavage.) The coeloblastula usually becomes ciliated and breaks free of the fertilization membrane as a swimming embryo. As in many other phyla, this stage of development is known as the **primary larva**, characterized in part by the **apical organ**—a cluster of ciliated cells with sensory ability thought to aid in orientation of the larva during settlement. Although there is evidence that the apical organ is homologous across many invertebrate phyla, the number of cells in, and the overall shape of the apical organ varies among the five echinoderm classes.

The blastula flattens slightly at the vegetal pole, forming the gastral plate from which some cells proliferate into the blastocoel as primary or larval mesoderm (sometimes called "mesenchyme"), which is destined to become larval muscles, skeletal elements (Figure 26.17G), and coelomic pouches. In most echinoids these cells are micromeres. The surrounding macromeres are presumptive endoderm and adult mesoderm; the vegetal mesomeres are presumptive ectoderm. A coelogastrula is produced by invagination of the vegetal pole cells. The blastopore typically forms the anus; the archenteron grows to connect with a stomodeal inpocketing that forms the mouth. Before the gut is complete, the inner end of the archenteron proliferates, as do one or two evaginations of mesoderm, into the blastocoel. Thus, coelom formation is by archenteric pouching (enterocoely).

Some types of echinoderm larvae also develop a **larval skeleton**, composed of spicules and ossicles. The functions of the larval skeleton include defense, physical support, sites of muscle attachment, and passive orientation of larvae in the form of "arms" (not homologous to arms of starfish and other echinoderm adults) that aid in swimming and feeding. The larvae

of some echinoderms have distinctive reddish pigment spots that contain carotenoproteins, red pigments that can react to light and change the characteristics of cell membranes. The specific functions of these pigments in echinoderm larvae remain unknown. Planktotrophic echinoderm larvae use bands of cilia along the "arms" or on the body itself to swim and generate feeding currents. However, lecithotrophism is common and apparently evolved numerous times within some echinoderm classes.

In order to understand the development of echinoderm larvae and their eventual metamorphosis to radially symmetrical adults, it is necessary to examine the embryogeny and fates of the coeloms. There are some differences in details among groups, but there is enough similarity to allow a generalized summary. The initial archenteric pouching occurs from the blind end of the developing gut, either as a pair of coeloms or as one cavity that divides into two. These coeloms pinch off another pair of cavities posteriorly, and then a third pair between the anterior and posterior ones (Figure 26.18A). From front to back, these pairs of coelomic spaces are the left and right **axocoels** (known in other deuterostomes as the protocoels), the hydrocoel and "dorsal sac" (left and right mesocoels), and left and right somatocoels (metacoels in the nonechinoderm literature), as seen in other trimeric deuterostomes. The left axocoel and hydrocoel remain connected to one another. From the left axocoel-hydrocoel complex, a "hydrotube" extends to the "dorsal" surface of the larva, opening to the outside via a hydropore. The dorsal sac becomes associated with the hydrotube leading to the hydropore. Usually, the right axocoel disappears.

The fates of coelomic derivatives are outlined in Table 26.1. As the time for metamorphosis approaches, the larva swims to the bottom, selecting and attaching to an appropriate substratum. In general, the larval left and right sides become the adult oral and aboral surfaces, respectively, although this pattern does not always reflect a precise 90° reorientation. The change from bilateral to radial symmetry involves shifts in the positions of mouth and anus, which both close during

TABLE 26.1 Adult Fates of the Major Coelomic Derivatives in Generalized Echinoderm Development

Embryonic Coelomic Structure	Adult Fate
Right somatocoel	Aboral perivisceral coelom; imperforate extraxial body wall
Left somatocoel	Oral perivisceral coelom; genital sinuses; most of the hyponeural sinus; perforate extraxial body wall
Right axocoel	Largely lost
Hydropore	Incorporated into madreporite
Hydrotube and dorsal sac	Parts of madreporite vesicle and ampulla
Stone canal	Stone canal
Left hydrocoel	Axial region; ring canal; radial canals; lining of tube feet lumina, plus other components of the water vascular system, including Tiedemann's bodies and Polian vesicles

metamorphosis. Typically, embryonic openings disappear, and the stump of the foregut swings from its larval anteroventral location to the left side within the developing rudiment. The hindgut moves anteriorly and to the right (Figure 26.18B,C). Once in the adult positions, the mouth and anus reopen. Aborally, the madreporite complex arises from various parts of the left axocoel and its derivatives plus the dorsal sac. The axial sinus arises from an outpocketing of the left axocoel. The hydrocoel forms a crescent around the foregut as precursor to the ring canal, which grows radial extensions (Figure 26.18D,E), the primary lobes, destined to become the radial canals and all their derivatives. The ring canal closes to form a torus. Outgrowths of the left somatocoel produce the hyponeural sinus, interacting with the primary lobes to elaborate the structure of the rudiment. The left somatocoel comes to lie just internal to the hydrocoel, interacting with it to pattern the body cavities of the adult. The right somatocoel "stacks" just internal to the left somatocoel, forming a quasi-linear anterior-posterior axis during a process called "coelomic stacking." As these transformations take place, much of the original larval body is lost or resorbed, and the juvenile assumes benthic life. Although echinoderms are noted for this remarkable metamorphosis, it is expressed to varying degrees in the different classes because of differential expression of the axial and extraxial components that are related to the rudiment and larval body, respectively.

Echinoderm Phylogeny

Living echinoderms are so highly derived compared with other deuterostomes that meaningful comparisons of adult body plans seem almost futile. In spite of a rich fossil record and many decades of work, the origin and subsequent evolution of echinoderms remain controversial, stemming from differing interpretations of echinoderm homologies originating from various sources in paleontology, morphology, and embryology. Importantly, however, all data support the idea that each extant class is monophyletic. But there is much more contention concerning the relationships among fossil taxa.

First Echinoderms

Echinoderms have an abundant fossil record with 13,000 to 15,000 recognized species. They likely originated with a Precambrian/Cambrian infaunal bilaterian deuterostome with similarities to the sister group of the echinoderms, the hemichordates. Echinoderms diversified rapidly, and fundamental body plans of almost all groups have roots in the early Cambrian, possibly back to the Fortunian Age. By the end of the Ordovician, all the extant classes had been established. Diversity and disparity among what seem now to be bizarre forms reached their zenith during the early to mid-Paleozoic (Figure 26.19). By the beginning of the Mesozoic, this disparity among major taxa had declined greatly, leaving the five extant classes persisting to the present.

Echinoderm origins involved modifications to the ancestral, bilaterian trimeric larval trajectory such that the hydrocoel could initiate the appearance of the pentaradial adult with its unique water vascular system. Coupled with evolution of the stereom endoskeleton, these traits make it easy to distinguish echinoderms from all other early phyla (Figure 26.20). However, all echinoderm larvae retain their ancestral bilateral, trimeric condition. The expression of genes that dictate radiality thus occur relatively late in development, and the evolution of radiality must have involved major modifications of the roles of certain homeobox genes.

There are differing opinions about the significance of extinct groups such as the carpoids, helicoplacoids, and ctenocystoid homalozoans. Some members of these groups did not have the full complement of five rays (Figure 26.19A,B), and they are thus considered by some to be fossilized representatives of the transition to

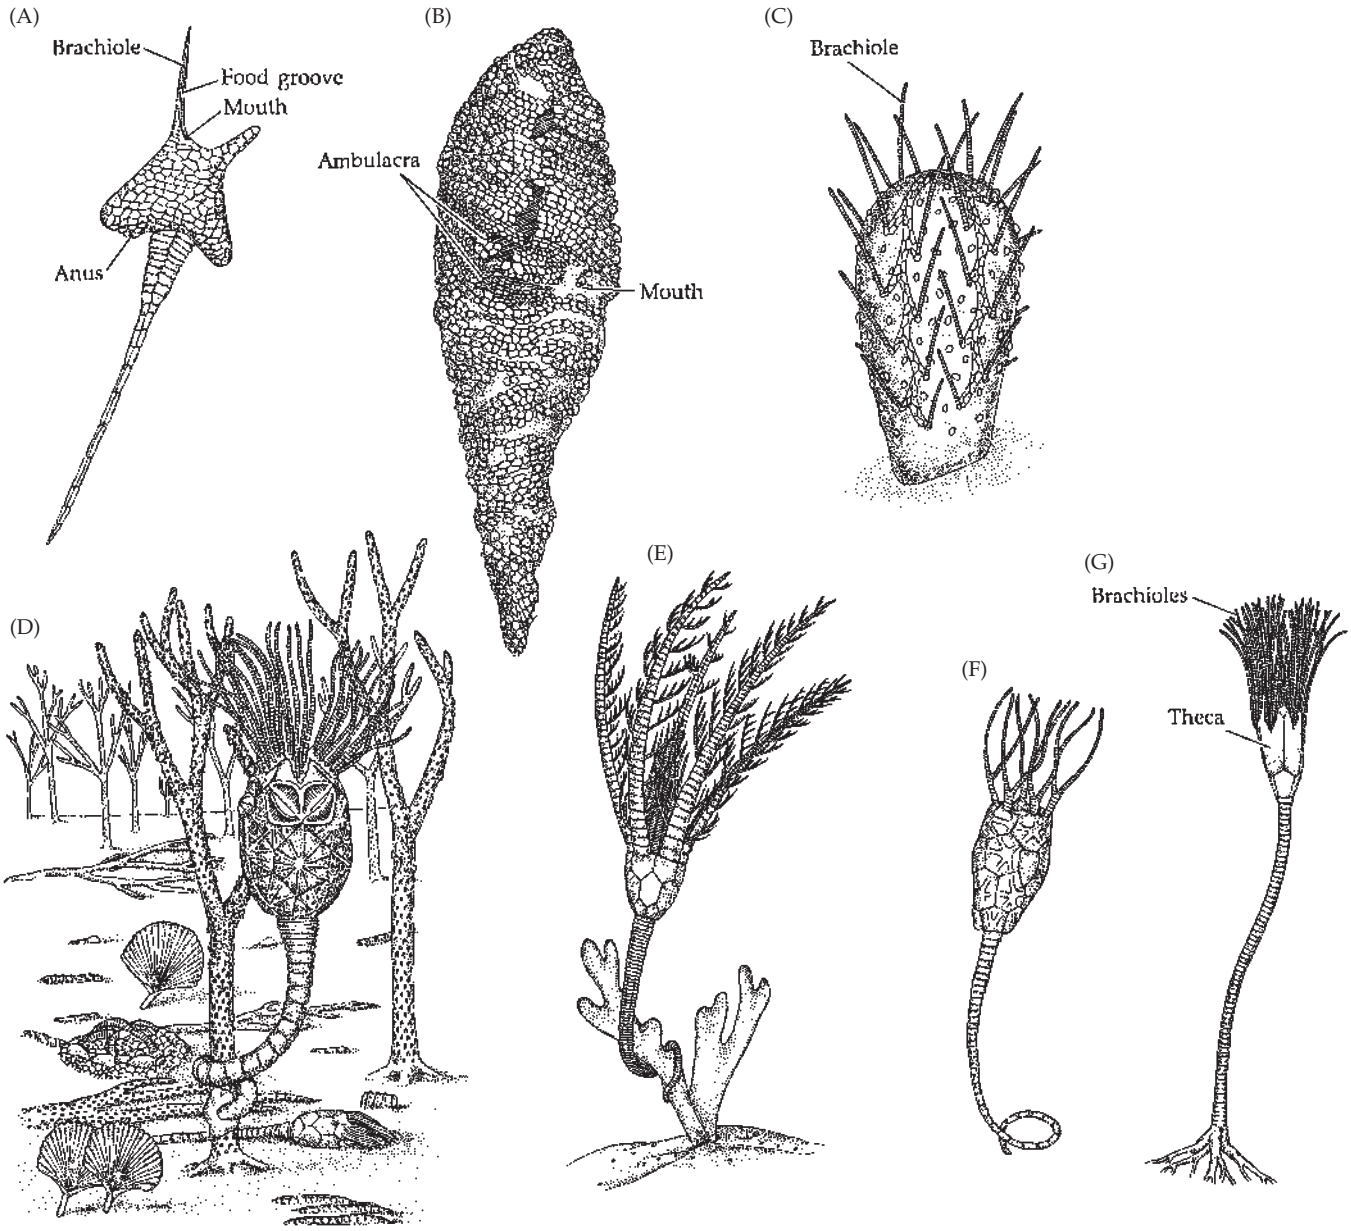

FIGURE 26.19 Fossil echinoderms. (A) *Dendrocystites*, an early Cambrian carpoid with a single brachiole. (B) *Helicoplacus*, a triradiate echinoderm from the lower Cambrian. (C) A generalized cystoid. (D) *Lepadocystis*, a stalked Ordovician cystoid. Note the edrioasteroid in the background, attached to the substratum. (E) *Eifelocrinus*, an extinct crinoid. (F) The eocrinoid *Macrocystella*. (G) A generalized blastoid from the Carboniferous.

pentaradiality. This hypothesis makes certain assumptions about the homologies of various feeding appendages, structures supposed to be gill slits, and a superficial bilateral morphology in the skeleton.

Other workers have applied models of echinoderm homology and embryology to argue that the first echinoderms were likely already pentaradial. If this is true, forms such as *Stromatocystites* are representative of the earliest echinoderms, with the pentaradial axial region expressed as narrow ambulacra. These thin rays remain embedded in the oral, perforate extraxial region marked by the hydropore, anus, and other small body openings (Figure 26.4A). The imperforate extraxial region is a large component devoid of orifices that aborally sealed the body wall. Under this view, nonpentaradial forms (Figure 26.19A), or the bizarre helicoplacoids (Figure 26.19B), are not representatives of earliest echinoderms, but offshoots from the main lineages leading to other major echinoderm clades—lineages that were ancestrally pentaradial (Figure 26.20). Thus, this view sees the first echinoderms as already being pentaradial, and the hydrocoel having already established pentaradiality at the cost of larval bilaterality (which is completely obliterated in the adult). Also in this view, there can be

for more ebook/ testbank/ solution manuals requests email 960126734@qq.com

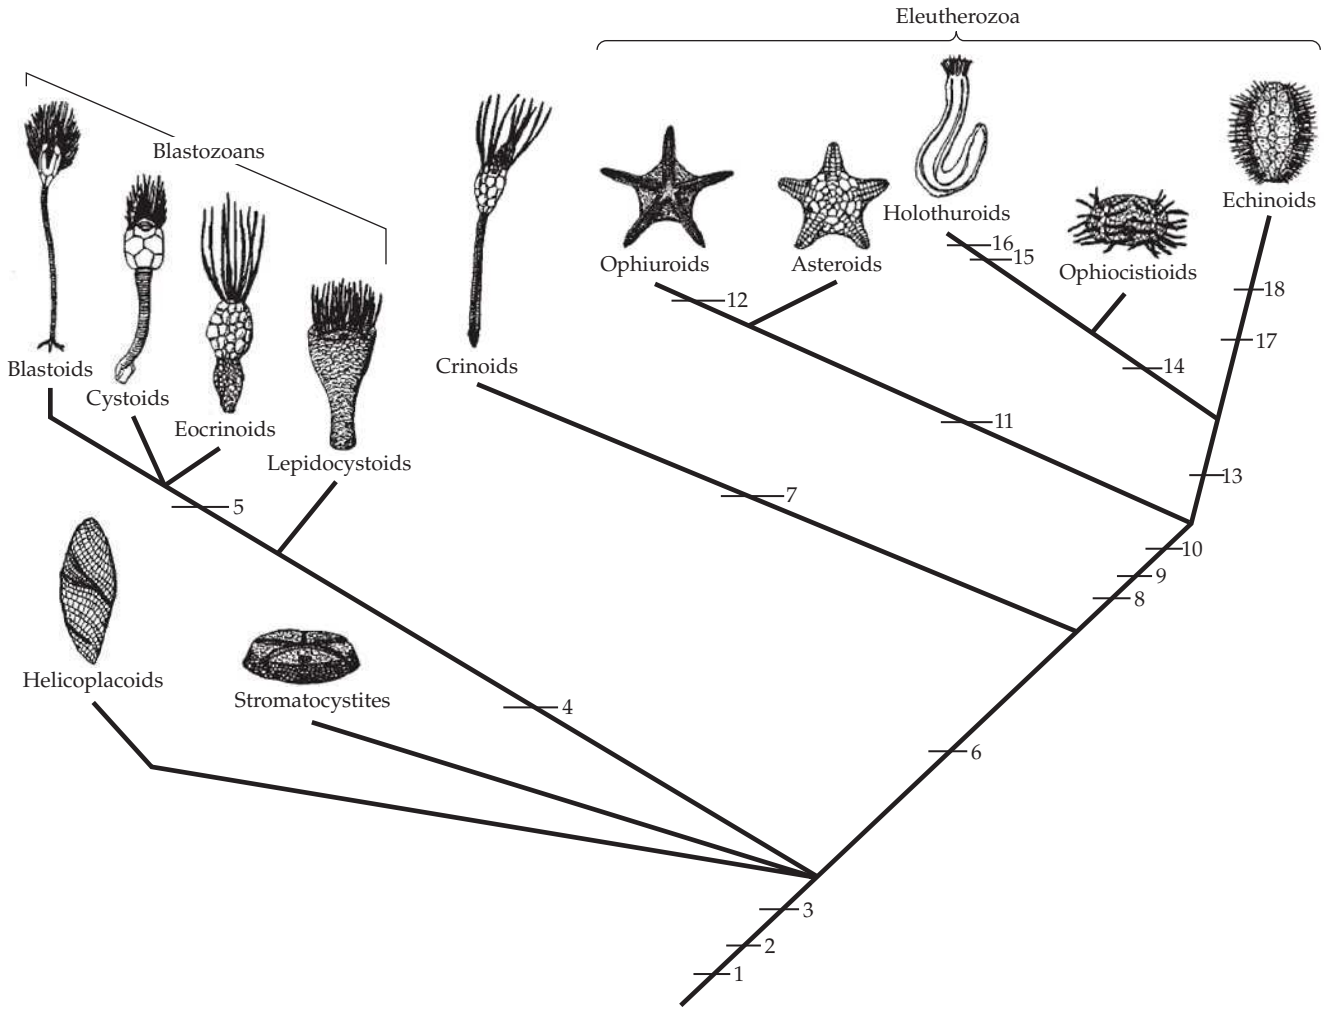

FIGURE 26.20 A phylogenetic hypothesis for the main groups of echinoderms, with suggested major synapomorphies. Echinoderms probably evolved from an infaunal ancestor similar to the sister group Hemichordata by inducing pentaradiality through a rudiment produced from the hydrocoel (1) and the evolution of a stereom endoskeleton (2). *Stromatocystites* is an edrioasteroid-like taxon likely representing the morphology of the first echinoderms—sessile animals with narrow rays (axial region), anus, and hydropore set in an upward-facing perforate extraxial region. Enigmatic derivations from this morphology had already appeared in triradial helicoplacoids. The imperforate extraxial region became an elongated sac enclosing aboral portions of the viscera (3). A diverse, entirely extinct clade, the blastozoans, are distinguished by possession of brachioles (4), feeding structures distinct from arms and made entirely of axial body wall, representing "naked" ambulacra unaccompanied by left or right coelom elements. Elaborations from the earliest blastozoans (*Lepidocystis*), included development of a stalk fashioned from imperforate extraxial region (5). Eocrinoids show the earliest morphology, with development into a demarcated stalk in cystoids and blastoids. Early, derived echinoderms such as carpoids fall into this clade by possession of a brachiole and highly defined stalk. The clade with the first extant forms is characterized by true arms containing extensions of left and right somatocoels (6). Crinoids independently evolved a stem inserted as a module within the imperforate extraxial region (7). Starfish, brittle stars, sea urchins, and sea cucumbers possess a madreporic sieve plate (8), robust tube feet for locomotion and food gathering in ambulacra lacking cover plates (9), a downward-directed mouth with the anus on the opposite (aboral) surface in which the imperforate extraxial region is virtually lost (10). Ophiuroids and asteroids are characterized by specialized plate systems such as lateral arm plates (11). Ophiuroids evolved fused ambulacral plates (vertebrae) that demarcate arms from the central disk (12). The ancestor of echinoids and holothuroids possessed an outpocketing of the left somatocoel (peripharyngeal coelom) in which the jaw apparatus develops (13). Aristotle's lantern is expressed in echinoids and early holothuroid-like forms (ophiocistioids), which begin shortening the rays and enlarging tube feet that become restricted to the oral region (14). Holothuroids take this to the extreme, suppressing the lantern as paedomorphic "giant larvae" (15). Earliest holothuroids were like modern apodids, lacking tube feet along the body. Only in more recent taxa do secondary, interradial canals (not homologous to the radial canals of other echinoderms) induce formation of tube-foot-like structures along the body (16). Echinoids lost nearly all of the extraxial region, restricting it to a few plates in the unique apical system (17). Echinoids also uniquely internalized the radial water vessel (18). The earliest echinoids did not actually have a rigid test (the plates did not tightly suture together to make the test until later).

no "head," no "tail," and clearly no "gill slits" in any member of the phylum, fossil or extant, despite attempts to identify these structures in the fossil record.

Helicoplacoids that appeared in the early Cambrian and died out soon thereafter were cigar shaped, with only three ambulacra arising from a lateral mouth and spiraling around the body among interradial plating (Figure 26.19B). How these echinoderms made their living remains conjecture. It is tempting to consider the three-ray pattern of helicoplacoids to be a precursor to the 2-1-2 pattern seen in the ambulacral branches of other fossil genera, such as *Stromatocystites*, in which there seem to be two bifurcating branches (the "2" in the pattern) and one nonbifurcating branch (the "1") to make a total of five rays. However, there are no parsimonious arguments against the idea that helicoplacoids (or any of the echinoderms with fewer than five rays) represent a reduction in ray number. The 2-1-2 pattern is also expressed in modern crinoids, but the five radial canals come off the ring canal in perfect pentaradiality, suggesting that the 2-1-2 pattern does not reflect embryological patterning of the water vascular system itself.

The one-armed carpoids seem to be derived members of the Blastozoa, a large, extinct group that includes cystoids, blastoids, and rhombiferans (Figures 26.19A,C,D,F,G and 26.20). All these taxa possess unique "free ambulacra" composed only of axial elements called **brachioles**. The earliest blastozoans were primitively pentaradial and derived from fossils such as *Lepidocystis* that illustrate origins of brachioles, as well as origins of the multiplated stalk derived independently from the stem seen in crinoids. Brachioles are not homologous to arms, as they do not include any coelomic elements other than the hydrocoel. "True" arms such as those seen in crinoids comprise both axial and extraxial elements, incorporating major coelomic outpocketings of both the left and right somatocoels.

Modern Echinoderms

The oldest fossil record of an extant echinoderm group is for Crinoidea, and among living taxa the crinoids constitute the sister group to the four classes that comprise a clade called Eleutherozoa. Crinoids include extinct forms, the protocrinoids, as well as sea lilies that proliferated during the Paleozoic. Crinoids bear attachment stems (distinct from the stalks of blastozoans in the nature of their ontogeny, as well as overall anatomy) arising from the aboral surface (Figure 26.2A). Protocrinoids possessed calcified ambulacral plates in the arms, but these were lost in more highly derived forms.

Eleutherozoa (composed of asteroids, ophiuroids, echinoids, and holothuroids) are the more mobile echinoderms in which the mouth was directed toward the substratum (except in the unusual holothuroids). The tube feet became more robust and deeply involved in all aspects of life, including locomotion and active hunting of prey. Asteroids, ophiuroids, and echinoids do not appear in the fossil record until the Ordovician; the holothuroids first appear in the Upper Ordovician, perhaps having evolved by way of paedomorphic reduction from strange extinct forms, the ophiocistioids. Recent evidence, including molecular phylogenetics, strongly supports placing asteroids and ophiuroids in one clade, and echinoids and holothuroids in another, sister clade. Asteroids and ophiuroids are constructed along very much the same body plan—so close in fact that there remain arguments over which fossils should be placed in which of the two groups.

With molecular evidence, a close relationship between echinoids and holothuroids is well supported. However, holothuroids are not simply decalcified echinoids, as once supposed. With the realization that holothuroids are likely paedomorphic, morphological synapomorphies linking them with echinoids are difficult to identify and will require examination of ontogenetic patterns, such as those involved in formation of the peripharyngeal coelom and Aristotle's lantern.

In summary, the ancient origin of the stereom and pentaradial hydrocoel patterning to induce adult pentaradiality are keys to understanding echinoderm evolution. These features allowed a transformation, from infaunal creatures like hemichordates to epibenthic surface-dwelling animals. The water vascular system probably originally served for suspension (and perhaps detritus) feeding, facilitated by small tube feet in narrow ambulacra oriented around an upward-facing mouth. The small ambulacra (i.e., axial region) in the body plan of early echinoderms indicate that they retained large amounts of extraxial region during development, even as the bilaterality of the larva was lost. As tube feet and the attendant water vascular system became increasingly significant in echinoderm lifestyles, pentaradial expression in the body plan also increased, leading to more pronounced larval metamorphosis to suppress the extraxial larval body in the adult. Concomitant with the more errant, active feeding lifestyle of modern taxa, specialized feeding structures such as enlarged suckered tube feet, buccal feeding tentacles, and even jaws and teeth were elaborated.

The proliferation of the echinoderm body plan since the Cambrian might seem surprising given the unique adoption of radial morphology. But it is clear that the combined qualities of supportive endoskeleton, coelomic water vascular system, and pentaradial symmetry have provided the basis for diversification and extremely disparate variations on this basic theme among the echinoderm lineages.

Chapter Summary

This chapter introduced you to some of the animal kingdom's strangest creatures, the phylum Echinodermata. No other phylum has pentaradial body symmetry or such strange expressions of body form. The 7,300 described echinoderm species include the familiar starfish (Asteroidea), brittle stars (Ophiuroidea), sea urchins and sand dollars (Echinoidea), and sea cucumbers (Holothuroidea), as well as the less familiar sea lilies and feather stars (Crinoidea). Ranging in size from 10 mm to over 3 m in length (some sea cucumbers), echinoderms occur exclusively in the sea, where they are found at all depths, and can be extremely abundant in some deep-sea environments. Adults of almost all species are benthic, but a few pelagic holothurians are known. Larvae in all classes are almost always pelagic, but many species adapted to cold environments have become brooders. All living echinoderms possess a well-developed coelom and a mesodermally derived endoskeleton composed of unique calcareous elements—ossicles and plates formed by microscopic, secreted crystals of calcium carbonate with small amounts of organic tissue forming a skeletal material called stereom. Echinoderm adult pentaradiality is coupled with another unique body feature known as the water vascular system, a complex of tubes and canals derived from the coelom. The water vascular system serves a variety of functions, notably in giving rise to tube feet, which are crucial to nearly every interaction between echinoderms and their environment. Echinoderms comprise one of the three deuterostome phyla (the other two being Hemichordata and Chordata) and thus have radial cleavage, enterocoely, and a mouth not derived from the blastopore. Important areas of future research for echinoderms include understanding their unusual regenerative capabilities, including their nervous system, and their ecological roles in maintaining or disrupting ecosystem function, given their regulation of algal growth and coral health, among other effects.

Phylum Chordata

Cephalochordata and Urochordata

We are chordates (Latin, *chorda*, "cord"). So are cats and dogs, lemurs and anteaters, birds and fishes, frogs and snakes, whales and elephants—all conspicuous by their size and familiarity. All of these animals have a vertebral column (backbone) housing the dorsal nerve cord, and this is the key feature defining the subphylum Vertebrata. But, besides the vertebrates there are two other subphyla in the Chordata, and they both lack backbones. These are the invertebrate chordates—the subphyla Cephalochordata and Urochordata. The Cephalochordata comprise about 35 species of small, fishlike animals called lancelets, or amphioxus. The Urochordata (= Tunicata) are composed of about 3,000 species of marine, filter-feeding chordates usually organized into three classes: the planktonic larvalike tunicates called appendicularians, or larvaceans (class Appendicularia); the sessile sea squirts, or ascidians (class Ascidiacea); and the pelagic tunicates, or salps (class Thaliacea). However, because recent phylogenetic studies show thaliaceans to be a clade of derived ascidians, we demote them from class status and incorporate them within the Ascidiacea. An additional group of abyssal, carnivorous ascidians, the sorberaceans, were also once designated a separate class, but these too have been shown to be embedded within Ascidiacea. It was the body-covering tunic of urochordates that led Lamarck to combine these animals in one group.

Vertebrates, chordates with a backbone, account for only about 4% (about 58,000 species) of all described animal species. Those chordates that do not possess a backbone (plus the other 31 animal phyla previously described in this book) constitute the invertebrates. So we see that the division of animals into invertebrates and vertebrates is based more on tradition and convenience, reflecting a dichotomy of interests among

zoologists, than it is on the recognition of natural biological groupings. "Invertebrates" is a paraphyletic group because it excludes the clade Vertebrata, a subgroup of the phylum Chordata. The vertebrates, on the other hand, are a monophyletic group.

The monophyly of the phylum Chordata has (in modern times) never been seriously questioned. One of the key synapomorphies defining the phylum is the **notochord**, a dorsal, elastic rod derived from a mid-dorsal strip of embryonic (archenteric) mesoderm, that provides structural and locomotory support in the body of larval or adult chordates. In addition, chordates have (at some point in their life history) a hollow **dorsal neural tube**, **pharyngeal gill slits**, and a **postanal tail** (a tail that extends beyond the anus) (Box 27A; Figure 27.9). They are an ancient group, with a fossil record dating to the early Cambrian, at least 530 million years ago, and with dated molecular phylogenies suggesting even an earlier age. Recent molecular phylogenomic studies have overturned the older view that Cephalochordata is the sister group to vertebrates, and instead the evidence today suggests that Urochordata is the sister group to Vertebrata (a clade known as Olfactores) and Cephalochordata is the sister group to those (Figure 27.9 and the Chordate Phylogeny section).

BOX 27A Characteristics of the Phylum Chordata

1. Bilaterally symmetrical, coelomate deuterostomes (coelom greatly reduced in some groups)
2. Pharyngeal gill slits present at some stage in development; used for feeding in Cephalochordata and Urochordata
3. Mesodermally derived, dorsal notochord present at some stage in development; notochord lying dorsal to the digestive tube and ventral to the neural tube
4. Dorsal, hollow nerve cord, at least in some stage of life history; compartmentalized anteriorly and, in Vertebrata, giving rise to the brain
5. Muscular, locomotor, postanal tail at some stage in development
6. With an endodermal, pharyngeal endostyle (Urochordata, Cephalochordata) or thyroid gland (Vertebrata)
7. Gut complete, usually regionally specialized
8. Circulatory system with a contractile blood vessel or heart; gas exchange across the body wall or across epithelial tissues
9. Gonochoristic or hermaphroditic; development variable; cleavage radial, holoblastic, subequal, or slightly unequal; tadpole larva stage expressed at some point in the life history of all taxa

CLASSIFICATION OF CHORDATA

SUBPHYLUM CEPHALOCHORDATA The lancelets or amphioxus. Marine, fishlike chordates (to 7 cm) with notochord extending anteriorly to the brain; gill slits, dorsal nerve cord, unique wheel organ, and postanal tail present in adults, but without vertebral column or cranial skeleton structure; gonads numerous (25–38) and serially arranged. Found in marine and brackish water environments, usually associated with clean sand or gravel sediments in which they burrow. (e.g., *Asymmetron, Branchiostoma, Epigonichthys*)

SUBPHYLUM UROCHORDATA (= TUNICATA)
The tunicates. Adult body form varies, but typically covered by thick or thin tunic (test) of a cellulose-like polysaccharide; without bony tissues; notochord restricted to tail and usually found only in larval stage (and in adult appendicularians); gut U-shaped or straight, pharynx (branchial chamber) typically with numerous gill slits (stigmata); coelom not substantively developed; dorsal nerve cord present in larval stages. Strictly marine; 2 recognized classes.

CLASS APPENDICULARIA (= LARVACEA)
Appendicularians, or larvaceans. Solitary planktonic tunicates; body enclosed in a complex, temporary, secreted gelatinous "house" used for feeding. (e.g., *Fritillaria, Oikopleura, Stegosoma*)

CLASS ASCIDIACEA Ascidians, or sea squirts and salps. Benthic or planktonic, solitary or colonial, sessile or free-living tunicates; the sessile sea squirts with incurrent and excurrent siphons generally directed upwards, away from the substratum; without dorsal nerve cord in adult stages; occurring at all depths. About 13 families of sea squirts and many genera. (e.g., *Ascidia, Botryllus, Chelyosoma, Ciona, Clavelina, Corella, Diazona, Didemnum, Diplosoma, Lissoclinum, Megalodicopia, Molgula, Octacnemus* [formerly in the class Sorberacea], *Psammascidia, Pyura, Styela, Trididemnum*). The relationships of three traditional ascidian orders (Aplousobranchia, with simple branchial sacs; Phlebobranchia, with vascular branchial sacs; Stolidobranchia, with folded branchial sacs) are in flux. Also, we include the former class Thaliacea (pelagic tunicates, or salps) within Ascidiacea. Salps are solitary or colonial; have incurrent and excurrent siphons at opposite ends, providing locomotory current; lack a tail as adults; and have gill clefts not subdivided by gill bars. There are 3 groups: Pyrosomida, Salpida, and Doliolida (e.g., *Dolioletta, Doliolum, Pyrosoma, Salpa, Thetys*).

SUBPHYLUM VERTEBRATA (= CRANIATA)
The vertebrates. Chordates with a skeletal brain case and, except for members of the Agnatha, jaws and a vertebral column (backbone) that forms the axis of the body skeleton; most with paired appendages. Several classes are generally recognized, although not all are strictly monophyletic: classes Myxini and

for more ebook/ testbank/ solution manuals request: email:960126734@qq.com

Cephalaspidomorphi are the hagfishes and lampreys, respectively (united as the jawless or agnathan fishes); Chondrichthyes are the sharks, skates, and rays; Osteichthyes are the bony fishes (e.g., trout, tuna, perch); Amphibia includes the salamanders, frogs, toads, caecilians; Reptilia (a paraphyletic group) traditionally included the turtles, snakes, lizards, and crocodilians, but modern classifications place birds and reptiles together as Sauropsida (or Reptilomorpha). Mammalia comprises the vertebrates with mammary glands.

Phylum Chordata, Subphylum Cephalochordata: The Lancelets

Like all chordates, cephalochordates—the lancelets—possess a notochord, dorsal hollow nerve cord, pharyngeal gill slits, postanal tail (that persists into adulthood), and true coelom (Figures 27.1 and 27.2). The name (Greek *cephala*, "head"; *chordata,* "chord") derives from the unique extension of the notochord beyond the brain into the animal's head. Lancelets are small (to 7 cm), resembling a colorless anchovy but without obvious eyes or lateral fins. The vernacular name "amphioxus" is frequently used for the common species *Branchiostoma lanceolatum* (and sometimes for others as well). Cephalochordates are cosmopolitan in shallow marine and brackish waters at tropical and warm-temperate latitudes, where they lie burrowed in clean sands with only the head protruding above the sediment. Generally, they reside semivertically in burrows, or they rest on their sides on surfaces. They can and do swim, and locomotion is important to their dispersal and mating habits. However, they tend to swim erratically and without clear dorsoventral orientation. A few fossil lancelets have been described, as old as the early Cambrian.

Surprisingly, most biologists have never seen a living lancelet in the field. They can be somewhat common, but only in the right environment, and seeing them requires a bit of time on one's knees on tidal flats. Most species seem to prefer clean, fine-grained sediments, which in some places are referred to as "amphioxus sands," but even when they are present, it takes a keen eye to spot them. They can be seen swimming about in very shallow tidal pools on sand flats, darting in and out of the sediment. During spawning season, the sex of an individual is quickly revealed by the white testes of the males and yellowish ovaries of the females, both visible through the translucent body wall. In some areas of Asia they are common enough to be harvested for human and animal food. Written records of lancelets date back to Tang dynasty of China in the seventh to tenth centuries. Ernst Haeckel was convinced lancelets were the ancestors of the vertebrates, and he devoted so much thought and writing to this subject that he was served lancelets (with black caviar) at his sixtieth birthday party.

The Cephalochordate Body Plan

Body Wall, Support, and Locomotion

The body of cephalochordates is completely covered by an epidermis of simple columnar epithelium, underlain by a thin connective tissue dermis. The body wall muscles are vertebrate-like and occur as chevron-shaped blocks called **myotomes** arranged longitudinally along the body. These muscle blocks are large and occupy much of the interior of the body, thereby reducing the coelom to relatively small spaces. The notochord persists in adults and provides the major structural support for the body (Figure 27.1A–C).

The notochord also plays a major role in locomotion in lancelets. As a result of the action of segmental myotomes, swimming in cephalochordates is much like that of fishes, consisting largely of lateral body undulations that drive water posteriorly to provide a forward thrust. The propulsive action of these body movements is enhanced by a vertically aligned caudal fin. Unlike the vertebral column and its articulating bones, however, the notochord is a flexible elastic rod. It prevents the body from shortening when the muscles contract, causing lateral bending instead. Its elasticity tends to straighten the body, and it thus assists the antagonistic action of paired myotomes. The notochord extends beyond the myotomes both anteriorly and posteriorly, providing support beyond those muscles, and apparently aids in holding the body stiff during burrowing.

Although the notochord of cephalochordates is homologous with the same structure in other chordates, it displays some unique and rather remarkable structural and functional characteristics associated with its persistence into the adult stage. The notochord of lancelets is built of discoidal lamellae that are stacked like poker chips along its length and surrounded by a sheath of collagenous connective tissue. The lamellae are composed of muscle cells whose fibers are oriented transversely. A significant amount of extracellular fluid exists in spaces and channels around and between the lamellae within the collagenous sheath. These muscle cells are innervated by motor neurons from the dorsal nerve cord. Upon contraction, the hydrostatic pressure in the extracellular spaces increases, thereby resulting in increased stiffness of the whole notochord complex. It is suspected that this action may facilitate certain kinds of movement patterns, especially burrowing.

Although commonly called "fins," the unique dorsal and ventral finlike structures are perhaps more appropriately called **dorsal and ventral storage organs** (Figure 27.1A,C). They are not homologous with the fins of fishes, and their function appears to be housing a buildup of nutritional reserves for gamete formation.

Feeding and Digestion

Cephalochordates are ciliary-mucous suspension feeders, and they employ a food-gathering mechanism very similar to that of tunicates (see below). Water is driven into the mouth and pharynx via cilia in the **branchial chamber**, which creates the so-called **branchial pump**, and out through the pharyngeal gill slits into a surrounding **atrium**; it exits the body through a ventral **atriopore** (Figure 27.1A). Unlike the gill ventilation currents of aquatic vertebrates that are generated by muscular action, the feeding currents (the branchial pump) of lancelets are driven largely by pharyngeal cilia, as in tunicates. The pump is driven by metachronal waves of lateral cilia on the branchial bars. The gill slits in lancelets function largely for feeding and have little to do with gas exchange. There are up to 200 gill slits, separated from one another by gill bars, which are supported by cartilaginous rods.

Filter feeding in lancelets involves the trapping of food, primarily phytoplankton, from the inflowing water, combined with complex handling and sorting activities that occur before the water enters the mouth. The mouth is housed within a depression called the **vestibule**, which is formed by an anterior extension of the body called the **oral hood** (Figure 27.1B). The oral hood is supported by the notochord and bears fingerlike projections called **oral cirri** (= **buccal cirri**). As water enters the vestibule, the cirri act as a coarse filter to prevent sediments and other large particles from reaching the mouth. The mouth itself is a perforation in a membranous velum, which bears a set of **velar tentacles**; the tentacles provide a second screen, preventing large material from entering the mouth. The lateral walls of the vestibule bear complex ciliary bands that collectively constitute the wheel organ. The **wheel organ** appears as brown, thickened, folded epithelium in the roof and sides of the vestibule and is visible through the translucent skin of living animals. Cilia of the wheel organ drive food particles to the mouth and give the impression of a rotation, hence the name. Lying on the roof of the vestibule is a mucus-secreting structure called **Hatschek's pit** (Figure 27.1B). Mucus from this pit flows over the wheel organ, and food particles trapped by the mucus are carried to the mouth along the ciliary tracts. This material is then incorporated into the general water current moving through the mouth and into the pharynx. Threadlike feces are ejected from the anus, which is several millimeters posterior to the atriopore, just to the left of the ventral midline.

When feeding, most lancelets lie completely or partially buried in the bottom sand with the ventral side turned upward and the mouth opening free from interference of sand or sediment. Experiments have shown that, in *Branchiostoma lanceolatum*, particles greater than or equal to 4 μm are retained by the mucus filter with 100% efficiency. Both the oral cirri and velar tentacles bear numerous sensory cells that respond to mechanical and chemical stimulation. If the velar tentacles are stimulated, contraction of the velar muscles flicks them forward and a "cough" reaction is evoked. Clogging of the oral tentacles by detritus also results in a rapid body contraction, forcing water out of the mouth such that the buccal region is flushed and cleaned.

The ventral surface of the pharynx bears the **endostyle**, or hypobranchial groove (Figure 27.1A–C). An endostyle is found in Cephalochordata and Urochordata (the so-called **protochordates**) that filter feed using the pharynx and gill slits, as well as in primitive vertebrates (e.g., lampreys), and it is generally viewed as a synapomorphy of the Chordata. It functions by secreting mucus on which suspended particles are trapped and conveyed into the midgut. As in tunicates, the endostyle of lancelets binds iodine, although the specific cells involved differ between the two lineages. Many workers view the endostyle of urochordates and cephalochordates as homologous and a possible precursor to the vertebrate thyroid gland. As in tunicates, the endostyle produces strings of mucus that trap food from the water as it passes through the gill slits and into the atrium. The food-laden mucus is then passed dorsally along the walls of the pharynx by ciliary tracts and into the epibranchial groove, which carries the material by cilia along the dorsal midline of the pharynx and into a short esophagus. The gut extends posteriorly as an elongate intestine and opens through the anus just in front of the caudal fin. Near the junction of the pharynx and esophagus, there arises an anteriorly projecting pouch called the **digestive cecum** (sometimes called the hepatic cecum, or hepatic diverticulum). Studies indicate that this organ functions in lipid and glycogen storage and protein synthesis, and it is regarded by most workers as the evolutionary precursor of the vertebrate liver and perhaps the pancreas. Just as the liver does in vertebrates, the digestive cecum synthesizes vitellogenin, a yolk protein precursor that is carried in the blood to the ovary, where it is used in the production of yolk proteins in eggs. Digestion initially is extracellular in the gut lumen and is completed intracellularly in the walls of the intestine and especially in the cecum. In addition to storage in the cecum, food reserves accumulate in longitudinally arranged dorsal and ventral storage chambers (the "fins") along the dorsal midline and along the ventral body margin posterior to the atriopore (Figure 27.1A).

Circulation, Gas Exchange, and Excretion

The circulatory system of lancelets comprises a set of closed vessels through which blood flows in a pattern similar to that in primitive vertebrates (e.g., fishes). It is generally said that lancelets are heartless, but the main contractile vessel running ventral to the pharynx (often referred to as an aorta) is probably homologous with a structure in tunicates that has been called the heart, and the vessel's muscular contractions are powered

by cells thought to be homologous with the vertebrate myocardial cells. Blood flows posteriorly along the pharyngeal region in a pair of dorsal aortae. Just posterior to the pharynx, these vessels merge into a single median dorsal aorta that extends into the region of the caudal fin (Figure 27.1D). Blood is supplied to the myotomes and notochord via a series of short segmental arteries and to the intestine through intestinal arteries. A capillary network in the intestinal wall collects the nutrient-laden blood and leads to a series of intestinal veins that join a large subintestinal vein called the cecal portal vein, which carries blood forward beneath the gut to another capillary bed in the digestive cecum. As in vertebrates, the vein that connects two capillary beds is called a portal vein (e.g., the hepatic portal vein and renal portal veins in fishes). Indeed, the cecal portal vein of cephalochordates is probably the homologue of the hepatic portal vein of vertebrates. In the digestive cecum, the nutrient and chemical composition of the blood is regulated somewhat before being distributed to the body tissues. (The vertebrate liver serves the same function via the hepatic portal system.)

Leaving the cecal capillaries is a cecal vein, which is joined by a pair of common cardinal veins formed by the union of paired anterior and posterior cardinal veins returning from the body tissues. These vessels merge to form the ventral aorta beneath the pharynx. From here blood is carried through the gill bars via afferent and efferent branchial arteries to the paired dorsal aortae, thus completing the circulatory cycle. Blood is moved through this system by peristaltic contractions of the major longitudinal vessels and by pulsating areas at the bases of the afferent branchial arteries.

The blood contains no oxygen-carrying pigments or cells and is thought to function largely in nutrient distribution rather than in gas exchange and transport. Although some diffusion of oxygen and carbon dioxide may occur across the gills, most of the gas exchange probably takes place across the walls of the **metapleural folds**, thin flaps off the body wall that lie just anterior to the atriopore (Figure 27.1C).

The excretory units in cephalochordates are protonephridia similar to the solenocytes of some other invertebrates. Numerous clusters of protonephridia accumulate nitrogenous wastes, which are carried by a nephridioduct to a pore in the atrium. However, despite the structural similarities, the homology of lancelet protonephridia with those of other invertebrates is uncertain, and some specialists regard this as a case of convergent evolution.

Nervous System and Sense Organs

The central nervous system of cephalochordates is very simple. A dorsal, hollow nerve cord extends most of the length of the body and is generally expanded slightly as a **cerebral vesicle** in the base of the oral hood. Segmentally arranged nerves arise from the cord along the body in the typical vertebrate pattern of dorsal and ventral roots. The epidermis is rich in sensory nerve endings, most of which are probably tactile and important in burrowing. Some lancelets have a single simple eyespot (sometimes called a "frontal eye") near the anterior end of the dorsal nerve cord.

Reproduction and Development

Cephalochordates are gonochoristic, but the sexes are structurally very similar. Rows of 25 to 38 pairs of gonads are arranged serially along the body on each side of the atrium (Figure 27.1C). The volume of gonadal tissue varies seasonally, and during the reproductive period it may occupy so much of the body as to interfere with feeding. Spawning typically occurs at dusk. The atrium wall ruptures, and eggs or sperm are released into the excurrent flow of water from the atrium; external fertilization follows.

The ova are isolecithal, with very little yolk. Cleavage is radial, holoblastic, and subequal; the first cleavage starts at the animal pole, the second is at right angles, and the third cleavage divides the embryo into an animal and vegetal half, forming a coeloblastula. The coeloblastula then gastrulates by invagination (Figure 27.2). The roof of the archenteron eventually produces first a solid middorsal strip of mesoderm destined to become the notochord and then, sequentially, an anterior-to-posterior series of paired archenteric pouches along each side of the notochord. These enterocoelic pouches form the coelom and the other mesodermally derived structures such as the muscle bundles. The roof of the archenteron closes following mesoderm proliferation.

Dorsally the ectoderm differentiates into a neural plate. The neural plate eventually rolls inward, separating from the bordering cells, and then sinks inward as a neural tube, which forms the dorsal hollow nerve cord. As this process occurs at the posterior end of the embryo, the developing nervous tissue contacts the blastopore, which remains open temporarily and connects the archenteron to the lumen of the nerve cord as a **neuropore**. Later the two structures separate, and the blastopore opens to the exterior as the anus. The mouth breaks through as a secondarily produced opening at the front end of the developing gut, an event that is arbitrarily taken to divide the embryonic and larval stages.

In the absence of abundant yolk reserves, development of the ciliated embryo into a free-swimming larva takes place rapidly. As soon as they are able, the planktotrophic larvae swim upward in the water column, where they remain planktonic for 75 to 200 days.

Lancelet larvae resemble the adult form but are notable for their body asymmetry (in the right–left axis), including having the mouth opening on the left side of the head, the initial lack of gill slits and atrium, possession of only a few myotomes, and a

heavily ciliated epidermis that is used for locomotion. The asymmetry of the body causes the larva to move in a helical or spiral fashion, ciliate-like, as it moves through the water driven by metachronal waves of beating epidermal cilia. However, most of its time is spent alternating between hovering in the sea, with the metachronal beat of the body cilia holding it more or less head up in the water column, and passively sinking, with its body held horizontally and the mouth directed downward, feeding on plankton and other suspended matter. Larvae gradually increase in size, following a nearly linear growth curve. As metamorphosis approaches, the atrium and gill slits form, the number of myotomes (muscle blocks) increases, and movement by cilia is gradually replaced by muscular propulsion. As more gill slits are enclosed by the growing atrium, the amount of water exiting the atriopore increases, and the motile cilia gradually disappear from the external epidermis. As the larval-juvenile transition ensues, body flexions increase in complexity until a complete undulatory wave propagates down the body in an adult manner. Metamorphosis is completed as ciliary locomotion ceases and the larva settles to the bottom.

Phylum Chordata, Subphylum Urochordata: The Tunicates

Once relegated to near obscurity, tunicates are getting more attention lately; some ascidians have become model organisms whose genomes have been studied to better understand chordate development and gene regulatory networks. The genomes of tunicates have not undergone whole genome duplications, which has provided a simplified system closely related to the more complex genomes of vertebrates. Ascidians are also getting substantial ecological attention as some of the most dangerous marine invasive species, covering and smothering thousands of square meters of benthic substrate and causing economic losses in aquaculture worldwide. The developmental and ecological attention focused on tunicates has in turn highlighted the surprising gaps in knowledge about their systematics, distribution, reproductive and larval biology, ecology, evolutionary relationships, and regeneration abilities.

Members of the three urochordate classes are almost all marine suspension feeders, but they conduct their lives in very different ways (Figures 27.3 and 27.4). The sessile ascidians (class Ascidiacea) include both solitary and colonial forms, with individuals ranging in size from less than 1 mm to 60 cm, and some colonies measuring several meters across or more. Ascidians are found worldwide and at all ocean depths, attached to nearly any substratum. They are most abundant and diverse in rocky littoral habitats and on deep-sea muds. The unusual *Octacnemus* (formerly in the class Sorberacea, but now regarded as ascidians) are carnivorous, abyssal, benthic species possessing a dorsal nerve cord in adult stages and lacking the typical perforated branchial chamber of other tunicates. The free-living salps (thaliaceans; also now in the class Ascidiacea) are pelagic tunicates that float about singly or in cylindrical or chainlike colonies sometimes several meters

long. They are known from all oceans but are especially abundant in tropical and subtropical waters. Salps occur from the surface to depths of about 1,500 m. The larvaceans (class Appendicularia), or appendicularians, are solitary bioluminescent planktonic creatures generally not more than about 5 mm long. They resemble in certain ways the larval stages of some other tunicates, hence the name "larvaceans." Their retention of a notochord and a nerve cord in the adult stage indicates that these are plesiomorphic characters for chordates. The feces of salps and larvaceans, and the abandoned houses of the latter, constitute important sources of food and particulate organic carbon in the open sea and the seabed. In fact, the filtering of submicron particles by pelagic tunicates, and subsequent repackaging as denser fecal pellets that sink more quickly, is considered to be an important aspect of biogeochemical cycling towards the deep ocean affecting carbon budgets and nutrient supplies. It has been shown that discarded mucus feeding structures of larvaceans carry a substantial portion of the upper ocean's productivity to the deep seabed.

With the increasing application of DNA barcoding to identify cryptic species, the number of extant species of ascidians appears to be growing substantially. Ascidians, or their ancestors, probably date to the Precambrian. However, morphological change is so slow among living ascidian species that it is often impossible to distinguish sister species without genetic analysis, despite large genetic distances. Rapid genetic change has been documented in both mitochondrial and nuclear genomes of tunicates. Further, recent studies of mitochondrial gene order reveal rearrangements, even among species in the same genus. And nuclear genomes show dramatic changes in gene content (e.g., loss of a Hox gene cluster) and dramatic changes in intron organization. Appendicularians have been shown to have some of the fastest evolving metazoan genomes known.

Biogeographical distributions of tunicates are not well known in many cases, due to several factors: a historic lack of attention in comparison with many other groups, habitats that are challenging to survey in some cases, difficult morphological characters for taxonomic identification, anthropogenic effects on distributions, and challenges in working with preserved specimens. More recently, combined technological advances in morphological and genetic analysis, along with targeted collection efforts in areas of high biodiversity, are beginning to result in rapid advances in our understanding of tunicate distributions and evolutionary relationships.

The Tunicate Body Plan

Tunicates are bilaterally symmetrical, at least during early developmental stages. Most utilize mucus-covered **pharyngeal gill slits** (= **stigmata**) for suspension feeding (Figure 27.5A,B,H). Although the feeding system is modified in the appendicularians, water still flows into the mouth and pharynx by way of an incurrent **oral** (**branchial**) **siphon**, passes through the pharyngeal gill slits into a spacious water-filled atrium (**cloaca**), and exits through an excurrent **atrial siphon**. The gut is simple, straight or U-shaped, with the anus emptying into the excurrent flow of water as it leaves the body. Because urochordates differ greatly

in body form from the more familiar chordates, the general orientation of the bodies of urochordates is not immediately apparent and can only be fully understood by examining the events of metamorphosis. The oral siphon is generally anterior, and the atrial siphon is either anterodorsal (in ascidians) or posterior (in thaliaceans) (Figures 27.5 and 27.6). However, the dorsoventral orientation of the body can be determined internally by the locations of the dorsal ganglion and a thickened ciliated groove, called the endostyle, that runs along the ventral side of the pharynx or branchial chamber (Figures 27.5A–E and 27.6C,D,H). The oral

and atrial siphons are generally directed away from the substratum and set at an angle to one another, thereby reducing the potential for recycling wastewater.

The Ascidiacea is the largest and most diverse class of tunicates. Some interstitial forms are known, and a few live anchored in soft sediments, but the majority of ascidians are attached to hard substrata (Figure 27.3), whereas the salps are free-living. Three general morphological body plans of ascidians are usually recognized, although these categories do not relate directly to formal taxa, since they have evolved multiple times in separate orders. The bodies of some solitary, social, and colonial forms are set on stalks and elevated off the substratum, although the compound forms typically grow as thin or thick sheets generally conforming to the topography of the surface on which they live. Many larger species (up to 60 cm long) are solitary ascidians, with each individual developing from a single larva and being genetically unique (e.g., *Ciona, Molgula, Styela*; Figure 27.3A,C). Some solitary ascidians are found in dense aggregations, particularly on artificial substrata such as docks, pilings, and submerged ropes, where their tunics may even appear glued together, although they are still physiologically distinct. These aggregations may result from gregarious settlement or simply limited dispersal in brooding species. Social ascidians tend to live in clumps of individuals that are at least initially vascularly attached to one another at their bases (e.g., *Clavelina*; Figure 27.3D,E), although in some taxa these connections may degenerate over time (e.g., *Metandrocarpa*). Finally, a great number of species are colonial and compound ascidians and are characterized by many small feeding and reproductive units (zooids) held together in a common gelatinous matrix (e.g., *Aplidium, Botryllus*; Figures 27.3B,H,I and 27.4 A,B) and proliferating via asexual reproduction following establishment by a single sexually produced colonizing larva. In extreme cases, colonies may measure several meters across or potentially even larger in some taxa (e.g., colonial didemnid ascidians) by way of fusion of distinct genetic individuals to form chimeric colonies. Colonial ascidians may regress or fragment as well, leaving a pattern of physically isolated colonies that are genetic clones distributed across the substratum.

In compound ascidians, zooids are arranged in regular (or irregular) rosettes and share a common atrial chamber that leads to a shared excurrent siphon within the outer body wall, or tunic (Figure 27.4A,B,E,F), while in colonial species, each zooid retains a distinct atrial siphon associated with each single branchial

siphon. Zooids in some taxa are arranged seemingly haphazardly in the tunic, while in other taxa the zooids are arranged in regular patterns called "systems." The tunic varies from thick to thin, and from smooth and slick to wrinkled and leathery. In some families, the tunic can be reinforced with calcareous spicules—as in the Didemnidae. Many ascidian species are brightly colored, in some cases due to pigmented cells associated with the blood and in some tropical taxa due to symbionts. Compound ascidians frequently are some of the most colorful animals living on lower intertidal rocks and in the subtidal environment. Some solitary and social tunicates have clear tunics, so most parts of the internal anatomy are visible, sometimes highlighted with dramatic, seemingly fluorescent coloring (e.g., the pink endostyles of "light bulb" tunicates, such as *Clavelina*). Ascidians are eaten by people in both the Mediterranean region and the Far East. Interestingly, in 2015 the Yamauchi Company in Japan began brewing beer using the ascidian *Halocynthia roretzi*, a species that has been eaten raw or cooked for many years in Japan and Korea (with a flavor likened to rubber dipped in ammonia, by Western palates).

Ascidians have become so highly modified during their evolution as sessile suspension feeders that adults are not easily recognizable as chordates. The larval pharyngeal gill slits persist into adulthood. However, the dorsal hollow nerve cord and the notochord, present in the larval stage, are lost in adults, and additional neural differentiation occurs that provides sensory abilities more relevant to a sessile adult lifestyle. This neural differentiation is currently being studied with regard to relationships to vertebrate neural crest differentiation and neural placodes (embryonic ectodermal thickenings on the edge of the neural crest that give rise to neurons and sensory structures). In vertebrates, cells generated from the neural crest migrate throughout the body to give rise to diverse cell lineages producing nervous system elements and many other structures.

Thaliaceans are pelagic ascidians called salps (Figure 27.6A–F). They are constructed much like their sessile counterparts except that the oral and atrial siphons are at opposite ends of the body, and in many forms the pharyngeal filtering basket is modified to accommodate the linear flow of water through the animal. The exiting water provides a means of "jet propulsion." Most are highly gelatinous and transparent. Thaliaceans comprise three lineages: Pyrosomatida, Doliolida, and Salpida. Pyrosomes are remarkable colonies of tiny ascidian-like zooids embedded in a dense gelatinous matrix and arranged around a long central, tubular chamber called a common cloaca (Figure 27.6A,B). The cloaca receives exhalant water from the inwardly directed atrial siphons of all the zooids; the water then exits through a single large aperture, thereby propelling the barrel-shaped colony slowly through the water. As in the ascidians, water movement in pyrosomes is generated entirely by ciliary action of the individual zooids. The remarkable light displays of large pyrosomes have long attracted interest and awe, as the size of the entire colony can be several meters in length. On viewing a smaller captured specimen in a bucket on board a ship, the famed naturalist Thomas Henry Huxley commented in 1851, "The phosphorescence was intermittent, periods of darkness alternating with periods of brilliancy. The light commenced in one spot, apparently on the body of one of the 'zooids,' and gradually spread from this as a centre in all directions; then the whole was lighted up; it remained brilliant for a few seconds, and then gradually faded and died away." Huxley made these observations on his single specimen after noting that the entire sea was lighted intermittently by "miniature pillars of fire" producing "an ever-waning, ever-brightening soft bluish light as far as the eye could reach on every side."

Doliolids and salps include thaliaceans that alternate between solitary sexual forms and colonial asexual stages (Figure 27.6C–E). Doliolid individuals are generally small, less than 1 cm long, whereas a single salp may be 15 to 20 cm long but form a chainlike colony several meters in length. The members of these two groups move water through their bodies but propel themselves partially (salps) or wholly (doliolids) by muscular action, contracting their circular muscles to jet propel themselves through the water.

Thaliaceans are predominately warm-water creatures, although certain species are found in temperate and even polar seas. They are particularly abundant over the continental shelf and are frequently captured in surface waters or seen stranded on wave-swept sandy beaches after storms. Some, however, have been recorded from depths to 1,500 m. It has been suggested that the very fine mesh filters of thaliaceans are easily clogged in nutrient-rich waters, potentially explaining their abundance in offshore and tropical waters.

Appendicularians may be the strangest of all urochordates, and they are characterized by the retention of a notochord and a nerve cord in the adult stage, as in the other chordate lineages. Because they were once thought to be derived ascidians, this condition was interpreted as paedomorphosis. However, given their current phylogenetic position, it seems that the derived condition is that found in Ascidiacea. These solitary animals live in a gelatinous casing, or **house**, that they secrete around their body (Figures 27.6G–I), a synapomorphy of the group. The bulbous trunk of the body contains the major organs, including the gut, and bears a muscular tail in which the notochord is retained. The dorsal nerve cord, though reduced, extends partway along the length of the tail. (The phenomenon of paedomorphosis is discussed in Chapter 4.)

The pharynx of appendicularians is reduced and bears only two clefts. When positioned within its house, the animal produces a complex water current

for more ebook/ testbank/ solution manuals Request: email:960126734@qq.com

by beating its tail. Filtering is accomplished by meshes in the house wall and by mucous nets secreted by the animal (Figure 27.6I). The mesh filters are complex and vary among species, often being constructed of more than one size of interlaced fibers. The exiting water provides the locomotor force. Appendicularians are found near surface waters of all oceans and are sometimes extremely abundant. Large species attain lengths to 60 mm, and their fragile gelatinous houses can exceed a meter in diameter.

Body Wall, Support, and Locomotion

The body wall of tunicates includes a simple epithelium overlain by a secreted tunic of varying thickness and consistency (Figure 27.5A,D,H). The tunic is most well developed in the ascidians and some thaliaceans. It varies from soft and gelatinous to tough and leathery, and it sometimes includes calcareous spicules. The matrix of the tunic contains fibers and is composed largely of a cellulose polymer called tunicin produced by cellulose synthase genes that are thought to have been acquired via horizontal gene transfer from an actinobacterial genome. The tunic is not a simple, secreted, nonliving cuticle, however, since it also contains amebocytes and, in some cases, blood cells and even blood vessels. The tunic is an exoskeleton providing support and protection. Some ascidians harbor symbiotic bacteria in their tunics. These bacteria include a variety of species from several major groups, including taxa unique to tunicates. The ability to construct protective coverings with a cellulose material may have been a key innovation providing protection to these soft-bodied organisms.

Beneath the epidermis are muscle bands. In many species, especially among ascidians, these muscles lie within an ectodermally produced mesenchyme called the mantle (Figures 27.5A,B). Ascidians possess longitudinal muscles extending along the body wall that serve to pull the flared siphons down against the body, while circular sphincter muscles close the siphonal openings. Fine neural control of these muscles is part of the development that occurs during the transition from the motile larval to the sessile adult stage. This control allows the filter feeders to respond quickly to unwanted particles or predators near the siphonal openings. Doliolids and salps have well-developed bands of circular muscles that pump water through the body for feeding and locomotion. When they contract, water within the body is forced out the atrial siphon, thereby propelling the animal forward. When they relax, the body expands because of the resilience of the tunic, and water is drawn in through the oral siphon. In appendicularians, the tail muscles provide action for moving water through the houses.

Tunicates have an extremely reduced coelom, considered absent by some researchers; the body cavity has been lost in concert with the evolution of the large pharynx and cloacal chamber. The cloaca is a saclike, ectodermally derived structure continuous with the epidermis of the atrial siphon (Figure 27.5A,B). The inner wall lies against the pharynx and is perforated over the gill slits, or stigmata. Thus, water enters the pharynx via the oral siphon, flows through the stigmata, into the cloacal chamber, and out the atrial siphon.

Feeding and Digestion

We have hinted at various aspects of the feeding biology of tunicates in our comments. Most of these animals are suspension feeders and use various kinds of mucous nets to filter plankton and organic detritus from the seawater. A few ascidians live partially embedded in soft sediments and feed on organic material in the substratum, and certain bizarre deep-sea species actually prey on small invertebrates by grasping them with the lips of the oral siphon (Figure 27.3K). Next we provide a more detailed description of feeding and digestion in a suspension-feeding ascidian and then compare this with feeding in thaliaceans and appendicularians.

Water is moved through the body of an ascidian largely by the coordinated action of cilia lining the expanded pharynx, called the **pharyngeal chamber** (also known as the branchial chamber, branchial basket, or branchial sac). Water enters the oral siphon and passes through a short siphonal chamber, at the inner end of which is the mouth. A ring of fleshy tentacles encircles the mouth and prevents the entrance of large particles (Figure 27.5A,G). Food-laden water passes into the pharynx, which bears a ventral longitudinal groove, the **endostyle**. The bottom of the groove is lined with mucus-secreting cells and bears a longitudinal row of flagella; the sides of the groove bear cilia (Figure 27.5F). The mucus, a complex mucoprotein containing iodine, is moved to the sides of the endostyle by the basal flagella and then outward by the lateral cilia. Cells near the opening of the endostyle are responsible for binding environmental iodine and incorporating it into the mucus. Sheets of mucus then move dorsally along the inner wall of the pharynx and pass over the **stigmata**. The slitlike stigmata are arranged in rows and bear lateral cilia that drive water from the pharynx into the surrounding atrial water chamber (Figure 27.5A–D,H). Thus, water passing through the stigmata also passes through the mucous sheets, on which food particles are retained. On the dorsal surface of the pharynx is a longitudinal curved ridge called the **dorsal lamina**, or a row of ciliated projections called **languets**, or both (Figure 27.5A–E). These structures serve to roll the mucous sheets into cords, which are then passed posteriorly to a short esophagus and then to the stomach. Attached to the stomach is a small pyloric gland that

extends around the intestine as a network of small tubes. Some species also bear an accessory digestive gland (Figure 27.5A). Digestive enzymes are secreted into the stomach lumen by secretory cells of the gut wall and perhaps by the associated glands, and digestion is largely extracellular. From the stomach, the gut loops forward as an intestine, through which undigested material passes to the anus, which opens into the atrium near the excurrent siphon.

The family Didemnidae comprises some of the compound ascidians in which the cloacal systems are shared and the colonies are usually hardened with aragonitic "spiculospheres." Among certain tropical genera (e.g., *Didemnum, Diplosoma, Lissoclinum, Tridemnum*) are species that maintain symbiotic bacteria in the tunic, the pharyngeal chamber, or the cloacal system. Three broadly different types of bacteria are found in apparent symbiotic association with tropical ascidians: cyanobacteria (including the genus *Prochloron*, a unicellular oxygenic photosynthetic prokaryote), alphaproteobacteria, and gammaproteobacteria. These bacteria produce a variety of secondary metabolites, including some unusual compounds found at startlingly high concentrations in the ascidians. Unusual oxidation states of vanadium are found at high levels in some taxa, and some secondary metabolites are highly toxic biomolecules currently used in cancer treatment and antivirals more potent than remdesivir, which has been tested for COVID-19. The roles of these compounds in ascidians are not well known, but it is assumed there are antipredator benefits to the toxic compounds and nutritive benefits to hosting photosynthetic organisms, such as those found in corals and sponges. Some didemnid ascidians housing such symbiotic bacteria are also remarkable for their powers of locomotion, limited though it is—colonies have been clocked at speeds of 4.7 mm per 12-hour period. Such movement may allow these ascidians to position themselves in light conditions favorable to their bacterial symbionts.

Adult filtration rates for solitary species are extremely high, on par with the bivalve filter feeders such as mussels and oysters with which they are commonly found, especially in fouling communities. Intriguingly, a large solitary *Pyura* species, invasive in Chile, has taken on the ecological role of a mussel bed, with masses of these large solitary ascidians packed together in a broad swath of the intertidal. Ecologically, ascidians have long been known to be highly efficient filtration engineers on reefs and in other habitats, including man-made structures such as marinas, pilings, and aquaculture facilities. The high filtration and growth rates of some solitary and colonial ascidians allow them to compete effectively with aquaculture species such as bivalves. The removal of these ascidians is a costly and unwelcome addition to bivalve culture operations. Unfortunately, the rate of human-accelerated ascidian range spread is increasing globally. Recently, ascidians have become particularly infamous and menacing invasive species, in the case of *Didemnum vexillum* even covering acres of benthic habitat in the Gulf of Maine in the northwest Atlantic. In some cases, ascidians have been observed in invasions of natural habitat, outside of harbors and bays where they have long been observed as suspiciously "cosmopolitan" species. These incursions may reflect broad changes in community structure in marine environments, including the elimination of many predators, an increase in available particulate food, and increasing sea surface temperatures.

Thaliaceans feed in much the same way as the sessile ascidians, except that the siphons are at opposite ends of the body. The number of pharyngeal stigmata is usually reduced, especially in doliolids, and restricted to the posterior portion of the pharynx (Figure 27.6D). The intestine extends posteriorly from the pharynx and opens into the enlarged cloacal chamber.

Appendicularians (Figure 27.6F–H) secrete an intricate, hollow, gelatinous (mucopolysaccharide) house in which they reside and upon which they depend for feeding. The animal's tail is directed through a tube in the house structure toward an excurrent opening. Sinusoidal beating of the muscular tail generates a current that pulls water into the house through coarse, meshlike, mucous filters that screen out large particles; eventually the water leaves the house via the excurrent opening. The pharynx of appendicularians bears only two small gill slits, which open directly to the exterior. Mucous feeding nets are secreted through the mouth and lie within the house chamber. The water current is directed through these fine-mesh nets, where food particles are concentrated, and the fragile house collapses when water is no longer pumped through it. The food, net and all, is periodically ingested by way of a short buccal tube. The houses of most appendicularians bear an additional opening that serves as an escape hole through which the animal can leave and reenter. The houses are fragile and easily damaged. Damaged or clogged houses are abandoned, and new ones are manufactured rapidly, in a matter of seconds or minutes. In some species a new or "spare" house may be found beneath the functional house; after the animal escapes the clogged house, the "spare" is rapidly inflated.

The gut of appendicularians is U-shaped, and the anus opens directly to the outside rather than into a cloacal chamber. Fecal material is released into the path of excurrent water leaving the filter nets. Appendicularians are primarily herbivorous, feeding on minute phytoplankton and bacteria even below a size of 0.1 μm. They sometimes constitute the dominant planktonic herbivores in waters over the continental shelf, reaching densities of many thousands per cubic meter.

Circulation, Gas Exchange, and Excretion

The circulatory system is weakly developed in urochordates, especially in the planktonic thaliaceans and appendicularians. It is best understood in ascidians, which possess a short, valveless, tubular heart that lies posteroventrally in the body near the stomach and behind the pharyngeal chamber (Figure 27.5A,D,E). The heart is surrounded by a pericardial sac, sometimes referred to as a vestige of the coelom. Blood vessels extend anteriorly and posteriorly, opening into spaces around the internal organs and also providing the blood supply to the tunic. The heartbeat is by peristaltic action driven by two myogenic pacemakers, one at either end of the tubular heart, and the direction of this motion is periodically reversed, flushing the blood first one way through the heart and then the other. Blood physiology and function are still largely matters of speculation. Curiously, many ascidians accumulate high concentrations of certain heavy metals in their blood, especially vanadium and iron. Some evidence suggests that the presence of high vanadium levels in at least some species serves to deter would-be predators. In addition, the blood includes a large variety of cell types, including amebocytes that are thought to function in nutrient transport, tunic deposition, and accumulation of metabolic wastes.

Gas exchange occurs across the body wall in tunicates, especially across the linings of the pharynx and the cloacal chamber. Little is known about respiratory physiology in these animals. In most ascidians and some other tunicates, two evaginations arise from the posterior wall of the pharynx and lie along each side of the heart. These structures are called **epicardial sacs**, and they are thought to represent coelomic remnants. In some species the epicardial sacs are involved in bud formation during asexual reproduction, and they may also function in the accumulation of nitrogenous waste products by forming storage capsules called **renal vesicles**. Other than by these vesicles and certain blood cells (nephrocytes), it is likely that much of the metabolic waste is lost from the body by simple diffusion.

Nervous System and Sense Organs

While the nervous system of tunicates is reduced, perhaps reflecting their relatively inactive sessile or floating planktonic lifestyles, it has recently received attention as possibly containing precursors of nervous system elements thought to be vertebrate innovations, such as placodes and the neural crest. In addition, a secondary mechanoreceptor organ, the **circumoral ring**, is found in some ascidians (including thaliaceans). This ring may be a precursor to the vertebrate secondary mechanoreceptor hair cells found in the ear and the lateral line organ. In ascidians the secondary mechanoreceptors are located around the siphons, and they show varying complexity among taxa that may relate to different feeding strategies.

A small cerebral ganglion lies just dorsal to the anterior end of the pharynx and gives rise to a few nerves that go to various parts of the body, especially the muscles and siphonal areas. A well-developed dorsal nerve cord is present in the tails of tunicate larvae, but this structure is lost during metamorphosis, except in the appendicularians. Most tunicates possess a **neural**, or **subneural**, **gland** located between the cerebral ganglion and the anterodorsal portion of the pharynx (Figure 27.5A,D). This gland opens to the pharynx through a small duct, but its function is unknown. Some workers have suggested that it may be the precursor of the pituitary gland of vertebrates. Sensory receptors are poorly known in tunicates, although touch-sensitive neurons are prevalent around the siphons.

Ascidian larvae are well known to be responsive to light and gravity, often with a general pattern of initially swimming upwards, toward the light, but then eventually settling in darker, shaded areas, though the pattern varies among species. Ascidian larvae possess several sensory receptors that function in settling and probably substratum selection, but they are absent from the adults. A small **sensory vesicle** lies near the anterior end of the dorsal nerve cord adjacent to the developing cerebral ganglion (see Figure 27.8C). This vesicle houses a light-sensitive ocellus and a statocyst (called an otolith). Most, though not all, ascidian larvae become negatively phototactic and positively geotactic at the time of settlement. The anterior end of the larva bears two or three **adhesive papillae**, each of which is supplied with two sets of neurons. A primary, more exposed set of papillae may serve in determining an appropriate settlement location via chemosensory abilities, while the secondary set of more protected neurons may be more involved in aspects of metamorphosis related to mechanoreception following attachment.

Reproduction and Development

Asexual reproduction While appendicularians are probably entirely sexual in their reproductive habits, thaliaceans and many other ascidians include asexual processes in their life history strategies. In social and especially colonial and compound ascidians, asexual budding allows rapid exploitation of available substrata and recovery from partial predation, as we have seen in other sessile invertebrates such as sponges and bryozoans. Remarkably, some colonial ascidians can regenerate their entire bodies from small amounts of vascular tissue, an impressive feat for a chordate and a subject of ongoing investigation into the nature of regeneration pathways that differ to some extent from asexual proliferation. In fact, regeneration studies in

the solitary ascidian *Ciona intestinalis* and colonial botryllid ascidians have been going on for over a century.

Budding in tunicates occurs in a great variety of ways and from different organs and germinative tissues (Figure 27.7). In general, initial buds are formed by a sexually produced individual (**oozooid**), then the asexually produced individuals (**blastozooids**) produce additional buds. The simplest and perhaps most primitive budding process occurs in certain social ascidians, including species of *Perophora* and *Clavelina*, where blastozooids arise from the body wall of stolons. In more complicated budding processes, the germinal tissues include various combinations of the epidermis, gonads, epicardial sacs, and gut. Doliolid thaliaceans often produce chains of buds. The chains are sometimes released intact, but eventually each blastozooid breaks loose as a separate individual. Budding in pyrosomes results in the characteristic floating colonies seen in species of this family (Figure 27.6A,B).

Some workers have divided the various types of budding among ascidians into two categories on the basis of their functional significance. Propagative budding generally occurs during favorable environmental conditions and serves to increase colony size and exploit available resources. On the other hand, survival budding tends to take place during the onset of adverse conditions and may be viewed as an overwintering or other survival device. With the return of more favorable growing conditions, these "prebuds" quickly develop as new blastozooids. More recently, particular attention to aspects of asexual reproduction has focused on the model colonial species *Botryllus schlosseri*, where a regular weekly cycle of zooid degeneration and replacement by developing buds (**pallial budding**) has served as a platform to investigate the relationship between developmental processes and regeneration. Recent discoveries have uncovered the presence of stem cell niches associated with the ascidian endostyle, as well as stem cells circulating in the vascular system that allow whole-body regeneration from isolated fragments of vascular tissue (**vascular budding**).

In botryllid ascidians, including *Botryllus schlosseri*, studies have shown that variation in blood pigments is genetically determined. The blood also contains several vertebrate-like hormones, including thyroxine, oxytocins, and vasoconstrictors. Compound species, such as those in the genera *Botryllus* and *Botrylloides*, have special blood components that play a vital role in rejecting adjacent conspecific colonies unless they are closely related (e.g., close relatives and clonemates), in which case the interaction may lead to colony fusion. This system is of great interest to comparative immunologists. Through breeding studies and genetic analyses, the "fusibility system" continues to be elucidated in these species. Populations of botryllids are highly genetically polymorphic at fusibility loci, with hundreds of alleles present even in invasive populations worldwide. Colonies that share at least one fusibility allele can fuse to form chimeras, while non-allele-sharing colonies undergo cytotoxic rejection processes and form permanent borders. The fate of the chimeras after fusion is less well known and also a subject of ongoing inquiry. Ascidian species vary in the intensity of the physiological engagement and subsequent rejection cytotoxicity when it occurs, and additional genes (and environmental variation) are thought to also play a role in determining the outcome of these immune-like interactions. This system is also being studied as a model for the evolution of kin recognition interactions in a medical context using natural transplantation phenomena related to host-graft acceptance or rejection.

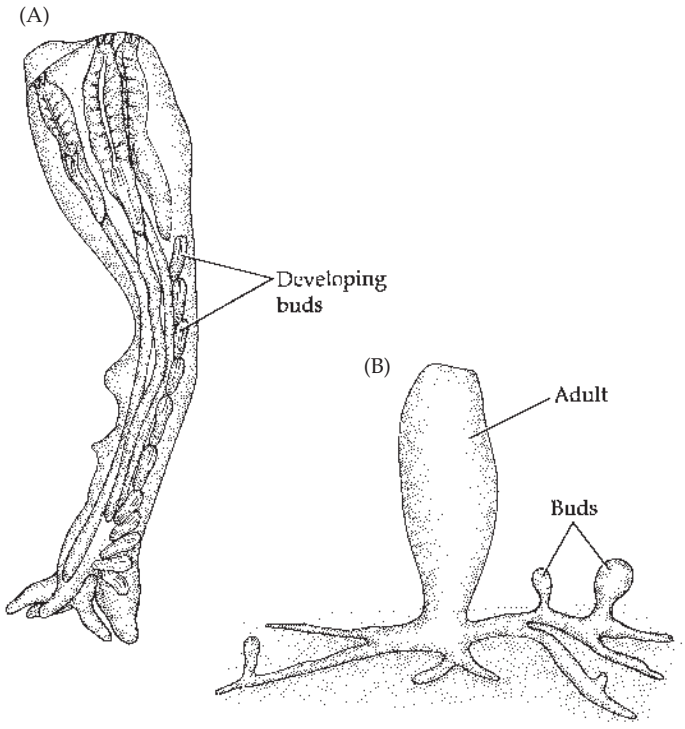

FIGURE 27.7 Asexual reproduction in ascidians.
(A) Formation of buds in the colonial ascidian *Aplidium*.
(B) General pattern of stoloniferous budding in an ascidian.

Sexual reproduction Tunicates are hermaphroditic, with relatively simple reproductive systems. Generally a single ovary and a single testis lie near the loop of the digestive tract in the posterior part of the body and, in most cases, connect through a separate sperm duct and oviduct to the cloacal chamber near the anus (Figure 27.5). However, some species have a single gonad (ovotestis), with one gonoduct, and members of a few families (e.g., Pyuridae, Styelidae) have multiple gonads. In some species, the ovaries contain high amounts of silica, but the significance of this is unknown.

There is considerable variation in overall reproductive strategies among tunicates. Most large solitary

for more ebook/ testbank/ solution manuals Request: email 960126734@qq.com

ascidians produce high numbers of ova with little yolk, which are shed into the sea coincident with the release of sperm from other individuals. External fertilization is followed by the development of a free-swimming **tadpole larva**, which eventually settles and metamorphoses to an oozooid (Figure 27.8). In contrast to this fully indirect life history pattern, many compound ascidians composed of tiny zooids produce relatively few eggs, but each egg has a high yolk content. These eggs are fertilized and subsequently brooded while attached to a parent zooid, or they are detached but located in various places within the tunic or within the cloacal chamber; they are not released until the swimming tadpole larvae develop. Some compound ascidian larvae are smaller with less yolk, but they retain a nutritive connection to the parent zooid in what is called a placental developmental mode. And various degrees of larval suppression also occur among some ascidians with this mixed life history strategy, with some species undergoing fully direct development. For example, *Protostyela longicauda* produces nonswimming larvae that are brooded. In this species, the larval "tail" is simply an extension of the tunic and contains no cellular material. The larva is sticky and when it is released, it quickly adheres to any object it contacts, later making a permanent attachment. At least some of these tailless species have been shown to be derived from tailed species, and genes controlling tail development are present but suppressed in expression.

Although all thaliaceans lack a free-swimming larva, they differ markedly in their approaches to direct development. In pyrosomes, each zygote develops directly to an oozooid, with no evidence of a larval stage. The oozooid then buds to produce a colony. Doliolids produce tailed larvae, but each is encased in a cuticular capsule and does not swim. The larva metamorphoses to an oozooid. Salps undergo internal fertilization in the oviduct. The zygotes implant and form a placenta-like association with the parent in a uterine chamber in the oviduct. Here the embryos develop directly to the adult form.

Appendicularians free-spawn, and fertilization occurs externally. They develop to a tadpolelike stage and then mature into the characteristic adults that resemble the larvae of ascidians.

In most tunicate species studied, cleavage is radial, holoblastic, and slightly unequal; it leads to the formation of a coeloblastula, which undergoes gastrulation by invagination. The blastopore lies at the presumptive posterior end of the body but closes as development proceeds. There is a long history of experimental work on developmental stages of ascidians, which has led to insights in areas such as cytoplasmic regulation within the egg and the relationship of egg and larval body axes. More recently, developmental studies in basal chordates including urochordates have focused intensely on understanding the derivation of vertebrate neural development. The solitary ascidian *Ciona intestinalis* has been the subject of a complete cell fate mapping project, including neural mapping of the larva, which has allowed extensive comparison of the transition from the larval sensory architecture to the very different adult architecture, with particular attention being paid to the search for homologies to vertebrates.

The development of chordate features is most easily seen and understood in those species that form free tadpole larvae, such as most Ascidiacea. In fact, the larvae of most ascidians consist of countable numbers of cells, making these animals excellent models for studying cellular events early in chordate development; gastrulation in ascidians starts as early as the 110-cell stage. As the embryo elongates, the gut proliferates three longitudinal strips of mesoderm—a middorsal strip that becomes the notochord, and lateral strips that form the mesenchyme and body musculature. Thus, even though the mesoderm arises from the archenteron (endoderm), it does not pouch substantively from the gut wall. A middorsal strip of ectoderm differentiates as a neural plate, which sinks inward and curls to produce the dorsal hollow nerve cord. The epidermis secretes a larval tunic, which often develops dorsal and ventral **tail fins**. The anterior part of the gut differentiates as the pharyngeal chamber (or basket) during larval life, and the rudiment of a cloacal water cavity forms by an ectodermal invagination producing the atrial siphon. However, these ascidian larvae are all lecithotrophic, and the gut and filtering devices do not become functional until metamorphosis. Social and colonial tunicate larvae are usually much larger than solitary larvae. The greater size includes a more highly developed adult rudiment in the trunk of the tadpole along with additional yolk, generally rendering the larval features more difficult to visualize. However, some colonial larvae are smaller and less yolky but maintain a nutritive connection to an adult zooid with a longer development time, in comparison to solitary larvae. Some species with symbiotic photosynthetic partners show a variety of structures associated with the larval and adult forms for housing the symbionts. Similarity in such structures does not necessarily correlate to phylogenetic affinities; instead, it suggests that the partnerships have evolved multiple times.

Ascidian larvae outside of the parent are short-lived. When development is fully indirect, the larvae are planktonic for only about two days or less. In some forms with a mixed life history pattern (e.g., *Botryllus*), the free larval life lasts only a few minutes and larvae may even settle and metamorphose upon the releasing parent colony, which then resorbs them. While the larval body is no longer visible, the germline of the resorbed larva may actually take over the germline of the resorbing adult in a phenomenon known as **germ cell parasitism**. This phenomenon is thought to be driven by kin selection and potentially

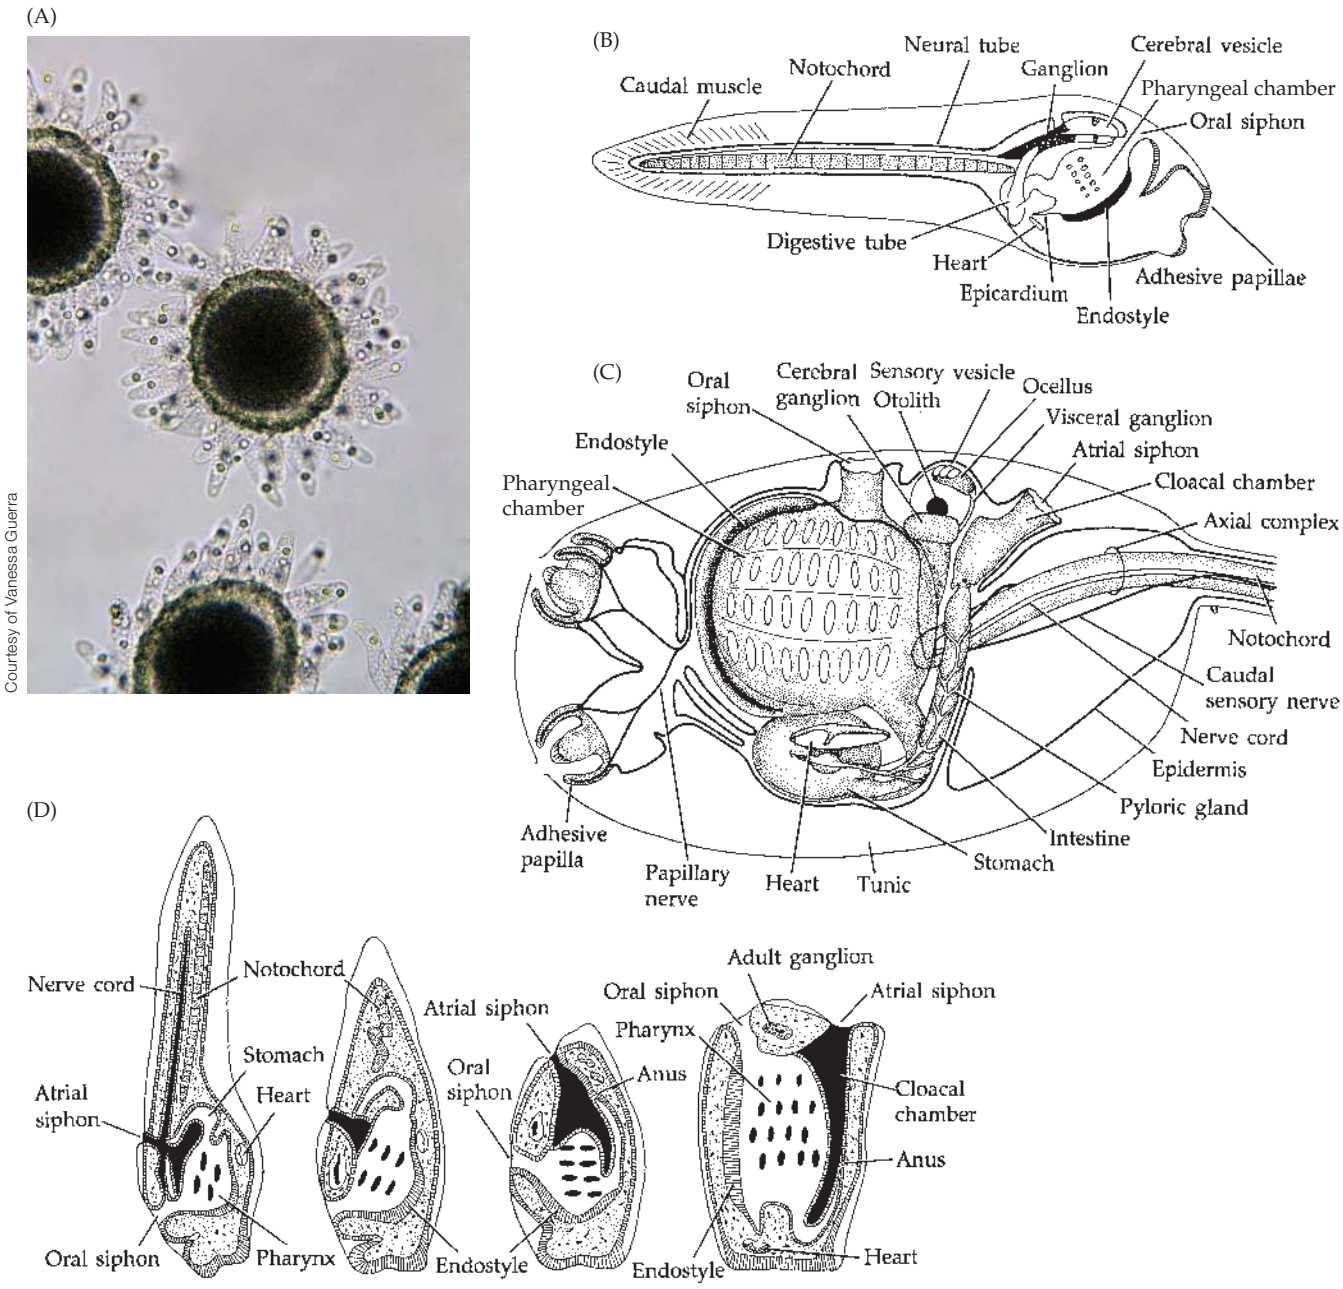

FIGURE 27.8 Sexual reproduction, larvae, and metamorphosis. (A) *Ciona intestinalis* eggs surrounded by follicle cells. (B) An ascidian tadpole larva has many chordate features. (C) The anterior end of the larva of *Distaplia occidentalis*. (D) Metamorphosis of a settled tadpole larva. Tail resorption is followed by a reorientation of the body to bring the siphons to the adult position. (E) Internal and external fertilization in the solitary ascidian *Corella*. Arrows show direction of water flow, in the branchial siphon and out the atrial siphon. In *C. willmeriana* eggs are being released from the atrial siphon, to be fertilized in the water (self-fertilization in this species is rare). In *C. inflata*, embryos and larvae are found within the atrial brood chamber, resulting from internal fertilization (which may be self-fertilization under certain conditions). (F) Tadpole larva of *Botryllus schlosseri* (with ampulla).

by advantages accrued to both partners. Larvae may escape the high mortality common for young juvenile stages and find a ready place to settle in space-limited environments. Adults may gain benefits in avoiding senescence through an infusion of juvenile stem cells. Even though a short larval life allows dispersal over only small distances, the larvae probably play a key role in the selection of suitable substrata. The events of settling and metamorphosis of ascidian larvae are complex and varied.

The settling larva of an ascidian contacts a substratum with its anterior end and may secrete mucus and undergo searching motions before releasing an adhesive from the papillae. In the larvae of many compound ascidians, the papillae evert during this process. The secretion of the adhesive apparently triggers an

irreversible sequence of metamorphic events. Within minutes after attachment, resorption of the larval tail commences by one of several methods involving various contractile elements in the tail region. The animal's viscera and siphons then undergo a remarkable 90° rotation that brings these organs to their adult position. The outer layer of the cuticle is shed, removing the larval fins from the settled juvenile (Figure 27.8D). The pharynx enlarges and the filtering mechanism becomes functional as the siphons open to the environment. During all of these processes secondary attachment organs, called **ampullae**, extend from the body and permanently affix the animal to the substratum. Finally, various transient larval organs are lost, such as most of the larval nervous system and sense organs.

Larvae of some species have been reported to practice aggregated settlement. Experimental studies suggest early juvenile mortality rates may be very high. Colonial species may have several advantages at this stage, as they start life at a larger size and are thus able to filter water more efficiently. Tiny early settlers may suffer from a low profile in the hydrodynamic boundary layer where flow rates are near zero, making food capture challenging. Some newly settled juvenile ascidians appear to have adaptations to increase their ability to filter feed near the boundary layer, including temporary growth of a stalk, enlarged siphon diameters relative to body size, and specific orientation relative to flow. As ascidians increase in size and escape the boundary layer, their growth rates sometimes increase dramatically.

Chordate Phylogeny

Recent phylogenomic analyses have largely, though not entirely, resolved the broad structure of chordate relationships (Figure 27.9). Both molecular and morphological analyses agree that the phylum Chordata is monophyletic. Its anatomical synapomorphies include the notochord, the endostyle (thought to be represented by the thyroid gland in vertebrates), and the muscular postanal tail. All chordates also have pharyngeal gill slits, epithelial tissue that binds iodine and secretes iodotyrosine, and a dorsal nerve cord, but these three features also occur in hemichordates, and some consider them synapomorphies of deuterostomes lost in crown-group echinoderms. However, homology of the solid dorsal nerve cord of hemichordates and the hollow cord of chordates has been challenged by recent work and needs further investigation. The notochord plays an important embryological role in inducing the chordate central nervous system, so absence of a notochord in hemichordates might be evidence in support of the idea that the hemichordate dorsal nerve cord may not be homologous with the chordate dorsal nerve cord, although this remains an open question. Gill slit endoderm in both hemichordates and chordates expresses *pax1/9* and *six1* genes, supporting their homology in these two phyla, and some authors consider gill slits to be present in stem-group echinoderms. Some juvenile enteropneusts have a postanal tail that has been homologized with the stalk of pterobranchs (Hemichordata). However, recent work has shown that the enteropneust tail expresses the *Hox11/13* gene, whereas the vertebrate postanal tail expresses the orthologous *Hox10–13* gene, suggesting possible homology in the postanal body regions, though not necessarily in the tail itself (the functions of these structures are altogether different in the two phyla).

Several recent phylogenomic analyses have agreed on some structure for chordate phylogeny (Figure 27.9). Urochordata (tunicates) and Vertebrata are sister groups (a clade named Olfactores by Richard P. S. Jefferies in 1991), and this forms a sister group to Cephalochordata (lancelets). Within the Urochordata,

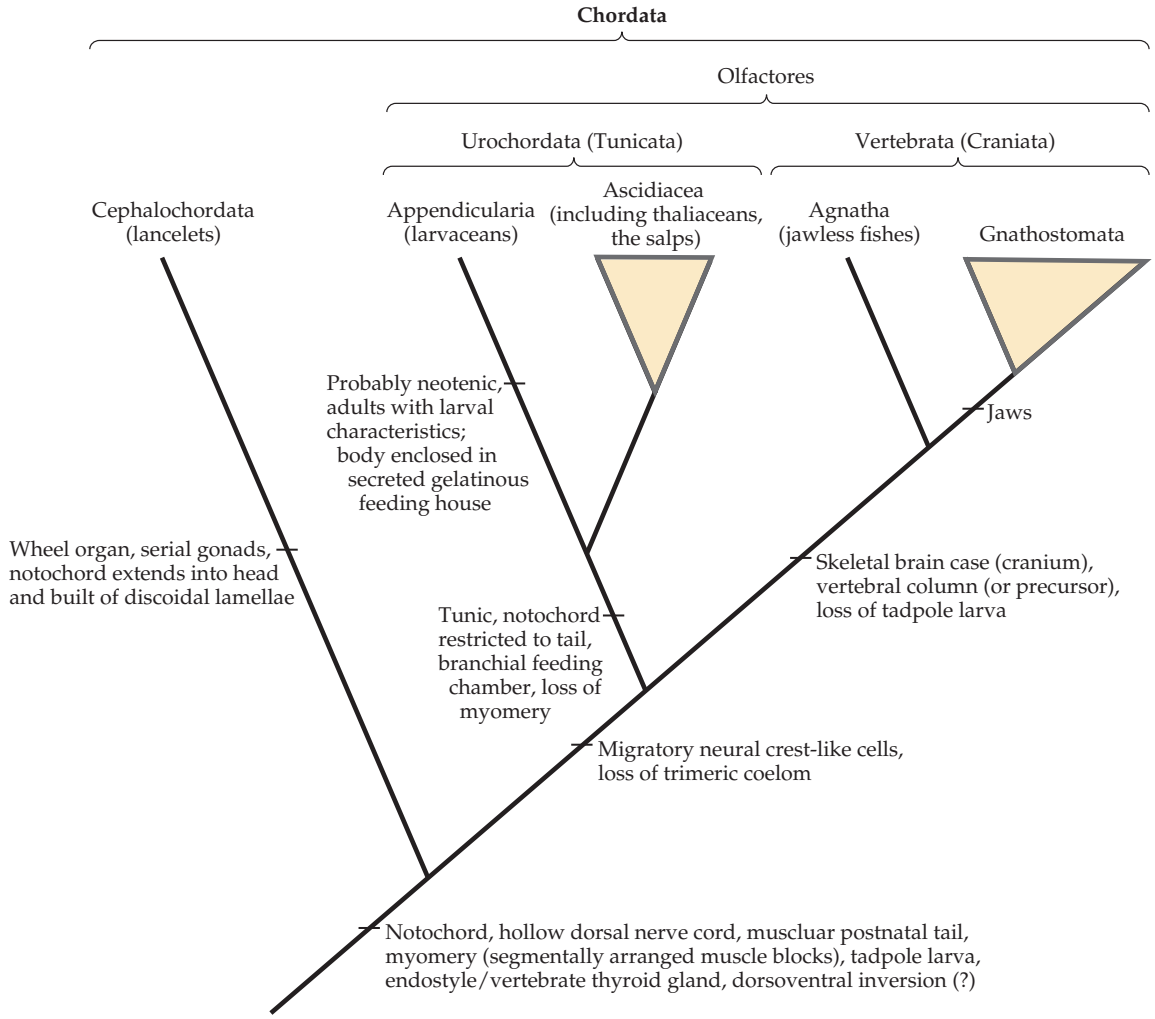

FIGURE 27.9 Phylogeny of the Chordata. See text for details.

Appendicularia (larvaceans) is the sister group of all other urochordates, and thaliaceans are derived ascidians. Ascidiacea is probably not monophyletic as traditionally defined, as it should be redefined to include thaliaceans, as we do here. The implication of this is that thaliaceans reacquired a pelagic lifestyle from their benthic ancestry.

The central nervous system of chordates shows a wide variety of forms, from a few small ganglia with a tail nerve cord in urochordates, to a swimming spinal cord with a hardly recognizable cerebral vesicle in cephalochordates, to a fully developed brain and spinal cord in vertebrates. The nerve cord of chordates develops dorsally as a hollow neural tube above the notochord. In the vertebrates, the nerve cord differentiates during embryogeny into a large brain and usually a well-developed spinal cord protected by the backbone. The notochord is a rodlike, skeletal structure dorsal to the gut and ventral to the nerve cord. It should not be confused with the backbone, or vertebral column, of adult vertebrates. The notochord appears early in embryogeny and plays an important role in promoting or organizing the chordate embryonic development of nearby structures. In most adult chordates, the notochord disappears or becomes highly modified. In some protochordates, and some fishes, it persists as a flexible but incompressible skeletal rod that supports the body during swimming. The embryonic development of the notochord in ascidians has been well studied. In *Ciona intestinalis* (Figure 27.3F) it is composed of only 40 cells, which align to form a single row by an event called convergent extension. The cells undergo vacuolation to transform the notochord into a single hollowed tube. The restricted number of notochord cells is achieved by the regulated number of cell divisions under the control of a key transcription factor, brachyury. The stomochord (buccal diverticulum) of hemichordates, once thought to be homologous with the chordate notochord, is now viewed as evidence of convergence or parallelism.

The vertebrate thyroid gland sequesters iodine and secretes T3 and T4 hormones, which regulate metabolism, postembryonic development, and

for more ebook/ testbank/ solution manuals Request: email:960126734@qq.com

metamorphosis. The lancelet and urochordate thyroid homolog, the endostyle, is primarily involved in mucus production for feeding, but it also incorporates iodine and synthesizes thyroid hormone. However, the exact role of TH in these groups is not well understood. In lampreys, the larva concentrates iodine and synthesizes TH in an endostyle, a thyroid homolog that reorganizes into a follicular thyroid at metamorphosis to the adult. Specialized secretory cells in hemichordates also bind iodine, but these are found throughout the pharynx, so a direct homology with the endostyle may not be appropriate, although these cells could have been the precursors to the chordate endostyle. Although no other animals possess an endostyle, TH does occur in other invertebrates.

Deuterostomes may be a small branch on the tree of life, but there are no stranger animals than echinoderms and chordates (especially vertebrates!). And this brings up one of the most profound synapomorphies of Chordata—the dorsoventral axis, which is thought to be inverted in comparison to the dorsoventral axis of the hemichordates (and probably all other bilaterians). Early in their evolution, chordates apparently turned themselves upside down! Hemichordate gill bars and gill slits are located dorsally (opposite the ventral mouth), while in cephalochordates and craniates the gill bars and slits are located ventrally. Gill openings are also dorsal in stem-group echinoderms. And, the dorsal epibranchial ridge of enteropneusts appears to be the anatomical and histological homolog of the ventral endostyle of chordates. Furthermore, the dorsal side of a juvenile hemichordate is determined by an expression stripe of the bone morphogenetic protein gene (*BMP*), which is expressed dorsally, and its ventral side is shown by an expression stripe of *BMP* antagonists, including chordin, just as has been shown for arthropods. In contrast, in vertebrates *BMP* is expressed ventrally and chordin is expressed dorsally. However, as the mouth is ventral in both chordates and nonchordates, the evolution of chordates must have also entailed moving the mouth from the opposite side of the gill slits to the same side as the gill slits, while presumably also evolving a notochord and dorsal central nervous system from a ventral enteropneust-like nerve net. The hypothesis of chordate dorsoventral axis inversion has been around since the early nineteenth century, and it has not been without its detractors (e.g., van den Biggelaar et al. 2002). However, current evo-devo research tends to support the idea.

But deuterostome (and chordate) oddness doesn't stop there. One of the other trends in deuterostome evolution is gene duplication, which appears to be widespread. The cephalochordates had long been thought to have the basic deuterostome Hox cluster of 14 genes, but in 2008 a fifteenth Hox gene was identified from the lancelet *Branchiostoma floridae*. In addition, in cephalochordates and vertebrates, *Hox9–14* show an independent duplication compared with protostomes. And a duplication of the posterior Hox genes into three genes (named *Hox11/13a*, *Hox11/13b*, and *Hox11/13c*) characterizes both echinoderms and hemichordates. In contrast, *Hox14* has been lost from all tetrapods and teleost fishes so far examined. Many other genes have been identified in amphioxus that show two to four paralogs in vertebrates, derived from two whole-genome duplication events. However, urochordate genomes seem to have lost many genes. Hox gene duplication, of course, is especially important for opening up new evolutionary-developmental avenues, since these are the "master genes" that are involved in anterior–posterior patterning in bilaterians.

The realization that urochordates, and not cephalochordates, are the most closely related group to Vertebrata is a recent discovery resulting from multigene analyses. It appears that earlier phylogenetic studies using a few genes that had hypothesized the cephalochordates to be the sister group of the vertebrates suffered from long-branch-attraction problems. Interestingly, R. P. S. Jefferies had predicted the tunicate-craniate relationship in 1991 on anatomical grounds. It was Jefferies who coined the name Olfactores, on the basis of a putatively homologous olfactory apparatus in fossils that was proposed as the precursor of the tunicate-craniate clade. We now know that the presence of migratory neural crest–like cells in urochordates probably also represents an anatomical-developmental synapomorphy of the Olfactores. The discovery that tunicates and craniates may be sister groups implies that characters common to cephalochordates and craniates (e.g., segmentally arranged muscle blocks) might be ancestral to all Chordata.

Cephalochordate synapomorphies include the unique wheel organ (an anterior vestibule formed by the oral hood bearing buccal cirri and ciliary bands). They share with Vertebrata the segmentally arranged blocks of muscles, developed from rows of mesodermal pockets from the archenteron, and this feature might be a synapomorphy of the Chordata that has been secondarily lost in the Urochordata. Fossil cephalochordates have been described from the middle Cambrian Burgess Shale and from the early Cambrian of China.

Urochordates possess several synapomorphies, including a unique cuticle of tunicin, a greatly enlarged pharynx forming a branchial feeding chamber, and oral and atrial siphons opening to an ectodermally derived atrium (cloacal chamber). Very few fossil tunicates have been described, but those also date to the early Cambrian.

The Vertebrata, or Craniata (as the name implies), are defined by an endoskeletal cranium and, in all but the Agnatha, a vertebral column (backbone). The evolution of the vertebrates from their protochordate ancestor involved a critical developmental innovation that led to the vertebrate head. This was the amplified **neural crest** and a distinctive cell population called the **neural crest cells**. These cells form at the neural plate border

and migrate extensively in the embryo to differentiate into numerous cell and tissue types, including connective tissues of the craniofacial skeleton, much of the peripheral nervous system, and pigment cells. They are responsible for many of the complex structures in the vertebrate head that are absent in cephalochordates and tunicates. Neural crest cells also give rise to various cranial ganglia and craniofacial cartilages and bones, and they even enter the pharyngeal pouches and arches where they contribute to the thymus, bones of the middle ear and jaw, and the odontoblasts of primordial teeth. So unique are these cells, and their derivatives, that some biologists consider them a "fourth germ layer." The migration of neural crest cells represents an epithelial-to-mesenchymal embryonic transition. Long thought to be an innovation of the Vertebrata, a migratory cell population resembling neural crest cells has recently been documented from urochordates. In *Ecteinascidia turbinata*, dye-labeled cells have been shown to emerge from the neural tube, migrate into the body wall and siphon primordium, and subsequently differentiate as pigment cells. These cells even express HNK-1 antigen and *Zic* gene markers as seen in vertebrate neural crest cells. Thus, it seems that the origin of neural crest cells lies in the common ancestor of vertebrates and urochordates. It is highly likely these cells gained additional functions, and were joined by other cell types, to generate the broad variety of derivative tissues typical of vertebrate neural crest cells.

Molecular clock analyses have suggested that the Deuterostomia (indeed, the Bilateria) might have arisen in the Precambrian.

Chapter Summary

The monophyletic phylum Chordata contains three major clades, ranked as subphyla: Cephalochordata (a small group of fishlike invertebrates known as the lancelets or amphioxus), Urochordata or Tunicata (a large group of filter-feeding invertebrates called tunicates that are benthic or planktonic), and Vertebrata (the vertebrates). The first two groups are strictly marine. Modern phylogenomic research shows that Urochordata is the sister group to Vertebrata, a clade known as Olfactores. Future research will continue to investigate the putative vertebrate precursor molecules in urochordates (e.g., thyroxin, oxytocins, and vasoconstrictors) and their evolutionary-developmental pathways, as well as the immunelike system in ascidians that is at play when colonies meet and "fight or fuse." Studies will also continue to use tunicates to better understand the derivation of vertebrate neural development. The question of dorsoventral inversion in Chordata needs further investigation.

CHAPTER 28

Perspectives on Invertebrate Phylogeny

By the time you have gotten to this chapter, you will have "toured" almost *all* of the Animal Kingdom, given that invertebrates comprise roughly 96% of all described, living animal species. What an incredible diversity of form and function you have seen! Isn't it curious how unevenly these animals are distributed across the 31 metazoan phyla? Vastly unevenly distributed—82% of all described animals are arthropods, 5% are molluscs, and only 4% are chordates. The other 28 phyla make up the remaining 9%! Six phyla have fewer than 100 described species in them, and half of those have fewer than a dozen known species. What are we to make of this? In fact, only 6 phyla comprise more than 1% each of the described animal species on Earth (Arthropoda, Mollusca, Annelida, Platyhelminthes, Nematoda, and Chordata). It would seem that the world belongs to insects, crustaceans, spiders, molluscs, worms, and vertebrates. Indeed, these are the only animals most humans ever see in their lifetimes (unless they happen to go diving on a tropical coral reef, in which case they are confronted by myriad sponges, cnidarians, and echinoderms). How fortunate that you have now been introduced to all 31 animal phyla, even the smallest and least understood groups.

In reading the "animal chapters" of this text, you have learned a good deal about the evolution of these 31 phyla, how they are related to one another, and what their internal relationships are. You have learned that phylogenies can be constructed from a variety of different kinds of data and that most recently the field of molecular phylogenomics (phylogenetics based on large amounts of genomic data) has proliferated, giving us new ideas about how Earth's creatures are related to one another. The idea of phylogenetic trees should now be quite familiar to you. But let's take one last look, a "higher view" of animal phylogeny, before we close the cover on this fourth edition of *Invertebrates*.

Molecular phylogenetics had only just begun to bear fruit in 2002, when the second edition of this book went to press. While some tantalizing suggestions of new and very different kinds of relationships among the animal phyla had been suggested, these new hypotheses had not yet been broadly tested. Since then, molecular phylogenetics has exploded onto the scene at a pace never imagined, and it now plays the primary role in reconstructing animal phylogeny. In just the past 20 years we have come from analyzing a few ribosomal genes to the point where new genome-level analyses are being published almost daily. Molecular phylogenetics is now being incorporated into studies of ecology, oceanography, biogeography, conservation biology, medicine, archeology, and anthropology. And it is building a new framework for the tree of life.

Unraveling the phylogenetic history of the animal kingdom has been one of biology's great challenges. The "new phylogeny," built with molecular data, has many similarities to older trees built on morphological and developmental data, but some big surprises have emerged and many uncertainties remain. The biggest challenge lies in the fact that life's deep lineages arose and began to diverge from one another so long ago, over half a billion years ago for most phyla. So the traits of animals, whether anatomical or genetic, that might be useful in revealing relationships among these ancient lineages are often obscured by hundreds of millions of years of evolutionary change. But, despite this, many relationships are now well resolved.

Early molecular phylogenetic studies relied heavily on the 18S ribosomal RNA gene (also known as the nuclear small-subunit ribosomal RNA gene, or SSU rRNA). However, it quickly became apparent that understanding deep-level metazoan phylogeny required analysis of additional genes, particularly nuclear protein-coding genes, and this led to an era of multigene trees that continues today as phylogeneticists add more and more loci (and taxa) to their data sets for analysis (reviewed in Chapter 2). Most recently phylogenomic studies using large parts of the genome (sometimes using the transcriptome[1] as a proxy for the whole genome but leaning more towards whole genomes in the past few years) and analyzing hundreds or even thousands of genes have begun to expand the scope of data available for phylogenetic analysis, and this has added increased stability to the structure of our phylogenetic framework. The advent of evo-devo, or evolutionary developmental biology, has also begun to significantly impact our understanding of how genes relate to specific morphologies, how they work, and what roles they might have played in the unfolding of animal radiations. These new techniques have provided answers to fundamental questions, such as the identity of arthropod appendages and the nature of segmentation in animals.

A large body of evidence, anatomical and molecular, has accumulated since the 1960s that supports the view that animals share a common ancestor with the protist group Choanoflagellata. The flagellated collar cells of sponges and choanoflagellates are nearly identical, and similar cells have also been described in a few other animal phyla, including some cnidarians, echinoderms, hemichordates, and ascidians. A few interesting differences between them have been noted, but some divergence over a half billion years is to be expected. The Metazoa are defined by a number of apomorphies, the most obvious being multicellularity arising through the embryonic layering process called gastrulation. Also, unlike coloniality, as seen in many protist groups (including choanoflagellates), in metazoans the epithelial cells are in contact with each other through unique junction structures and molecules, some of which make transport of nutrients between cells possible (e.g., septate or tight junctions, desmosomes, zonula adherens). Additional metazoan apomorphies include striate myofibrils, actin-myosin contractile elements, the possession of animal (type IV) collagen (although collagen, or a collagen homologue, also occurs in some fungi), and a basal lamina beneath the epidermis. In addition, sexual reproduction in animals involves a distinct pattern of egg development from one of the four cells of meiosis, whereas the other three cells degenerate.

Figure 28.1 is a working hypothesis of metazoan phylogeny, based primarily upon the most recent molecular phylogenetic research. Some of these studies have been in agreement that the phylum Porifera, the sponges, is the sister group to all remaining animals and thus could be considered the "oldest" animal phylum. However, other molecular phylogenies have suggested Ctenophora might occupy this position as the sister group to all other metazoans. The draft genome of *Pleurobrachia bachei*, together with other ctenophore transcriptomes, suggests that ctenophores may be rather distinct from other animal genomes in their content of neurogenic, immune, and developmental genes. However, a number of putative apomorphies link Cnidaria and Ctenophora with the Bilateria in a clade that has been called Neuralia. The "basal Ctenophora" hypothesis has been challenged by some authors as an artifact of methodological issues, yet others disagree and have found that the artifacts affect the more traditional placement of sponges. In fact, the placement of Ctenophora is only one area of uncertainty near the base of the animal tree. Strong resolution of the positions of Placozoa and Cnidaria has also yet to be achieved (and placozoans seem to be much more derived than their simple body plan would first suggest, contradicting the Neuralia hypothesis). This is why we represent the first node of our tree as a trichotomy between Porifera, Ctenophora, and the remaining animals, and the second node as a trichotomy between Cnidaria, Placozoa, and Bilateria.

The origin of the Bilateria, likely in the Precambrian, was a transformative event in the evolution of animals. The origination of fundamental bilateral symmetry led to cephalization and the innovation of mesoderm (a third germ layer), the latter allowing for the evolution of a variety of new organs and a new kind of underlying body cavity (the secondary coelom, or eucoelom). The appearance of mesoderm and a true adult coelom in animal evolution led to the ability to penetrate the substrate, which in turn led to three-dimensional ichnofossils such as the ones left by *Treptichnus pedum*, the first

[1] Whereas a genome is the complete set of genes present in a cell (or organism) and is sequenced from DNA, a transcriptome is a subset of those genes that are transcribed (or expressed) in a cell at any given time and is sequenced from RNA.

for more ebook/ testbank/ solution manuals requests: email 9601267346@qq.com

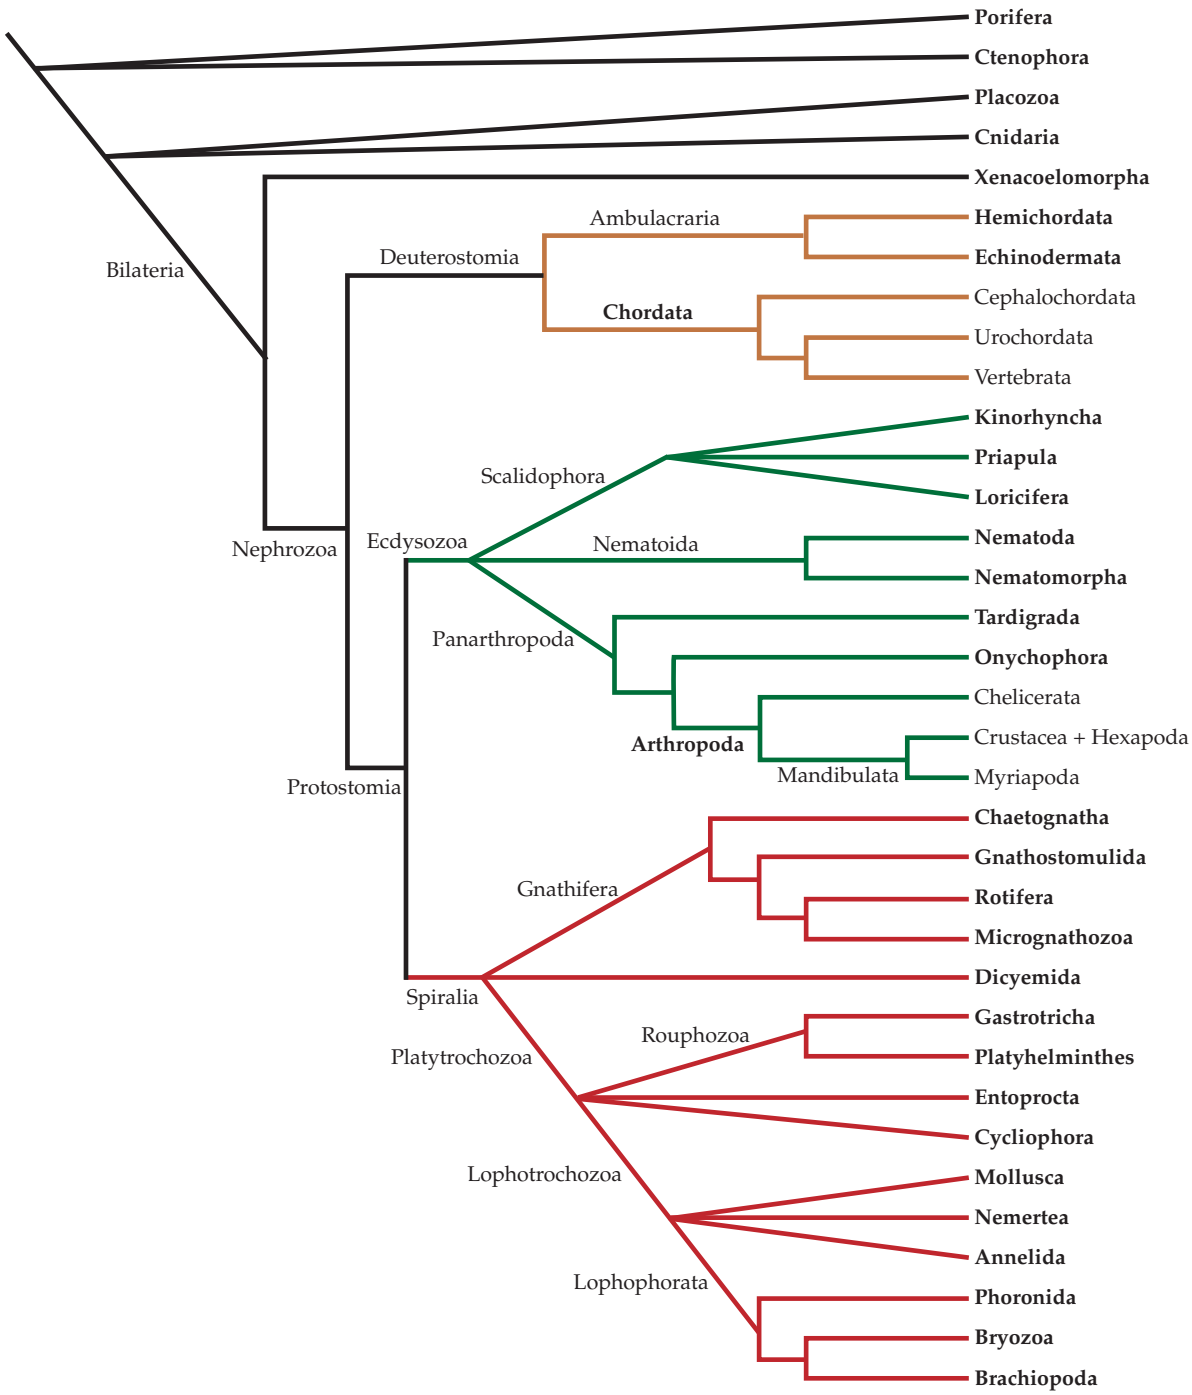

FIGURE 28.1 A phylogeny of Metazoa. This tree reflects a consensus view based primarily on recent molecular phylogenetic analyses. The 31 animal phyla are in boldface, whereas subphyla and other clades are in lightface. Spiralian lineages are in red, ecdysozoan lineages are in green, deuterostome lineages are in tan. Uncertainty still exists in several regions, and these are depicted as polytomies ("starbursts"). Thus, for example, the branching sequence for Placozoa, Cnidaria, and Bilateria is not yet resolved, so it is shown as an unresolved trichotomy. Similarly, two large polytomies exist among the Platytrochozoa, and the relationships of the three ecdysozoan clades are still unresolved, as are those of the three scalidophoran phyla. Due to uncertainty, Dicyemida is depicted in an unresolved trichotomy with Gnathifera and Platytrochozoa.

animal to burrow and consequently form the ichnofossil that defines the base of the Cambrian. It is likely that such anatomical innovation caused a dramatic increase in the depth and intensity of bioturbation in seafloor sediment, known as the "agronomic revolution." One of the earliest living phyla to appear once bilaterality was achieved may have been Xenacoelomorpha (but acoelomorphs are acoelomate and probably not

responsible for the *T. pedum* burrows). Early in the evolution of Bilateria the clade split into two great lineages, Deuterostomia and Protostomia.

The position of the phylum Xenacoelomorpha is still debated, although a general consensus is emerging that it comprises basal bilaterians and does not fall unambiguously within either Deuterostomia or Protostomia. Some molecular research had suggested that Xenoturbellida (and even Xenoturbellida + Acoelomorpha) were deuterostomes, but that hypothesis is not well supported. The weight of molecular and morphological evidence places Xenacoelomorpha as a clade and sister group to all other bilaterians, as shown in our tree. Apomorphies of Xenacoelomorpha may be their unique pulsatile bodies, their unique epidermal cilia, and their frontal organ/pore. Because xenacoelomorphs lack excretory organs and a through gut, and these (in their many forms) are present in most other bilaterians, the sister group to Xenacoelomorpha has been called Nephrozoa. Nephrozoa are distinguished by the presence of a through (complete) gut, discrete excretory organs, and the presence of a *Hox3* gene. Nephrozoa divides clearly into the two clades that have been accepted for many decades, Deuterostomia and Protostomia (although their composition has been in flux).

These two lineages were introduced to you in Chapter 8. Because of their great age, untangling the characteristics of the first deuterostomes and protostomes has been challenging. Deuterostome apomorphies are likely the presence of pharyngeal gill slits, a trimeric coelom, and enterocoelic development, although all three of these features have been lost in some modern forms. Protostomia is even trickier to define by any morphological synapomorphies, since so much animal diversity is encompassed by this clade, although the ventral nerve cord and circumesophageal brain are probably good apomorphies (but they are not distinct in a few soft-bodied worms). The relationships of the Deuterostomia are largely settled with the Ambulacraria (Hemichordata + Echinodermata) being the sister group to the Chordata (Cephalochordata, Urochordata, and Vertebrata/Craniata). Ambulacrarian apomorphies include a unique heart-kidney system and a specific larval form. But the relationships among the protostomian phyla still remain to be fully resolved.

Deuterostomia is a small radiation composed of just three phyla, two of which have been very successful—Echinodermata and Chordata (with 7,300 and 63,000 named living species, respectively). The protostomes, on the other hand, comprise 23 phyla and over 1.3 million living species. The Protostomia are divided into two large clades—Spiralia and Ecdysozoa. Ecdysozoans are distinguished by their molting process, whereas spiralians have spiral cleavage, although this distinctive feature has been lost many times in the course of spiralian evolution.

Relationships among the Ecdysozoa (the molting Protostomia) are partly resolved, although those among the three major clades (Scalidophora, Nematoida, Panarthropoda) remain unclear; thus these three lineages are depicted as a trichotomy in our tree. Similarly, the clade Scalidophora needs further study to verify its monophyly and the relationships of its three included phyla. The Nematoida and Panarthropoda trees are strongly supported, but admittedly, genomic resources are unevenly distributed among lineages, with lots of genomes for arthropods and nematodes and few to none for tardigrades, onychophorans, and nematomorphs, which makes phylogenomic results tentative.

Relationships within Spiralia also need further refinement, but recent phylogenomic data suggest there may be two clades—Gnathifera and Platytrochozoa. The position of Dicyemida (kidney parasites in cephalopods) remains unclear, and our tree shows this phylum unresolved with respect to the other two main spiralian clades. Most chaetognath morphological traits have no clear homologies in other lineages, but molecularly they group with the Gnathifera, and their cerebral ganglia resemble those of the spiralian phyla.

One of the major things we might notice in this view of phylogenetic relationships is that developmental systems are flexible. For example, a trait long thought to define the Deuterostomia is deuterostomous development itself. However, we now know that this mode of embryogeny also occurs in some phyla belonging to the clade Protostomia (e.g., in Nematomorpha, Priapula, Brachiopoda, many Crustacea, perhaps Chaetognatha). Thus, as noted early on in this book, the clade Deuterostomia cannot be defined by deuterostomy, nor can the clade Protostomia be defined by protostomy (which also occurs in Cnidaria and Ctenophora). Similarly, radial cleavage is likely plesiomorphic among Bilateria, while spiral cleavage, which is apomorphic for Spiralia, appears to have reverted back to radial or other idiosyncratic modes multiple times. Thus, the clade Spiralia in our tree has members whose cleavage patterns are radial (e.g., the three lophophorate phyla), whereas the Gastrotricha seems to have a unique form of cleavage. Several phyla of Spiralia have trochophore or trochophore-like larvae (e.g., some members in the phyla Mollusca, Annelida, Nemertea, and possibly Entoprocta), but these have not consistently been grouped together in the molecular phylogenies.

This brings us back to the question of why animal species diversity is so strongly dominated by arthropods, molluscs, annelids, and vertebrates. Unfortunately, there is no easy explanation for why these four groups have enjoyed such expansive radiations. Could it be that this is an artifact of time—perhaps during earlier eras, the Mesozoic or Paleozoic, other phyla dominated Earth's biosphere but simply left us little fossil evidence of their prior dominance, due to their

for more ebook/ testbank/ solution manuals requests: email 9601267346@qq.com

fragile bodies? If this were the case, many of those small phyla could be viewed today as "living relicts" (like horseshoe crabs). Did ctenophores, placozoans, acoels, gastrotrichs, nemerteans, chaetognaths, entoprocts, gnathostomulids, and other phyla that today seem almost inconsequential once dominate the world? Or perhaps the "big four" taxa have always been dominant due to something intrinsic in their biology that remains to be elucidated. Another possibility is that we simply haven't looked hard enough, spent enough effort combing through interstitial habitats, deep-sea sediments, and the parasitic world—there might well be an enormous biological diversity still waiting to be discovered in such poorly sampled environments (certainly we know this is true for the roundworms, Nematoda).

We finish this chapter with a note of caution and one of hope. Molecular phylogenies are resolving the puzzle of the animal tree of life one piece at a time, but morphology still has its role in phylogenetics. Gnathifera, for example, was first recognized by analyzing morphological traits, and it has subsequently been consistently recovered by both morphological and molecular analyses. The monophyly of other groups, such as Scalidophora, is supported more strongly by morphological data than by molecular data, but this clade is broadly accepted by invertebrate biologists. Many groups have been shuffled around the tree, mostly because they were once positioned based on single character systems (e.g., radial versus spiral cleavage; acoelomate versus blastocoelomate versus coelomate), and many of these character systems conflict with one other. Molecular phylogenetics has given us a new way to look at the animal tree, and robust and stable results have made us rethink certain long-held paradigms (e.g., Articulata versus Ecdysozoa; Atelocerata versus Pancrustacea). Morphology can be misleading in some cases, as molecular analyses can also be affected by many kinds of biases or be unable to reconstruct the interrelationships of some animal groups. Thus, only by combining the information derived from the careful study of both disciplines will we be able to generate a sound animal phylogeny and be in a position to comprehend what that phylogeny means in terms of the evolution of animal body plans.

CHAPTER 13

The field of malacology is so large, has had such a long history, and has so embraced the mixed blessings of contributions from amateur shell collectors that dealing with the literature is a daunting task. Many molluscs are of commercial importance (e.g., *Haliotis*, *Mytilus*, oysters, squid), and for these groups hundreds of studies appear annually; others are important laboratory/experimental organisms (e.g., *Doryteuthis*, *Octopus*, *Aplysia*), and many papers are also published on these groups. New taxonomic monographs on various groups or geographical regions also appear each year, as do countless shell guides and coffee-table books. Distilling all of this into a small set of key references useful for entry into the professional literature is difficult; the list below is our attempt to do so.

CHAPTER 21

The amount of published literature on crustaceans is vast. Much of the key work on classification and phylogenetics was reviewed by Martin and Davis (2001), and on larval development by Martin et al. (2014). We refer readers to those works for an entrée into those fields.

CHAPTER 22

The amount of published information on Hexapoda is overwhelming. We have thus had to be very selective in our reference list, emphasizing texts, conference volumes, and journal articles that present emerging new fundamental knowledge, are solid overviews in their respective fields, or are older classics worthy of mention. These will provide readers with an entry into the primary literature.

  extinctions of, 6
  invasive, 6, 662, 917, 926
  nomenclature on, 38–39
  number of, 2–3, 3t, 5–7, 16, 26, 35
  threatened, 6, 662, 737
  type specimen of, 39, 39n
Species Plantarum (Linnaeus), 38
specific epithet, **38,** 40n
Spelaeogriphacea, 664, 683f, 688, 704f
Spelaeogriphus lepidops, 683f, 688
Spemann, H., 91, 99
Spengel, J. W., 323, 860
Spengelidae, 862
Spengelomenia bathybia, 328f
Speonebalia cannoni, 674
sperm, 86f, 86–87
spermatic cysts of Porifera, **146**
spermatogenesis of Nemertodermatida, 265, 266f
spermatophores, **87**
  of Mollusca, **386,** 388, 389
  of Phoronida, 492f, 495
spermatozeugmata of Siboglinidae, 475, 476
sperm duct, **87,** 87f
sperm follicles of Porifera, **146,** 147f
sphaeridia of Echinodermata, **900**
Sphaeriidae, 340, 390
Sphaerocladina, 126
Sphaerodoridae, 422
Sphaeroeca, 114
  volvox, 113f
Sphaerolichida, 807
Sphaeromatidae, 644, 711, 724
Sphaeromatidea, 664
Sphaeromatoidea, 664
Sphaerotheriida, 786f
Sphaerotheriidae, 797
Sphaerotherium, 797
Sphaerulariopsis, 580f
Sphecidae, 747
Spheciospongia, 157
  confoederata, 122f
  vesparium, 156
spherical symmetry, **44,** 44f
spherulous cells of Porifera, **135**
Sphinctozoa, 160
Sphingidae, 751
Sphodros, 827, 829f
spicules
  of Nematoda, **594,** 595f
  of Porifera, 137–138, 138f–139f, 145, 155, 162, 163
spider silk and webs, 644, 819–823, 820f, 822f, 823f
  in feeding, 821, 827–830, 828f–829f
  in locomotion, 825, 825f
  in reproduction, 842, 843f
spidroins, **819**
Spinicaudata, 666, 698, 719
spinnerets, **819,** 820f, 821, 823, 825
Spinoloricus cinziae, 573, 573f
spinoscalids
  of Kinorhyncha, **565,** 566f, 568
  of Loricifera, **573,** 574f
Spinulosida, 878
Spiochaetopterus, 417f
Spionida, 423
Spionidae, 417f, 423, 432, 435, 436f
spiracles, **72, 645,** 646f
  of Hexapoda, 768, 769f, 770, 771
  of Myriapoda, 793
  of Onychophora, 624f, 625
spiral cleavage, 25, **96,** 97f, 97–99, 247, 275, 280
  of Acoela, 260–261
  cell fates in, 100, 101
  of Chaetognatha, 307
  coding system for, 97–99, 98f, 544, 728f
  of Crustacea, 727, 728f
  of Entoprocta, 313
  of Platyhelminthes, 544, 555
Spiralia, 241, 247, 273, 274–280, 311, 321
  Annelida, 415–485
  Dicyemida, 275–280
  Gastrotricha, 556–560
  gastrulation and gene expression in, 100f
  Gnathifera, 281–309
  as legacy name, 25, 275
  Lophophorata, 487–517
  Mollusca, 321–395
  Nemertea, 397–413
  phylogeny of, 24, 31n, 246f, 554, 556, 629, 652, 937f, 938
  Platyhelminthes, 520–546
  Platytrochozoa, 311–320
  Rhombozoa, 275–280
  Rouphozoa, 519–561
Spirobolida, 788, 789
Spirobranchus giganteus, 433f, 455f
spirocysts of Cnidaria, **216,** 220
Spirorbinae, 423
Spirostreptida, 789, 794
Spirostreptus, 792f
Spirula, 352
Spirularia, 192
Spirulida, 344
Spirulidae, 344
Spirurida, 584
Spodoptera, 829
Spondylidae, 339, 359
Spondylus, 382
Spongia, 137, 156
  officinalis, 137f
Spongiae, 124
Spongiaria, 124
Spongicola, 156, 678
  venusta, 679
Spongida, 124
Spongilla, 122f, 145f
Spongillida, 126

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Spongillidae, 145f
spongin, 124, 125, **134,** 137, 144–145
spongocoel, **129**
spongocytes of Porifera, **134,** 135f
spore valves of Cnidaria, **222**
sporocysts of Platyhelminthes, **551**
sporosacs, **236**
Squilla, 645f, 675f
stabilimentum of Eucheliceratа, **821,** 823f
stalk, of Cnidaria, **204,** 206f
stalking predators, 62–63
Staphylinidae, 749
star-cell organ of Entoprocta, **315**
statoblasts of Bryozoa, 497f, **509,** 509f
statoconia of Mollusca, **382**
statocysts, 77f, **77**–78
  of Acoela, 253f, 254f, 258–259
  of Annelida, 449–450
  of Brachiopoda, 515
  of Cnidaria, 230
  of Crustacea, 721, 722f
  of Ctenophora, **179,** 180f
  of Echinodermata, 900
  of Mollusca, 384
  of Nemertea, 409
  of Nemertodermatida, 261, 264, 264f, 265
  of Platyhelminthes, 539, 540f
  of Urochordata, 927
  of Xenoturbellida, 267, 270, 270f
statoliths, 77f, **77**–78
  of Acoela, 258, 259
  of Ctenophora, **179,** 180
  of Mollusca, **382**
  of Nemertodermatida, 261, 265
Stauroteuthidae, 342
Staurozoa, 188, 193, 210f
  evolution of, 2
  movement of, 214f, 215
  phylogeny of, 241, 242f
  polypoid stage of, 198
  reproduction of, 234
Stegodyphus, 823
Stegophrynus dammermani, 810f
Stegosoma, 923f
Steinböck, O., 262
Steinernema, 591f, 592f, 595f, 599f
Steinernematidae, 588
Stelletta, 144f
stem cells of Porifera, 134–135
stem nematogens of Dicyemida, 278f, 279
stenohaline animals, **67**
Stenolaemata, 499
Stenoplax, 389f
Stenopodidea, 664, 676, 678f, 678–679, 723f, 725
stenopods of Arthropoda, **635**
Stenopus, 678, 678f, 679
  hispidus, 723f
Stenorhynchus, 679f
Stephanian deposits, Onychophora in, 619, 620f
Stephanoceros, 285f
Stephanodrilus, 477f
Stephanoscyphistoma, 234
Stephen, A., 459
stereoblastula, **101,** 101f, 103, 153
stereogastrula, 102f, **103**
stereom of Echinodermata, **877,** 887, 905, 907f, 908
sternite of Arthropoda, **632,** 632f
Sterreria, 262f
  psammicola, 258f
Stiasny-Wijnhoff, G., 399
Stichocotylida, 525
stichocytes of Nematoda, 590
Stichodactyla mertensii, 198
Stichopus, 896
stichosome of Nematoda, **590**
stigmata of Urochordata, **925,** 926
Stilbonematidae, 588
Stoecharthrum monnati, 483
Štolc, A., 190
Stolidobranchia, 912
stolon, of Pterobranchia, 861f, **869**
stolonal funiculus of Bryozoa, **503**
Stolonifera, 188, 191
stoma, of Nematoda, **590**
stomachic plexus of Phoronida, **494**
Stomatolepas, 691
Stomatopoda, 664, 674, 675f
  circulation and gas exchange of, 645f, 717, 719
  excretion and osmoregulation of, 720
  feeding and digestion of, 710
  internal anatomy of, 715f
  locomotion of, 638, 703
  reproduction and development of, 725, 729f
  sense organs of, 722, 722f
Stombus, 356
stomoblastula of Porifera, 125, **151,** 152f, 162
stomochord of Hemichordata, **863,** 932
stomodeal ectoderm, **102**
stomodeal plane of Ctenophora, **174**
stomodeum
  of Ctenophora, **174,** 183
  of Nemertea, 404
Stomolophus meleagris, 235f
Stomphia, 213, 214f
stone canal of Echinodermata, **886,** 887
Strepsiptera, 738, 739, 747, 748f, 749
  phylogeny of, 37f, 781f
  wings of, 760
Streptomyces avermectinius, 600
Streptoneura, 323
streptoneury of Gastropoda, **355, 379**
stretch receptors, 78
Strickland code, 39
stridulation of Chelicerata, 842, 843f
Strigamia, 790f
strobila
  of Cnidaria, **233,** 234f
  of Platyhelminthes, **529,** 529f
Strobila, 190
strobilation
  of Cnidaria, **231, 233,** 234f, 235f
  monodisc, **233**
  of Platyhelminthes, **529**
  polydisc, **233**
stroma of Echinodermata, **877**
Stromatocystites, 882f, 906, 907f, 908
Stromatoporoida, 160, 161f
Strombidae, 335
Strombus, 380
Strongylida, 584–585, 589f, 592f
Strongylocentrotus, 880f, 899f
  droebachiensis, 40n
  purpuratus, 61, 874f, 889, 899f
Struck, T., 483, 484f, 519
Stunkard, H. W., 275
Styela, 60f, 918f, 922
Styelidae, 928
Stygiomysida, 664, 687
stygobionts, **22**
Stygobromus, 689
Stygocarella, 675f
Stygocarididae, 675
Stylaster, 202, 212f
  californicus, 439
Stylasterias, 890
  forreri, 884f
Stylasteridae, 194, 195, 212, 212f, 242
style sac of Mollusca, **372,** 373, 373f
stylet
  of Crustacea, **711**
  of Hexapoda, 755, 757f, 764
  of Loricifera, **573,** 575f
  of Nematoda, 403–404, **588**
  of Nemertea, 400
  of Platyhelminthes, **536, 542**–543, 544f
  of Tardigrada, 613f, **614,** 614f, **616,** 618
stylet glands of Tardigrada, 613f, 614f, **616**
Stylobates, 222
  aeneus, 224f
Stylochus, 544, 544f
Stylommatophora, 337, 353, 371f, 376f, 378
  reproduction of, 387f
  sense organs of, 380
Stylopallene cheilorhynchus, 853f
Styraconyx qivitoq, 611f
subenteric ganglion of Entoprocta, 315
subepidermal plexus of Ctenophora, **179**
subequal blastomeres, **96**
Suberites, 156
Suberitida, 126
sublittoral zone, **17**–18, 18f
subneural gland of Urochordata, **927**
substomodeal comb row of Ctenophora, 173f
substomodeal meridional canals of Ctenophora, 173f
subtentacular canals of Ctenophora, 173f
subtidal zone, 17–18
subumbrella, **205**
Succinea vaginacontorta, 40n
Succineidae, 337
sulcal side of Cnidaria, **199**
sulfur dioxide, atmospheric, 16
superpositional eyes of Arthropoda, **650**
Superstitionoidea, 807
support structures, 49–56
supralittoral zone, **17,** 18f
surface-to-volume dilemma, **47**–48, 400, 407
  and colony formation, 86
  and gas exchange, 72
  in Nemertera, 400, 407
  and osmoregulation, 67–68
  in Porifera, 142
suspension feeding, **57**–59, 89, 361
  ciliary-mucous mechanism, 58–59, 60f
  contact methods, 58
  mucous-net, 58, 60f
  scan-and-trap method, 58
  setal-net, 58, 59f
  tentacle or tube feet, 59, 60f
sutures of Mollusca, **352**
swimming bells, 202, 203f, 204
swimming motion, 20
  of Annelida, 430f, 431, 477, 481, 482
  of Arthropoda, 637, 638, 638f
  of Cephalochordata, 913
  of Cnidaria, 214–215, 219, 230
  of Crustacea, 703, 705f, 706
  of Echinodermata, 887
  and evolution of multicellularity, 114
  of Mollusca, 360–361, 361f
  of Nematoda, 588
  of Nematomorpha, 603
  Reynolds numbers in, 49–50
Sybota, 829f
Sycon, 121f, 130, 138f
  development of, 151, 151n, 152f
  distribution of, 154
syconoid sponges, 128f, **129**–130, 138f, 140, 151
sylleibid condition, **129,** 131
Syllidae, 418f, 422, 448
  reproduction and development of, 450, 451f, 452

Syllis ramosa, 451f
Symbiodiniaceae, 192n, 225
Symbiodinium, 157, 192n, 225, 370
Symbion
  americanus, 317, 319
  pandora, 317, 318f, 319
symbiotic relationships, 21, **22**–24, 57
  of Acoela, 252, 254f, 255

  colonial species, 917, 920f, 922, 926, 927–928, 928f, 929, 931, 934
  compound species, 919f, 920f, 921f, 922, 927, 928
  feeding and digestion of, 915, 917, 919, 920, 924, 925–926
  fossil record of, 933
  general anatomy of, 921f–922f
  genome of, 917, 919, 933
  invasive species, 917, 926
  nervous system and sense organs of, 83, 924, 927, 932
  number of species, 3t, 911
  phylogeny of, 24, 912, 919, 931–932, 932f, 933, 934, 937f, 938
  reproduction and development of, 922, 924, 927–931, 928f
  social, 920f, 922, 924, 928, 929
  symbiotic relationships of, 925, 926, 929
Urodasys, 557f
uropods of Crustacea, 663f, **701**
uropolar cells of Dicyemida, **276**
Uropygi, 817, 834, 842, 846, 855
  characteristics of, 818
  classification of, 807, 816
  examples of, 812f
  phylogeny of, 854f
Urosalpinx cinerea, 364
Uschakov, P. V., 473
uterine bell of Acanthocephala, 293f, **294**
uterus of Platyhelminthes, **542,** 551f, 552

V

Vaejovis spinigerus, 826
Vaejovoidea, 807
vagabond's disease, **765**
vagina, 87, 87f
  of Platyhelminthes, **546,** 551f, 552
vaginal nozzle of Acoela, **260**
Valvatida, 878
Valvatidae, 336
valves of Mollusca, **346,** 350f, 351, **351,** 358f, 360
Valvifera, 644, 665, 685f
Vampyromorpha, 342
Vampyroteuthis infernalis, 40n
Vanadis, 449f
vanadium levels in Urochordata, 926, 927
van Beneden, E., 23, 275
van der Horst, C., 860
vanes of Porifera, **129,** 159
van Leeuwenhoek, A., 285
Van Valen, L., 86
Vargula, 668f
vascular budding of Urochordata, **928**
Vauxia, 14f
vegetal pole, **95,** 96, 96f, 103
veins of insect wings, **756**–757, 759f
Velamen, 168f, 172
velarium of Cnidaria, **209,** 210f, 214
velar tentacles of Cephalochordata, 914f, **915**
Velatida, 878
Velella, 187f, 204, 205f, 220
veliger larva of Mollusca, **345,** 354f, 355, 360, **389**–390, 391, 391f, 395
velum
  of Cnidaria, 208f, **209,** 214
  of Mollusca, **389**–390
Velutinidae, 353
Vendobionta, 240
Vendozoa, 240
Venerida, 340
Veneridae, 338f, 340
venom
  of Cnidaria, 218
  of Echinodermata, 885
  of Eucheliceratа, 826, 829, 830
  of Mollusca, 365
ventral aorta of Cephalochordata, 914f, 916
ventral ganglion of Chaetognatha, 303f, 307
ventral jaws of Micrognathozoa, **298,** 300f
ventral muscle plate of Micrognathozoa, **298,** 300f
ventral nerve center of Chaetognatha, **307**
ventral organs of Onychophora, **622**
ventral storage organ of Cephalochordata, **913,** 914f
ventral vessels
  of Enteropneusta, 864f, **866**
  of Pterobranchia, 870
Vermes, 26, 416, 459, 522, 629
Vermetidae, 335
  feeding of, 366
  locomotion of, 356
Vermetus, 366
vermiform embryos of Dicyemida, **276,** 277, 278, 279
vermigon, **711,** 712f, 714f
vernal pools, 22
